Some workplace and ergonomic modifications can be made to minimize work tasks requiring awkward wrist postures, forceful exertions, and highly repetitive movements. For instance, a computer keyboard with a downward slope may reduce the wrist extension angle and the activity of the forearm muscles, in particular the wrist extensors.¹²⁷ A similar effect on the wrist extension angle has been observed when the keyboard was higher than elbow

height.¹²⁸

The patient with TrPs in the ECRL muscle or pain at the lateral aspect of the elbow should bend the elbow with the palms facing up in order to increase the use of the biceps brachii muscle and avoid overuse of the ECRL muscle when lifting objects, especially if repetitive lifting is required.⁷² Repeated lifting and grasping activities with the elbows fully straightened can be associated with relatively overused wrist extensors because of the excessive force placed on the outside of the elbow.

Self-pressure release for TrPs in the ECRL (Figure 34-7A), ECRB (Figure 34-7B), or ECU (Figure 34-7C) muscles can be performed in sitting by placing the forearm on the armrest of a chair or on a table with the palm down, using manual pressure or with a TrP self-release tool. Trigger point self-pressure release of the brachioradialis muscle is performed in the same position with manual pincer grasp (Figure 34-7D). For any of these self-pressure release techniques, the sensitive spot is located with the fingers or a tool, and light pressure (no more than 4/10 pain) is applied and held for 15 to 30 seconds or until pain reduces. This can be repeated five times, several times per day.

Figure 34-7. Self-pressure release of TrPs. A, Extensor carpi radialis longus muscle. B, Extensor carpi radialis brevis muscle. C, Extensor carpi ulnaris muscle. D, Brachioradialis muscle.

The patient can easily perform self-stretching techniques as part of self-management for TrPs located in the forearm muscles. Stretching of the ECRL and ECRB muscles should be performed with the elbow fully straightened, palm facing down, and wrist flexion with ulnar deviation (Figure 34-8A). The same procedure can be followed with the elbow bent (Figure 34-8B).⁸⁰ These self-stretches should be carried out gently, and attention to the reproduction of pain versus stretch is paramount. These stretches should not be painful. The same technique (see Figure 34-8B) but with an end position of wrist flexion with radial deviation can be used for stretching of the ECU muscle. Importantly, stretching

techniques may be counterproductive if an insertional tendinopathy of the wrist extensors is present.¹²⁹

Figure 34-8. Self-stretch of wrist extensors. A, Elbow straight, wrist gently pulled down and slightly out to focus stretch of the extensor carpi radialis longus muscle. B, Elbow is bent, wrist gently pulled down and slightly out to focus stretch on the extensor carpi radialis brevis muscle. Not pictured: to stretch the extensor carpi ulnaris muscle the same position as in B is utilized but the wrist is pulled slightly in.

To perform a self-stretch of the brachioradialis muscle, the elbow should be fully straightened with the thumb side of the wrist of the affected forearm pointing up. The patient grasps the tissue and radius bone just above the wrist and provides a gentle traction force of the soft tissues on the top of the forearm to provide a lengthening stretch of the myofascial structures (Figure 34-9). This self-stretch is difficult to perform.

Figure 34-9. Self-stretch of the brachioradialis muscle. The elbow is fully straightened, thumb side of the wrist is pointed up. The patient grasps the tissue and radius bone just above the wrist and provides a gentle traction force (blue arrow) of the soft tissues on the top of the forearm to provide a lengthening stretch of the myofascial structures. White arrow is the area of the forearm where the stretch should be felt.

Extensor Digitorum and Extensor Indicis Muscles

“Painful Pointers”

Orlando Mayoral del Moral and Robert D. Gerwin

1. INTRODUCTION

The extensor digitorum (ED) muscle arises from the lateral epicondyle of the humerus via the common extensor tendon. The muscle belly divides in the distal third of the forearm into four tendons, one to each finger. The tendons to the index and small fingers are accompanied by the extensor indicis (EI) and extensor digiti minimi tendons. The tendinous expansions and their complicated connections to intrinsic hand muscles provide for intricate interplay, producing fine finger movements. The juncturae tendinae and the intertendinous bands that stabilize each tendon to the finger it crosses limit the specificity with which the extensor muscles can control individual finger movements, which also depend on the lumbricals, interossei, and individual finger flexor muscles for precise movement. The referred pain and tenderness from trigger points (TrPs) in the ED muscle are projected distally in the forearm to the back of the hand, often to the fingers it moves, and proximally to the lateral epicondyle region. Pain from the EI is felt most strongly at the junction of the wrist and the dorsum of the hand. Symptoms may also include weakness, stiffness, and tenderness of the proximal interphalangeal joints. Differential diagnosis includes true tennis elbow, C7 radicular pain or radiculopathy (occasionally C6), and De Quervain’s stenosing tenosynovitis. Consideration of TrPs as the cause of symptoms identified as lateral epicondylalgia or TrPs in functionally related muscles including the supinator, brachioradialis, and extensor carpi radialis longus and brevis muscles should be differentiated. Corrective actions include avoidance of unnecessary muscular strain, postural education for grasping, proper sleeping and work postures, and establishing a home exercise program of TrP self-pressure release and self-stretching exercises to achieve and maintain full range of motion and functional muscle strength.

2. ANATOMIC CONSIDERATIONS

Extensor Digitorum

The ED muscle arises proximally from the lateral epicondyle of the humerus, from intermuscular septa, and from the antebrachial fascia (Figure 35-1A).¹ The ED muscle occupies the space on the dorsal surface of the forearm between the extensor carpi radialis brevis and extensor carpi ulnaris muscles. The three muscles form a common tendon at the lateral epicondyle. The muscle belly of the ED muscle divides into three muscle bundles, two of which have one tendon each, and the lateral muscle bundle which gives rise to two tendons, one to the long finger and one to the index finger.² The four tendons pass through the 4th compartment or tunnel under the extensor retinaculum^{2,3} in a common synovial sheath with the tendon of the EI muscle.¹ The tendons diverge on the dorsum of the hand, one to each finger.¹ The tendon to the index finger is accompanied by the EI muscle, which lies medial to it.¹ The tendon to the ring finger is connected by intertendinous junctions (juncturae tendinae)¹ to the tendons of the extensor digiti minimi muscle and the tendon to the long finger, so that the medial three fingers move together. Independent movement of these digits is most difficult with the wrist flexed. Distally, each tendinous slip of the ED muscle is bound by fibrous bands to the collateral ligaments of its metacarpophalangeal joint, as the tendon crosses the joint. The tendon spreads into an aponeurotic expansion (also called the extensor hood) to cover the dorsal surface of the proximal phalanx of each finger. Here, it is joined by tendons of the lumbrical and interosseous muscles.^{1,4} This aponeurosis then divides into a central and two collateral slips; the central slip inserts on the base of the 2nd phalanx, and the collateral slips continue on to unite and insert onto the dorsal surface of the distal phalanx of each finger as the terminal tendon.^{2,5} The ED muscle has tendons to the three middle digits (index, long, and ring) in 77% of dissections in one study but only 34% of the time to the extensor digiti minimi muscle.⁶

Figure 35-1. Attachments of the right finger extensor muscles and dorsal forearm muscles. A, ED muscle (red), showing oblique bands that interconnect the distal tendons, and the junction of the EI tendon with the index finger tendon of the ED muscle. Note that the tendon to the ring finger is connected by junctional tendons to the tendons of the long and small fingers, so that extension of the ring finger is usually accompanied by extension of all three fingers, so that extension of the ring finger is usually accompanied by extension of all three fingers. Also note that there are no junctional tendons to the index finger which can move independently. B, EI (red), which passes beneath the ED tendons.

Extensor Digiti Minimi

The extensor digiti minimi muscle (Figure 35-1A) is not considered separately in this chapter because its muscle belly is often connected to, indistinct from,¹ and sometimes

fused⁷ to the adjacent ED muscle and is usually covered by it.¹ The extensor digiti minimi muscle forms a long tendon that constitutes the 5th dorsal compartment as it proceeds beneath the extensor retinaculum.¹ Distal to it, the tendon typically splits into two, and the lateral slip is joined by a tendon from the ED muscle.

Extensor Indicis

The EI muscle (Figure 35-1B) is a pennate muscle⁸ that originates from the dorsal and lateral surface of the body of the ulna distal to the extensor pollicis longus muscle, from the interosseous membrane,¹ and in part, from the extensor pollicis longus septum.⁹ The muscle at the interosseous membrane arises directly from its dense connective tissue.¹⁰ The muscle belly of the EI muscle is the only muscle belly to enter the 4th tendon compartment, where its tendon runs under the extensor retinaculum deep to the tendons of the ED muscle.⁹ The musculotendinous junction of the EI muscle is under the extensor retinaculum in 95% of cases and is at its proximal edge in 5% of cases.⁸ Distally, at the level of the head of the 2nd metacarpal, it joins the ulnar side of the slip of the ED muscle going to the index finger and attaches into the extensor expansion.^{1, 11}

Anatomic Variations

Anatomic variations of the extensor muscles of the hand are common^{12, 13} and may be important causes of wrist pain and sources of misdiagnosis. The tendons of the ED muscle may be variably deficient,¹ although more commonly, they are doubled, or even tripled, in one or more digits: most frequently, the index finger or the middle finger. Rarely, a slip of tendon passes to the thumb. The arrangement of the intertendinous connections on the dorsum of the hand is highly variable. The medial connection is rather strong and pulls the tendon of the little finger toward that of the ring finger, whereas the connection between the middle two tendons is weak and may be absent.¹

The ED brevis manus muscle is a relatively rare anatomic variation occurring in 38 (1.1%) of 3,304 hands examined. When present, it is commonly symptomatic (50% of the 38 cases).^{11, 14} It is clinically important because it may become painful when overexercised¹⁵ and may be misdiagnosed as a ganglion cyst or tumor, resulting in unnecessary surgery.¹⁵ It originates on the distal margin of the radius or from the dorsal capsule of the wrist joint and inserts on the dorsal aponeurosis of the index finger.¹⁶ This muscle frequently appears as a variation of the EI muscle because when the ED brevis manus muscle is present, the EI muscle is usually absent.¹⁴

There are many variations of the EI muscle belly and tendon anatomy. The EI tendon is important because it is considered the best substitute for reconstruction of the hand after trauma or disease,¹¹ especially for the abductor pollicis longus and extensor pollicis longus tendons. Furthermore, variants of the EI muscle may result in a predisposition toward isolated neuropathy of the posterior interosseous nerve.^{12, 17}

Yoshida⁹ lists a number of variants encountered in his anatomic study of 832 upper

limbs. An EI ulnaris muscle (2.9%) lies medial to the EI muscle and is attached to the index finger more medial to the tendon of the EI muscle. The EI et medii accessorius muscle (1.4%) originates more medially on the dorsal surface of the ulna. Its tendon bifurcates: one part attaches to the index finger and the other one attaches to the middle finger. An extensor pollicis et indicis communis muscle arises from the interosseous membrane and the intermuscular septum. The tendon passes through the 4th compartment and bifurcates, the medial slip attaching to the medial aspect of the thumb and the ulnar slip to the radial dorsum of the index finger.¹¹ When this rare variant is present, it is always in addition to both the extensor pollicis longus and the EI muscles, and never replaces either. A variant of this is the supernumerary muscle that arises from an independent belly of muscle that is part of the muscle mass of the extensor pollicis longus muscle. The tendon from this supernumerary muscle follows an oblique course radial to the 2nd metatarsal bone, attaches to a thickening of the fascia between the accessory tendon and the ulnar portion of the extensor pollicis longus tendon. This accessory muscle corresponds to the EI radialis muscle, but the fascial connection results in its functioning as an extensor pollicis and extensor digitorum muscle.¹⁸ The importance of this description is emphasis on the relationship of the intertendinous fascia to the course of the tendons.

Variations of the origin of the EI muscle are also reported. The origin of the EI muscle can be the articular upper surface of the lunate bone and the dorsal radiocarpal ligament rather than the ulna. In this variant, the tendon of the EI muscle passes along with and joins the tendons from the ED muscle to the EI muscle, inserting on the base of the distal phalanx.¹⁹ There are variations of other extensor forearm muscles that affect the EI muscle. For example, a duplication of the extensor pollicis longus muscle gives rise to a tendon that courses with the tendon of the EI muscle and inserts with it. Likewise, a duplicated tendon and partial muscle belly of the EI muscle was found to arise from the normal muscle mass of the EI muscle and the ulna, its tendon inserting with the tendon of the extensor pollicis longus muscle.²⁰

2.1. Innervation and Vascularization

Both the ED and EI muscles are innervated by the deep branch of the radial (posterior interosseous) nerve, from spinal nerves¹ C7 and C8 through the posterior cord of the lower trunk of the brachial plexus.^{12,21}

Regarding vascular supply, the ED and EI muscles are supplied by branches of the brachial artery. The proximal third of the ED muscle is supplied by branches from the radial recurrent artery, and the distal two-thirds are supplied by branches from the posterior interosseous artery.¹ The very distal portion is supplied by a perforating branch from the anterior interosseous artery that passes through the interosseous membrane.^{1,22} The EI muscle is supplied on its superficial surface by branches from the posterior interosseous artery and on its deep surface by perforating branches from the anterior interosseous artery.¹

2.2. Function

The muscles controlling wrist and finger movements are important because of their constant use during functional activities and for their contribution to fine motor control. Consequently, musculoskeletal disorders involving muscle and tendon are very common in the hand and forearm. The ED muscle extends all phalanges of the fingers (2nd through 5th digits),^{1,23,24} especially the proximal phalanges,²⁵ and assists in extension of the wrist.^{1,23} It assists in abducting (spreading) the index, ring, and little fingers away from the middle finger.^{1,24} All of the extrinsic hand muscles become involved in a power grip, in proportion to the strength of the grip.^{23,26} The ED muscle acts in conjunction with the lumbrical and interosseous muscles to extend the middle and distal phalanges of the 2nd through 5th digits. When the proximal phalanges are held in flexion, the ED muscle extends the more distal phalanges, but when the proximal phalanges and the hand are held in extension, then, its contraction has little additional effect on the last two phalanges.^{24,27} These intrinsic and extrinsic digit extensors provide an essential synergistic function to permit selective control of individual fingers; recent research shows that the independent control of the output of the ED muscle is limited, which may reflect “spillover” of motor commands to other digital extensor compartments.²⁸ The movements are coordinated, so that extension of one finger coactivates the extension of additional fingers.^{28,29} Only extension of the index and small fingers occurs²⁸ more independently of extension of the other fingers because of both neurologic control²⁹ and anatomic reasons related to the tendons, reviewed earlier, and the presence of the EI and extensor digiti minimi muscles.

The EI muscle, in addition to acting on the index finger in the same way that the ED muscle acts, thus extending it, may assist in adducting the index finger toward the middle finger^{24,25} because of the angulation of its tendon across the dorsum of the hand. The EI muscle allows the index finger to function independently of the 3rd and 4th digits. Alone, or with the ED muscle, it extends the index finger¹ at the metacarpophalangeal joint and proximal interphalangeal joint and assists in wrist extension.^{1,12}

Hand grip is enhanced by wrist extension. Hand grip requires stabilization of the wrist through coactivation of forearm extensor and flexor muscles to counteract the force of the finger flexors that unopposed would cause wrist flexion. Therefore, the ED muscle and EI muscles improve hand grip by assisting in wrist extension.^{12,30}

2.3. Functional Unit

The functional unit to which a muscle belongs includes the muscles that reinforce and counter its actions as well as the joints that the muscle crosses. The interdependence of these structures is functionally reflected in the organization and neural connections of the sensory motor cortex. The functional unit is emphasized because the presence of a TrP in one muscle of the unit increases the likelihood that the other muscles of the unit will also develop TrPs. When inactivating TrPs in a muscle, one must be concerned about TrPs that may develop in muscles that are functionally interdependent. Box 35-1 grossly represents

the functional unit of the ED and EI muscles.³¹

Box 35-1 Functional unit of the ED and EI muscles

Action	Synergists	Antagonists
Finger extension	Lumbricals Interossei	Flexor digitorum superficialis Flexor digitorum profundus

Strong agonist–antagonist interactions are needed between the flexors and extensors of the hand and fingers to produce finger dexterity as well as to produce forceful hand grip. The flexor digitorum are antagonist muscles, but the synergic coactivation of both flexor digitorum muscles and the ED muscle increases grip strength and wrist stability.³² In fact, it has been shown that coactivation of the flexor digitorum muscles and the ED muscle requires cutaneous sensory feedback because elimination of cutaneous sensation in the digit reduces the maximum voluntary force of the ED muscle affecting that digit, thereby reducing the agonist–antagonist coactivation.³²

Powerful flexion of the distal phalanges requires strong activity also of the finger extensors. On the other hand, for the ED muscle to extend the interphalangeal joints, the lumbrical and interosseous muscles need to function.

The ring and little finger extensors form a functional unit with the supinator muscle for twisting motions, such as closing jar tops and door knobs.

The EI muscle is activated independently and is coactivated with the ED muscle and is thereby an agonist of the ED muscle. It is an agonist of all muscles that extend the wrist, including both extensor carpi radialis, extensor carpi ulnaris, and the short and long extensor muscles of the thumb. It is both an antagonist to the finger flexors in finger extension, and an agonist with these same muscles in stiffening the index finger and in stabilizing the wrist.²⁹ It shares the action of wrist stabilization with the ED muscle and the forearm flexor muscles.

3. CLINICAL PRESENTATION

3.1. Referred Pain Pattern

Extensor Digitorum

According to Simons et al³¹ involvement of the fibers of the ED muscle associated with the middle finger is extremely common. The pain, which is felt most intensely in the hand, forms a line that extends onto the dorsum of the forearm, wrist, and hand, including the metacarpophalangeal and proximal interphalangeal joints of the middle finger. There may

also occasionally be an area of pain on the volar side of the wrist (Figure 35-2A). Patients report pain in the hand and finger and of stiffness and soreness in the painful finger joints.³³⁻³⁵ The original report of this pain referral was based on 38 patients.³⁴

Fibers of the ED muscle associated with the ring finger refer pain similarly to the same finger.³⁵ However, unlike the middle finger extensor, TrPs in the ring and little finger extensors are likely also to project pain and tenderness proximally into the region of the lateral epicondyle (Figure 35-2B).

Other authors described the ED muscle as referring pain to the elbow or lateral epicondyle^{36,37} even from the middle finger³⁸ in patients with lateral epicondylalgia,^{39,40} to the forearm,^{33,-36,37} and to the hand.³⁶

Kellgren⁴¹ injected 0.2 mL of 6% sodium chloride solution into the belly of a normal ED muscle. Pain was developed in the dorsal forearm and more severely over the back of the hand. During the sensation of pain, there was slight tenderness to deep pressure, definite tenderness to tapping, but no hypersensitivity of the skin in the painful area. Dejung et al⁴² described the referred pain pattern from the ED muscle derived from examination of 10 patients. The referred pain in these patients extended from the elbow to the fingers, over the dorsum of the forearm, but most commonly over the wrist. Specifically, pain referred to the long axis of the wrist and forearm as opposed to encircling the wrist and into the finger of the affected slip of extensor muscle.

Extensor Indicis

Trigger points in the EI muscle refer pain toward the radial side of the dorsum of the wrist and hand but not into the fingers (Figure 35-2C).

Figure 35-2. Pain patterns (dark red) from TrPs in right ED and EI muscles (medium red). A, Pain pattern from TrPs in fibers of the middle finger. B, Pain pattern from TrPs in fibers of the ring finger. C, Pain pattern from TrPs in the EI muscle, dorsal view.

3.2. Symptoms

Patients with TrPs in the finger extensor muscles report pain in the dorsal aspect of the forearm, wrist, and fingers. When asked whether the pain is felt more on the top or the underside of the fingers, the patient may not be able to isolate the pain but is likely to show the location by rubbing the dorsal surface of the fingers. Pain from TrPs in the ED muscle may also be associated with symptoms of lateral epicondylalgia^{39, 40, 43} or with arthritis of the fingers. When the fibers of the middle finger alone are involved, the patient may report weakness in their grip, without pain.⁴⁴ The finger extensors are essential to a powerful grip, and this weakness in grip reported by the patient presents another example of inhibition weakness caused by the TrPs.

Symptoms of impaired finger flexion may be due to TrPs in the finger extensor muscles. Patients may complain of stiffness and tenderness of the proximal interphalangeal joints. Stiffness and painful cramping of the fingers prevented one patient from milking his cows until TrPs in his ED muscle had been inactivated.³³ A patient seen by Dr. Travell could not type because the ring and little fingers would “not work separately” until the TrPs were injected in the extensor fibers of those fingers.

The presence of an anomalous ED profundus muscle may cause pain and swelling over the dorsal aspect of the 2nd and 3rd metacarpals of the left hand in a guitar player.⁴⁵

3.3. Patient Examination

After a thorough subjective examination, the clinician should make a detailed drawing representing the pain pattern that the patient has described. This depiction will assist in planning the physical examination and can be useful in monitoring the progression of the patient as the symptoms improve or change. Because the ED muscle crosses the elbow, the wrist, and all joints of the fingers, the clinician needs to assess passive range of motion to identify limitations caused by TrPs or joint dysfunctions. It is best to extend the elbow and fully flex the fingers first, then slowly and gently flex the wrist, and finally, move the wrist into ulnar deviation to reveal increased muscle tension caused by either adaptive shortening of the muscle or TrPs. To examine the length of the EI muscle, the clinician passively flexes the wrist and the index finger joints together with some radial deviation.

Limitation of active range of motion can be tested with the finger flexion test by having the patient flex the interphalangeal joints to bring the tips of the fingers against the palmar pads, while extending the metacarpophalangeal joints (Figure 35-3A). Increased tension of an affected finger extensor muscle due to a TrP results in that finger standing out from the others, away from the palm, such as the index finger in Figure 35-3B. Passive flexion of the finger beyond this point is painful and differentiated from lumbrical muscle tightness.

Should the 2nd digit be affected, possible contribution by EI muscle should be considered.

Figure 35-3. Finger flexion test. A, Normal finger closure with all fingers flexed. B, Positive test for finger extensor muscle dysfunction. Note that the index finger is unable to achieve full flexion.

Inhibition weakness due to finger extensor TrPs is detected in the grip during a handshake by testing and comparing both hands simultaneously. This bilateral handgrip test is more painful when the patient holds the hands in ulnar deviation and flexed at the wrist. This test may reveal weakness without pain with latent TrPs.

Resisted extension of the middle finger produces pain over the lateral epicondyle (Maudsley's test) in persons with potential lateral epicondylalgia.⁴⁶ The muscle fascicle of the ED muscle to the long finger arises from the lateral epicondyle. Tenderness at the origin of the ED muscle directly correlates with pain on Maudsley's test.⁴⁶ These observations have led to the hypothesis that the pain of lateral epicondylalgia comes from the ED muscle.^{46, 47} Trigger points in ED muscle are very prevalent in patients with lateral epicondylalgia, ranging between 25%³⁹ and 83.3%.^{38, 40}

Weakness of the ED muscle can also be tested by resisting extension of the metacarpophalangeal joints of the 2nd through 5th digits with the arm resting on a table, as illustrated by Kendall et al.⁴⁸ Weakness in this muscle causes weakness in wrist extension. Weakness of the 2nd digit could also result from TrPs in the EI muscle.

Tenderness of the proximal interphalangeal joint is commonly associated with the finger stiffness and "soreness" because of finger extensor TrPs, sometimes without referred pain in the joint.⁴⁴ Accessory joint motion should be examined in the elbow, wrist, and hand. Decreased accessory joint motion may be a contributing factor to ED and EI muscle overload.⁴⁹

3.4. Trigger Point Examination

Gerwin et al⁵⁰ established that among experienced and trained clinicians, reliable criteria for diagnosing TrPs were the detection of a taut band, the presence of spot tenderness, the presence of referred pain, and reproduction of the patient's symptomatic pain. Although for some muscles tested, local twitch responses were not identified reliably, the ED muscle in

this study scored very high on interrater reliability for all examinations including the local twitch response. It is one of the easiest muscles to examine reliably for TrPs and also for eliciting a local twitch response. In fact, a recent study found that identification of TrPs within the forearm muscles is a skilled activity because an inexperienced clinician had more difficulty identifying a TrP in the ED muscle than an experienced clinician.⁵¹

To examine the ED muscle for TrPs, the patient is positioned with the forearm supported and the elbow placed between 90° and 135° of flexion, which allows for adequate cross-fiber flat palpation of the muscle (Figure 35-4A). The muscle may be identified and distinguished from other forearm extensor muscles by flexing the wrist and palpating over the dorsum or extensor surface of the muscle while extending the middle finger.

Figure 35-4. Cross-fiber flat palpation for TrPs in finger extensor muscles. A, Extensor digitorum muscle. B, Extensor indicis muscle.

The TrPs in the fibers of the ED muscle that supply the ring and little fingers are more difficult to locate because they are deep in the muscle mass beneath the aponeurosis of origin, part of which covers the surface of the muscle. These fibers lie next to the extensor carpi ulnaris muscle, which is the muscle mass just lateral to the palpable border of the ulna, and close to the underlying supinator muscle. On palpation, these two finger extensors tend to refer pain distally to the wrist and hand, and sometimes proximally to the lateral epicondyle (Figure 35-2).

Trigger points are identified in the EI muscle by cross-fiber flat palpation (Figure 35-4B). Examination of the EI muscle does not depend on the position of the elbow but is easier with the wrist slightly extended to put the muscle in mid-length. The patient is asked to move the index finger into extension at the metacarpophalangeal joint, allowing the contracting muscle to be identified.

4. DIFFERENTIAL DIAGNOSIS

4.1. Activation and Perpetuation of Trigger Points

A posture or activity that activates a TrP, if not corrected, can also perpetuate it. In any part of the ED or EI muscles, TrPs may be activated by unaccustomed eccentric loading,

eccentric exercise in an unconditioned muscle, or maximal or submaximal concentric loading.⁵² Trigger points may also be activated or aggravated when the muscle is placed in a shortened and/or lengthened position for an extended period of time.

Trigger points in the finger extensors commonly result from overuse during forceful repetitive finger movements or vigorous grip by professional musicians, carpenters, butchers, ice cream scoopers, plumbers, tennis players, mechanics, etc. The referred pain patterns from TrPs in the upper body, including the arm muscles, reproduced the pain patterns in the neck, shoulders, and arms of both laborers and office workers. The prevalence and distribution of TrPs were similar in both groups in this study.⁵³

Overuse of muscles arising in the forearm that control the thumb, wrist, and finger extension produces pain in the thumb and forearm as well as pain in the hand and digits. The widespread use of handheld devices like mobile phones and gaming controllers requires repeated movements of the thumb and digits. A retrospective study of individuals with musculoskeletal disorders who participated in a tertiary level rehabilitation center showed an important association between usage of these handheld devices and tendinosis of the extensor pollicis longus muscle and myofascial pain syndrome of the ED, the 1st interosseous, and the thenar musculature.⁵⁴

Trigger points in the ED and EI muscles occur with eccentric contraction when elongated.^{52,55} Office workers using computers are particularly susceptible. This phenomenon occurs with keyboard activity when the wrist is extended and the fingers flexed. Prolonged or repeated wrist extension, whether computer keyboard related factory work, or playing a musical instrument, can produce this condition. Forearm pain can be seen in guitarists and other string instrument players. Muscle- and tendon-related pain is reported in 64% to 76% of all instrumentalists surveyed.^{56,57} In sports activities, the backhand stroke in tennis overloads the wrist extensors, and the forceful grip overloads the finger extensors.⁵⁸

People with Ehlers-Danlos syndrome, who have hypermobility, often show signs of muscle pain and TrP formation.⁵⁹ Hyperextension of the finger joints commonly produces joint pain and can also produce forearm myofascial pain. Use of “silver rings” designed to prevent overextension of the small joints can prevent forearm and hand pain.

4.2. Associated Trigger Points

Associated TrPs can develop in the referred pain areas caused by primary TrPs.⁶⁰ Therefore, musculature in the referred pain areas for each muscle should also be considered. Trigger points can occur concomitantly in any of the muscles of the functional unit. The most commonly involved muscles are the extensor carpi radialis brevis and longus muscles, as they share action at the elbow and the wrist. However, the association with other muscles such as the supinator, brachioradialis, extensor carpi ulnaris, triceps brachii, and brachialis muscles or with the forearm antagonists in the flexor–pronator group is very common.

Moreover, pain in the dorsum of the forearm when using the hand, specifically when grasping and lifting, may alter the use of shoulder muscles and induce the formation of

TrPs and pain in the shoulder muscles, particularly the infraspinatus, upper trapezius, and levator scapulae muscles, as the shoulder braces or stabilizes during the activity. In addition to these related TrPs, Hong⁶¹ found that TrPs in either the scalene muscles or the serratus posterior superior muscle could induce associated TrPs in the ED muscle.

4.3. Associated Pathology

Differential diagnoses for TrPs in the finger extensors include lateral epicondylalgia, C7 (and occasionally C6) radicular pain or radiculopathy, and De Quervain's stenosing tenosynovitis. The common diagnosis of lateral epicondylalgia is frequently caused by TrPs in at least one muscle that attaches to the lateral epicondyle. Often several of them are involved,^{38–40, 43} and the prevalence of myofascial pain syndrome in patients with lateral epicondylalgia ranges between 90%⁴⁰ and 100%.⁴³ ED muscle activity may be altered in patients with lateral epicondylalgia where it contributes more to wrist extension than in normal controls, whereas the contribution of the extensor carpi radialis brevis muscle to wrist extension is reduced.³⁰

Common causes of dorsal hand pain are ganglion cyst, tenosynovitis, direct trauma, and soft-tissue tumors.¹² Reports of pain from muscle pathology itself are rare.¹¹ However, reports of pain from TrPs in these muscles are generally not found in the literature.

Acute spontaneous compartment syndrome following repetitive exertional stress produces severe pain and swelling. Pain can occur over the dorsum of the forearm one to several days prior to the onset of swelling. Pain may worsen with finger extension when the ED muscle is involved.^{62, 63} Decreased range of motion at the wrist may be seen in both compartment syndrome and in pain caused by TrPs. Pain can worsen with wrist or finger extension in both conditions. Neurologic impairment is more likely with compartment syndrome, except that it is also possible that patients may report paresthesias as a result of TrPs in the wrist and finger extensor muscles.

The sagittal bands are the primary stabilizers of the ED tendons over the metacarpal phalangeal joints in the hand. If disrupted due to a disease process such as rheumatoid arthritis or due to trauma, the ED muscle may sublux or become dislocated and lodged on the ulnar side of the joint. This condition is a serious source of muscular strain because of the resultant ulnar deviation of the finger, and the tendon displacement must be surgically repaired for restoration of function.

Closed wrist trauma can rupture muscle tendons, with or without distal radial fracture, but this condition occurs most commonly with the extensor pollicis longus muscle and only infrequently with the EI muscle. Spontaneous tendon rupture can also occur after corticosteroid injection.⁸ Wrist pain may also be caused by aberrant extensor tendon variants and their complications. One such variant from the extensor pollicis longus muscle passed over the extensor retinaculum and was associated with radial wrist pain and limited thumb extension, related to stenosing tenosynovitis. The symptoms improved after decompressive surgery.⁶⁴

5. CORRECTIVE ACTIONS

One of the most important corrective actions is to avoid extreme, prolonged, or repetitive wrist extension. These actions are not only considered a risk factor for carpal tunnel syndrome but also increase the activity of wrist extensors, including the ED muscle.⁶⁵ Nevertheless, when it comes to ED muscle overload, wrist extension past 45° should be avoided,⁶⁵ especially when performing repetitive flexion/extension activity of the fingers on a keyboard, a computer or a musical instrument, or a computer mouse.

If TrPs in the ED or EI muscles are highly irritable, the patient should be instructed in sleeping positions that keep the wrist and fingers from adapting a prolonged flexed posture that can perpetuate pain and symptoms from TrPs in the finger and wrist extensors. The patient can be instructed in the use of a support to prevent maximum finger flexion while maintaining the wrist in a neutral position. A small towel or pad can be placed on the front of the wrist and hand and then secured with a wrap to keep the wrist in a neutral position and the fingers in a relaxed position while sleeping (Figure 35-5A). If the patient's pain is acute or has spread to the elbow, a small towel can be wrapped around the elbow to prevent it from adapting a flexed posture during sleep (Figure 35-5B).

Figure 35-5. Sleeping position for supporting finger extensors. A, Wrist supported in neutral with fingers in a relaxed position and blocked from making a full fist. B, Towel wrapped around the elbow to prevent elbow flexion with wrist supported as in A for acute lateral epicondylalgia or irritable wrist extensor and finger extensor TrPs.

Interrupting prolonged typing or data entry every 30 minutes or so to do the finger-flutter exercise by dropping the hands to the sides of the body, completely relaxed, and moving the arms and elbows to cause passive relaxed shaking of the hands and fingers helps the extensor forearm muscles recover from prolonged activity. Regarding the use of virtual keyboards in tablets or in other devices, the split keyboard design proved better for the use of the tablet in bed,⁶⁶ while the wide keyboard gave better results in the traditional desk setting.⁶⁶

The patient must learn to avoid overload of the finger extensors. During grasping or repetitive gripping activities, it is best to keep the wrist in a neutral position, with the wrist stabilized to decrease the demand on the finger extensor muscles. When gripping or

twisting with the hand, as in playing tennis, the patient should maintain the hand slightly extended and radially deviated (in a cock-up position of the wrist), rather than flexed and ulnarly deviated. Avid tennis and golf players should seek professional advice regarding appropriate grip positions and biomechanics.

Self-pressure release for TrPs in the ED (Figure 35-6A) and EI (Figure 35-6B) muscles can be performed in sitting position by placing the forearm on the arm rest of a chair or on a table with the palm down with manual pressure or a TrP release tool. For any self-pressure release techniques, the TrP should be identified with the fingers or a TrP self-release tool. Light pressure (no more than 4/10 pain) is held for 15 to 30 seconds or until pain reduces. This technique can be repeated five times, several times per day.

Figure 35-6. Self-pressure release of TrPs. A, Extensor digitorum muscle. B, Extensor indicis muscle.

Figure 35-7. Self-stretch of finger extensor muscles. Note in small picture the fingers being passively taken into full finger flexion with wrist flexion.

The patient can easily perform self-stretch techniques as part of a self-management program for TrPs in the finger extensor muscles.⁶⁷ Stretching of the ED and EI muscles should be performed with the elbow bent, palm facing down, and wrist and fingers in full flexion (Figure 35-7). The same procedure can be followed with the elbow straight to thoroughly stretch the ED muscle (see Figure 34-9). These self-stretches should be carried out gently, and attention to the reproduction of pain versus stretch is paramount. These stretches should not be painful. The self-stretch enables the patient to relieve the tension of the taut finger extensors. It is essential for the wrist and finger joints to be fully flexed. Addition of postisometric relaxation with a gentle contraction can be helpful.

Supinator Muscle

“Elbow and Thumb Sabateur”

Orlando Mayoral del Moral and Isabel Salvat

1. INTRODUCTION

The supinator muscle is a deep muscle that surrounds the proximal third of the radius. It has two layers and the posterior interosseous nerve passes between them. It is one of the major supinators of the forearm, assists with elbow flexion, and could play a role in the lateral stability of the elbow. Trigger points (TrPs) in the supinator muscle primarily refer pain to the lateral epicondyle and to the dorsal aspect of the web of the thumb. Symptoms may include an aching pain in the dorsal proximal forearm, the lateral epicondyle, and the dorsal surface of the web of the thumb, especially following repetitive gripping and lifting with the elbows extended. Symptoms typically linger following the offensive activity. Activation and perpetuation of TrPs can occur from repetitive overload and playing racquet sports. Differential diagnosis includes “true tennis elbow,” entrapment of the posterior interosseous nerve, local arthritis at the elbow, C5-C6 radicular pain or radiculopathy, and De Quervain’s stenosing tenosynovitis. Corrective actions include postural and activity modifications such as keeping the wrist neutral to slightly extended and the elbow slightly bent to prevent strain while playing racquet sports, and supinating the forearms while carrying to transfer the load from the supinator muscle to the biceps brachii and brachialis muscles.

2. ANATOMIC CONSIDERATIONS

The supinator muscle spirals around the proximal third of the radius (Figure 36-1). Proximally, it has two layers, and the deep branch of the radial nerve, the posterior interosseous nerve, passes between them (Figure 36-1B and C).¹ Both layers share a proximal attachment on the lateral epicondyle of the humerus, the radial collateral ligament of the elbow joint, the annular ligament, the supinator crest of the ulna and the posterior part of the triangular depression in front of it, and an aponeurosis that covers the muscle.¹

The superficial layer arises through tendinous fibers^{1,2} and the deep layer through muscular^{1,2} and tendinous fibers.² The fibers of both layers unite³ and run distally, anteriorly, and laterally to wrap undivided around the radius (Figure 36-1C),^{2,3} and attach to the lateral surface of its proximal third,¹ down to the insertion of pronator teres.¹ This distal attachment extends onto the anterior and posterior surfaces of the radius, between the anterior oblique line and the posterior oblique “ridge.”¹ When the forearm pronates, the supinator muscle and the biceps brachii tendon wrap around the radius like a windlass into the space between the radius and the ulna.

Figure 36-1. Attachments of the right supinator muscle (red) and its relation to the deep radial nerve. A, ventral view of the forearm, hand supinated. In the foreground, the muscle attaches to the volar surface of the radius. In the background, the muscle crosses the interosseous space to its dorsal ulnar attachment. A small part of the deep layer is seen through the arched opening in the superficial layer. B, Lateral view of the forearm, hand in

neutral position. The deep radial nerve enters the arched opening in the superficial layer and continues between the two layers of the muscle. C, Same view as B, with the superficial layer of the muscle reflected to show the deep layer and the nerve. The area of the radius that is free of muscle fiber attachments is seen just above the nerve. This bare bone separates the two layers of muscle and provides space for the nerve. The division of the muscle into two layers does *not* extend into its distal half, where the nerve tunnels through the undivided muscle belly.

Two-thirds of the superficial aspect of the superficial layer is tendinous, whereas the entire deep aspect of the superficial layer and most of the deep layer are muscular.²

The proximal edge of the superficial layer of the supinator muscle, where the deep branch of the radial nerve passes between the two layers (Figure 36-1B), is called the arcade of Frohse,² especially when thickened.³ It was first described as a normal anatomic tendinous structure. Different studies have shown that it is muscular in newborn full-term fetuses, and it has been suggested that the fibrous structure of the arcade in adults may be related to repetitive pronation and supination movements.²

The supinator muscle is subject to frequent anatomic variants¹ around the superior radioulnar joint such as the lateral tensor muscle of the annular ligament, the medial tensor muscle of the annular ligament, and the accessory supinator muscle, with an incidence of 16.6%, 11.1%, and 16.6%, respectively.⁴ In a classical anatomic study, the incidence of these three anatomic variants was even higher (70%, 20%, and 40%, respectively).⁵

2.1. Innervation and Vascularization

This muscle is innervated by two to five muscular branches arising from the posterior interosseous nerve,² supplied primarily by the C6, sometimes by the C7,^{1,3} and partly by the C5³ spinal nerves, through the posterior cord. The muscular branches usually, but not always, come off the posterior interosseous nerve before it enters the muscle.²

The superficial layer of the muscle receives its vascularization through branches from the radial recurrent artery, and the deep layer receives vascularization through branches from the posterior interosseous artery and the posterior interosseous recurrent artery.¹

2.2. Function

The supinator muscle, as its name implies, together with the biceps brachii muscle, is one of the major supinators of the forearm.³ Supinator muscle activity predominates over biceps brachii muscle activity during unresisted supination of the forearm and “holds” the forearm in supination.^{6,7} The much stronger biceps brachii muscle assists supination when the forearm is at least slightly flexed at the elbow and when force is needed to overcome resistance to supination.⁶ However, the biceps brachii muscle assists very little, if at all, when the elbow is straight. Forceful supination, therefore, requires at least a slight degree of elbow flexion.

During electromyographic (EMG) studies of isometric supination with the elbow flexed at 90°, the activity of the supinator muscle was lower in full pronation compared with that in full supination, and the activity of the biceps brachii muscle in mid-supination was greater than that in neutral, mid-, and full pronation.⁸ The EMG activity of the supinator muscle in these efforts was higher than that of the biceps brachii muscle in every position of the forearm, especially in neutral and mid-pronation.⁸ These data suggest, as previously shown by Basmajian,⁷ that the supinator muscle is the primary muscle involved in supination as evidenced by the magnitude of its EMG activity exceeding that of other muscles, including the biceps brachii muscle.⁸

Based on EMG, forceful elbow flexion with the forearm pronated, as in Figure 36-2C, reduces contraction of the biceps brachii muscle and, therefore, tends to load the supinator, brachioradialis, and brachialis muscles. Forceful elbow flexion in the supinated position as in Figure 36-2A tends to load the biceps brachii muscle and unload the supinator muscle. The supinator muscle also assists flexion at the elbow when the forearm is held in neutral forearm rotation,³ as in Figure 36-2B.

Figure 36-2. Three hand positions for carrying a heavy object with the elbow flexed. A, Forearms supinated, which loads the biceps brachii muscle and unloads the supinator muscle. B, Hands in the neutral position, which loads both the muscles. C, Forearms pronated, which tends to unload the biceps brachii muscle and to load the brachialis, brachioradialis, and the few fibers of the supinator muscles that contribute to elbow flexion.

The supinator fibers that attach to the anterior capsule of the humeroulnar joint contribute primarily to elbow flexion, rather than to supination. The epicondylar fibers also may contribute to elbow flexion. The supinator muscle origin at the radial collateral ligament and annular ligament may point to an additional supportive or stabilizing role over the lateral aspect of the elbow.⁹

2.3. Functional Unit

The functional unit to which a muscle belongs includes the muscles that reinforce and counter its actions as well as the joints that the muscle crosses. The interdependence of these structures is reflected functionally in the organization and neural connections of the sensory motor cortex. The functional unit is emphasized because the presence of a TrP in one muscle of the unit increases the likelihood that the other muscles of the unit will also develop TrPs. When inactivating TrPs in a muscle, one must be concerned about TrPs that may develop in muscles that are functionally interdependent. Box 36-1 grossly represents the functional unit of the supinator muscle.³

Box 36-1 Functional unit of the supinator muscle

Action	Synergists	Antagonists
Supination	Biceps brachii Extensor carpi radialis longus	Pronator teres Pronator quadratus
Elbow flexion	Biceps brachii Brachialis Brachioradialis Extensor carpi radialis longus	Triceps brachii Anconeus

The supinator muscle could be considered an agonist of the deep head of the pronator muscle in stabilizing the distal radioulnar joint.¹⁰ In vitro experiments show that the pronator quadratus and supinator muscles appear to relieve joint compression in the distal radioulnar joint induced through activity of the biceps brachii and pronator teres muscles.¹¹ This result may have implications regarding the application of the principle of

superposition for muscle forces in the estimation of distal radioulnar joint loading.

3. CLINICAL PRESENTATION

3.1. Referred Pain Pattern

Trigger points in the supinator muscle refer pain primarily to the lateral epicondyle and the anterior and posterior surrounding areas. They also project pain to the dorsal aspect of the web of the thumb, and if sufficiently intense, the pain may include some of the dorsal forearm¹² (Figure 36-3).

Dejung et al¹³ described a pain referral pattern observed in 27 patients. The essential pattern was very similar to the one described in Figure 36-3, but it also included some spread of pain to the anterior and the posterior aspects of the shoulder and to the parietal part of the head, close to its vertex.

Slater et al¹⁴ injected hypertonic saline in several parts of the forearm, including the supinator muscle. The injection of this muscle produced a very diffuse pain pattern, and the pain spread both proximally to the deltoid region and distally to the metacarpal and intercarpal joints.¹⁴ The referred pain evoked by the injection of the supinator muscle varied in subjects participating in the study, with reports of pain felt in the dorsolateral forearm, extending to the distal radioulnar joint and to the hand, and immediately proximal to the common extensor origin.¹⁴ A more recent study found that the referred pain elicited by active supinator TrPs contributed to the overall pain of patients with unspecific arm pain but without describing a specific pattern of pain for TrPs in this muscle.¹⁵

3.2. Symptoms

Patients with active TrPs in the supinator muscle primarily report aching pain in the dorsal proximal forearm, the lateral epicondyle, and the dorsal surface of the web space of the thumb. The patient's pain is aggravated by activities such as carrying a heavy briefcase with the elbow fully extended, playing tennis, and other functional activities that require excessively forceful, repetitive, or sustained supination of the forearm, especially with the elbow straight. Patients may also report pain that persists even after these activities have ceased.

According to Simons et al,³ nearly every patient with lateral epicondylar pain has a supinator TrP, and they state that the supinator muscle is the muscle most frequently contributing to the pain of "tennis elbow." Nevertheless, the only TrP prevalence study in lateral epicondylalgia that included the supinator muscle among the muscles studied reported just a 50% involvement rate of this muscle in patients diagnosed clinically and with ultrasound imaging as having an enthesopathy of the extensor-supinator muscle complex.¹⁶ Despite this discrepancy, the relevance of supinator TrPs in this condition is considered very important when it is involved, in which case its treatment can be decisive

in the outcome.¹⁷

3.3. Patient Examination

After a thorough subjective examination, the clinician should make a detailed drawing representing the pain pattern that the patient has described. This depiction will assist in planning the physical examination and can be useful in monitoring the progression of the patient as symptoms improve or change. Screening of the cervical spine and shoulder girdle should be conducted to identify any possible sources of symptoms or contributing factors to the patient's presentation of lateral elbow or thumb pain.

Active and passive range of motion including elbow flexion and extension, forearm pronation and supination, and a combination of elbow extension with forearm pronation should be examined. The clinician should test specifically for supinator muscle length by simultaneously passively pronating the forearm and extending the elbow. This test may show range of motion restriction if the supinator muscle is adaptively shortened or has TrPs. If the subjective reports include pain in the region of the web space of the thumb, the range of motion of the thumb and carpometacarpal joints should be assessed. Thumb motion is usually not restricted and often is not painful; however, the patient may be sensitive to palpation in this region, especially if the supinator muscle has active TrPs.

To test the supinator muscle for strength with minimum interfering assistance from the biceps brachii muscle, have the patient in a supine position with the elbow extended along the side of the body and the hand and forearm in a neutral position and resist a supination effort by the patient.

The Apley's Scratch Test (see Figure 21-3A) shows slight restriction, and causes pain in the distribution described in Figure 36-3. A handshake with a firm grip becomes painful when extensor muscles of the wrist and fingers have developed associated TrPs.

Figure 36-3. Referred pain pattern (dark red) of TrPs in the right supinator muscle.

There has been some speculation that the eccentric function of the supinator muscle is compromised in individuals with lateral epicondylalgia.¹⁴ Hypothetically, this dysfunction might lead to excessive medial and inferior displacement of the radius, with increased load on the common extensor origin¹⁴ and on radial joints. Accessory joint motion of the radioulnar (proximal and distal), radiohumeral, and humeroulnar joints should be assessed because hypomobility in any of these joints may overload the supinator muscle. The radioulnar (proximal and distal) and radiohumeral joints are most critical for normal supinator muscle function,^{3,18} and hypomobility in these joints can not only be a consequence of supinator TrPs but also act as an activating and perpetuating factor of TrPs in this and in other muscles in the area.¹⁷

Neurodynamic testing of the radial nerve should be conducted to identify potential neuropathic contributions to the patient's reported symptoms. A thorough sensory and motor examination of the radial nerve and C7 nerve root should be conducted because of the structural interface of the arcade of Frohse and the supinator muscle.

Two studies related the development of lateral epicondylalgia with inadequate grip strength.^{19,20} With slight extension and no ulnar deviation of the hand at the wrist, the increase in strength protects the supinator muscle from overload and is easily demonstrated on a grip-strength meter. A slight extension places the forearm flexors at some mechanical advantage. Ulnar deviation places the ring and little finger flexors at a mechanical disadvantage. The bent elbow provides biceps brachii muscle assistance in supination and

helps prevent supinator muscle overload. The two-handed backhand stroke protects the supinator muscle by preventing complete elbow extension during the stroke. Tennis players who use a two-handed backhand have much less trouble with tennis elbow.^{21, 22}

If the player still has difficulty with the racket slipping from the hand because the grip is weak, the size of the racquet handle should be reduced^{19, 20} so that the fingers wrap fully around it. Otherwise the extensors, especially those of the ring and little fingers that are essential for a strong grip, function at a disadvantage. The additional effort required to keep a tight grip on a large handle further strains the finger extensors. Sometimes, it is also recommended to change the grip position.²³

3.4. Trigger Point Examination

Gerwin et al²⁴ established that, among experienced and trained clinicians, three reliable criteria for diagnosing TrPs were the detection of a taut band, the presence of spot tenderness, and patient's recognition of pain elicited from the tender spot in the taut band. In several muscles, local twitch responses were not identified as reliable. The supinator muscle was not one of the muscles tested in this study, but based on comparable muscles that were tested, the supinator muscle would likely be one of the more difficult and skill-demanding muscles to reliably examine for a local twitch response. A recent study by Mora-Relucio et al²⁵ evaluated the interexaminer reliability of two experienced and one inexperienced clinicians on TrP location in extensor carpi radialis brevis and extensor digitorum muscles, and it proved that diagnosis of TrPs in both muscles through palpation is reliable when the evaluators are expert practitioners. The authors warn that the validity of their findings is limited to superficial forearm muscles and may not be generalized to deeper muscles such as the supinator muscle.²⁵ Nevertheless, clinical experience and some studies show that TrPs in supinator muscle can be readily identified^{15, 16} and its pain referral evoked by palpation,^{13, 15} dry needling,¹³ or injection.¹⁴

The supinator muscle can develop TrPs in any part of the muscle belly, but it is common to identify them on the ventral aspect of the radius, just lateral and somewhat distal to the biceps brachii tendon (Figure 36-4A). The forearm must be fully supinated, otherwise the TrPs may be hidden by the ulna. In this position, the supinator TrPs lie directly over the radius and immediately beneath the skin between the biceps brachii tendon and the brachioradialis muscle. Both muscular landmarks are readily identified by asking the patient to flex the forearm against resistance. Cross-fiber flat palpation of irritable TrPs may occasionally produce a confirmatory supination twitch response of the hand in spite of the shortened position of the muscle. The muscular nature of the deep layer and of the deep aspect of the superficial layer² makes it more likely that the TrPs are deeply located. A monofilament or injection needle may be necessary to accurately identify TrPs in the supinator muscle because palpation of the deeper portion can be highly unreliable.

Figure 36-4. Cross-fiber flat palpation for TrPs in the supinator muscle. A, Ventral approach. B, Dorsal approach.

Sometimes, TrPs in the supinator muscle may be found by pressing downward against the ulna on the posterolateral side of the forearm, close to the radius as the muscle approaches its attachment where the lateral joint capsule meets the ulna (Figure 36-4B). This TrP area is evidenced by deep palpation through the mass of the extensors, especially through the extensor carpi ulnaris³ or the extensor digitorum¹⁷ muscles. Trigger points in the supinator muscle can be associated with posterior interosseous nerve entrapment.

4. DIFFERENTIAL DIAGNOSIS

4.1. Activation and Perpetuation of Trigger Points

A posture or activity that activates a TrP, if not corrected, can also perpetuate it. In any part of the supinator muscle, TrPs may be activated by unaccustomed eccentric loading, eccentric exercise in an unconditioned muscle, or maximal or submaximal concentric loading.²⁶ Trigger points may also be activated or aggravated when the muscle is placed in a shortened and/or lengthened position for an extended period of time.

Supinator muscle strain may occur when resisting unexpected pronation, as when the tennis player hits the ball “off-center,” twisting the racquet with the elbow completely extended as in a one-hand backhand stroke. During full elbow extension, the biceps brachii muscle cannot assist the supinator muscle to resist the added force. This sudden overload could activate TrPs in the supinator muscle, which could give rise to “tennis elbow” symptoms (lateral epicondylalgia).

Elbow pain often begins when a person gets a new racquet that is too heavy, has a larger handle, or is unbalanced and too heavy at the head end. The position of the grip on the racquet may be shortened to reduce the length of the lever arm against which the forearm muscles must operate.

Tennis players with this elbow dysfunction should not play on consecutive days, but should rest the supinator muscle until the postexercise soreness from overuse has worn off, usually in a day or two. There is some evidence that the frequency of playing and/or the volume of play is important in the prevention of the condition.^{21, 23} The use of bracing

systems is controversial and there is not much evidence of its usefulness in the prevention or in the treatment of lateral epicondylalgia.^{19,27}

Any excessively forceful, repetitive, or sustained supination of the forearm, especially with the elbow straight, may initiate activation of TrPs in the supinator muscle. A forceful elbow flexion motion when the forearm is held in pronation may also activate or perpetuate TrPs (Figure 36-2C). Carrying a heavy briefcase, suitcase, or heavy bag with the elbow straight when it must be stabilized by the supinator muscle with each step is also traumatic, especially if the leg bumps the back end of the object during ambulation.

Additional activating and perpetuating stresses include turning stiff doorknobs, wringing out wet clothing or a washcloth, using a screwdriver, unscrewing a tight jar lid by movement only at the wrist, walking an undisciplined dog excessively pulling on a leash, washing floors by hand, and raking leaves.

4.2. Associated Trigger Points

Associated TrPs can develop in the referred pain areas caused by primary TrPs.²⁸ Therefore, musculature in the referred pain areas for each muscle should also be considered. With the symptoms of pain and tenderness in the region of the lateral epicondyle, TrPs are often also found in the triceps brachii muscle (in the lower end of the lateral margin of its medial head) in the long extensors of the fingers, in the extensor carpi radialis longus and brevis muscles, and in the anconeus and brachioradialis muscles. Other TrPs involved in this pain are the scalene muscles, the infraspinatus muscle, the supraspinatus muscle, and less commonly, the subclavius muscle. Additional muscles that may become involved as part of the supinator muscle's functional unit but which do not refer pain to the lateral epicondyle are the brachialis, the biceps brachii, and sometimes the palmaris longus muscles.

4.3. Associated Pathology

Differential diagnosis of the symptoms caused by supinator TrPs include lateral elbow pain or epicondylalgia, entrapment of the deep branch of the radial nerve (radial tunnel syndrome or posterior interosseous nerve entrapment), local arthritis at the elbow,²⁹ radiocapitellar pathology (ie, synovial plica at the humeroradial joint),^{30–32} C5-C6 radicular pain or radiculopathy,³³ posterolateral rotatory instability,^{34,35} and nonspecific arm pain³⁶ (defined as diffuse forearm pain not associated with any particular structure), De Quervain's stenosing tenosynovitis, trapeziometacarpal joint arthritis, recurring articular dysfunction at the distal radioulnar joint, and entrapment of the superficial radial nerve (cheiralgia paresthetica or Wartenberg syndrome).

Lateral epicondylalgia (tennis elbow, radial epicondylalgia, or lateral elbow tendinosis) is a fairly commonly diagnosed upper limb musculoskeletal disorder, and the most common cause of lateral elbow pain in adults. Its incidence is lower than 10% in the general population.³⁷

Some studies have investigated the degree of involvement of TrPs in individuals with

lateral epicondylalgia reaching as high as 90%¹⁶ or even 100%.³⁸ As described earlier, the only TrP prevalence study on lateral epicondylalgia, which included the supinator muscle, reported an involvement rate of 50% in patients diagnosed clinically with ultrasound imaging confirmation as having an enthesopathy of the common wrist extensor tendon.¹⁶ Other muscles involved in lateral epicondylalgia are the extensor carpi radialis brevis muscle: 65%,³⁹ 83.3%,¹⁶ or 100%³⁸; the brachioradialis muscle: 50%^{38,39} or 66.6%¹⁶; the extensor carpi radialis longus muscle: 70%,³⁹ 96%,³⁸ or 72.2%¹⁶; and the extensor digitorum muscle: 35%^{38,39} or 83.3%.¹⁶ In a cadaveric study,⁴⁰ the authors tensile-loaded different muscles arising in the lateral epicondyle and measured their contribution to the tensile force generated in the common extensor tendon. They concluded that there is a biomechanical basis for the superficial head of supinator muscle in the etiology of lateral epicondylalgia.

Several controlled trials have demonstrated significant improvement in pain and dysfunction after the application of soft tissue techniques, focusing on the myofascial component of patients with lateral epicondylalgia.⁴¹ Although the isolated contribution of TrPs in the supinator muscle is not accurately known, TrPs could be a major contributor to pain and dysfunction in lateral epicondylalgia.

As discussed earlier in the wrist extensors and brachioradialis muscles chapter (see Chapter 34), it is currently unknown as to what degree myofascial pain coexists, causes, or predisposes sensory and motor impairments reported in individuals with lateral epicondylalgia. Nevertheless, given the high prevalence of TrPs found in people with lateral epicondylalgia,^{16,-38,39} their contribution to pain symptoms,^{16,-38,39} and the effectiveness of treatments focusing on myofascial components in this population,^{41,42} clinicians are encouraged to evaluate and treat TrPs as an essential component for the routine management of lateral epicondylalgia (see Chapters 34 and 35 for further information on this issue).

Entrapment of the deep branch of the radial nerve⁴³ (posterior interosseous nerve¹) as it enters the supinator muscle has been commonly accepted in the literature as a cause of neuropathic epicondylalgia,^{40,44} and it is sometimes referred to as “radial tunnel syndrome.”⁴⁴ It may or may not produce symptoms often identified in patients presenting with lateral epicondylalgia. The clinician should note that: (1) the painless weakness of muscles supplied by the radial nerve is frequently caused by a tumor⁴⁵; (2) a painful lateral epicondyle without muscular weakness or signs of nerve entrapment (usually diagnosed as lateral epicondylalgia) is often caused by TrPs without radial nerve compromise; and (3) the mixture of lateral epicondylalgia and evidence of radial nerve entrapment in the region of the supinator muscle suggests the possibility of both nerve entrapment and supinator TrPs. A study in cadavers demonstrated a biomechanical basis for the superficial head of the supinator muscle in the etiology of both lateral epicondylalgia and radial tunnel syndrome.⁴⁰

True posterior interosseous neuropathy causes neurogenic weakness in the muscles innervated by the nerve,⁴⁶ distal to the point of entrapment. The typical pattern of

weakness does not involve the extensor carpi radialis muscle, so wrist drop is absent, but because of weakness of the extensor carpi ulnaris muscle, the patient may radially deviate the wrist during wrist extension.⁴⁶ Finger extension at the metacarpophalangeal joints is impaired, as is the action of the abductor pollicis longus and extensor pollicis longus and brevis muscles.⁴⁶ Pain and focal tenderness are not necessarily present in patients with this presentation and no sensory deficits are reported.⁴⁶

Surgical reports of radial nerve entrapment make it clear that the problem frequently occurs as the posterior interosseous nerve enters the supinator muscle (Figure 36-1B and C).⁴⁷ An anatomic study showed that the proximal edge of the superficial layer of muscle fibers formed a tendinous thickened border in 30% of 50 “normal” adult arms.⁴⁸ As stated earlier, different studies have shown that it is muscular in newborn full-term fetuses, and it has been suggested that repetitive pronation and supination movements probably form this semicircular fibrous arcade in adults.² Actually, the thickened arch was much more common in patients who received surgical intervention for a supinator syndrome than in “normal” arms.

Moreover, supinator TrPs can also cause entrapment of the deep radial nerve if those supinator fibers that are attached to an arcade with a thick tendinous edge are shortened by activity of these TrPs and create tension on the arcade of Frohse.

Clinically, it is often found that inactivation of all TrPs relieves the pain, and usually relieves the deep radial nerve entrapment, without surgical intervention. Patients with a hypertrophied arcade⁴⁰ may be more vulnerable to entrapment of the radial nerve by supinator TrPs. There is a paucity in the literature, and not one paper could be located that reported systematic examination of patients for TrPs with this entrapment or for the results of treating TrPs. Competent research studies of this type are sorely needed.

5. CORRECTIVE ACTIONS

According to the literature, the prevalence of lateral epicondylalgia in tennis players ranges between 14.1%¹⁹ and 35%,²¹ or even up to 50% throughout their tennis career.⁴⁹ To decrease these rates, tennis players should keep the wrist slightly extended⁵⁰ and the elbow slightly bent during play (Figure 36-5A). Allowing the head of the racquet to drop (Figure 36-5B) reduces grip strength. Consultation with a professional for appropriate racquet size, weight, and grip is highly recommended.

A patient with supinator TrPs or lateral epicondylalgia is encouraged to use rolling luggage, or carry his or her briefcase or purse tucked under the arm with the elbow bent. While pulling the luggage, the patient should be sure to keep the elbow in slight flexion and the wrist in slight extension with radial deviation to decrease the external load on the supinator muscle.

Figure 36-5. Use and misuse of the tennis racquet (backhand stroke). A, Effective position. The elbow is slightly bent and the wrist cocked in radial extension to raise the head of the racquet. B, Ineffective position. The elbow is straight and the wrist dropped, which overloads the supinator muscle during supination at the end of the stroke and weakens the grip.

For some activities, wrist-rotation stress may be avoided temporarily by using the other hand or by using the affected hand differently. Instead of wringing washed clothes or a cleaning rag, they may be pressed against the bottom of the sink to drain the water from them. Raking leaves and walking a large dog that pulls on a leash should be discontinued. If shaking hands in a receiving line is unavoidable, the patient is encouraged to do a fist bump.

The patient with supinator TrPs should learn to carry packages with the forearms supinated (Figure 36-2A) rather than pronated (Figure 36-2C). This position substitutes the biceps brachii muscle for the supinator muscle as an assistant to the brachialis muscle in flexing the elbow while lifting loads. The biceps brachii muscle is much stronger than the supinator muscle for this purpose. Patients may also need to assume a sleeping posture as described in Figure 35-5B.

It is very difficult to perform self-pressure release or self-stretching exercises for self-management of supinator TrPs. Patients with lateral elbow pain are encouraged to seek care from a clinician who has knowledge and expertise in myofascial pain and dysfunction.

Palmaris Longus Muscle

“Variant Vandal”

Wesley J. Wedewer

1. INTRODUCTION

The palmaris longus muscle is a highly variable muscle of the anterior forearm that, when present, is commonly observed in clinical practice to have trigger points (TrPs). It mainly functions to flex the wrist and tense the palmar fascia and may contribute to abduction of the thumb. Trigger points in this muscle refer a superficial, needle-like prickling pain that centers in the palm and extends to the base of the thumb and to the distal crease of the palm. Occasionally, the referred pain may include the distal volar forearm. Palmaris longus TrPs frequently develop in manual laborers, carpenters, and novice athletes who improperly grip their equipment. Patients often report pain in the palm and difficulty in handling tools or equipment. This muscle may be involved in several different conditions including carpal tunnel syndrome and Guyon canal syndrome. Modification of tools or correction of improper gripping techniques can help decrease stress and pressure onto the palm and is a critical component of management of TrPs in this muscle for laborers and athletes. Self-stretches to the palmar fascia and the palmaris longus muscles are effective for resolution of TrPs.

2. ANATOMIC CONSIDERATIONS

In its most frequent form, the palmaris longus muscle arises from the medial epicondyle of the humerus via the common flexor origin and from adjacent intermuscular septa and deep fascia. It is a long slender fusiform muscle with its belly located in the proximal half of the forearm between the flexor carpi radialis and flexor carpi ulnaris muscles. It becomes tendinous in the mid-forearm, and the long tendon overlies the flexor digitorum superficialis muscle. At the wrist, its tendon passes superficial to the flexor retinaculum. A few fibers leave the tendon and interweave with the transverse fibers of the retinaculum, but most of the tendon passes distally. As the tendon crosses the retinaculum, it broadens out to

become a flat sheet that becomes incorporated into the triangular palmar aponeurosis (Figure 37-1).¹ The tendon stands out clearly when the hand is actively flexed and the palm cupped, because the tendon is superficial to the carpal tunnel and ends in the hand as the palmar aponeurosis (Figure 37-1).²

Figure 37-1. Ventral forearm muscles including the usual attachments of the palmaris longus muscle (red). It originates at the medial epicondyle, and attaches distally to the palmar aponeurosis. The superficial layer of the palmar aponeurosis has fibrous bands that extend into the fingers and often to the thumb.

The palmar aponeurosis comprises two layers. A superficial layer of longitudinal fibers extends directly from the palmaris longus tendon at the wrist to the fingers. There, the fibers fan out in bundles to cover the flexor tendons of each finger and often of the thumb. Some of the superficial fibers attach to the skin of the flexor crease at the base of the fingers. Others continue into the digits to merge with the digital sheaths. The rest of the distal superficial fibers arch as bands transversely across the underlying tendons and muscles. The deep layer, which consists mainly of transverse fibers, blends with the transverse metacarpal and transverse palmar ligaments. The fibers of the two layers of aponeurosis intertwine.³ A lateral slip from the palmaris longus tendon attaches to the superficial surface of the abductor pollicis brevis muscle, and this connection may account for a role of thumb abduction.⁴⁻⁶ The palmaris longus muscle is occasionally absent on one or both sides and is anatomically highly variable.⁷

Variations of the palmaris longus muscle include congenital absence, unilateral,^{8,9} or more commonly, bilateral^{10,11}; reversal of the muscle belly-tendon relationship (tendinous at its proximal end and muscular at its distal end); a distally placed muscle belly¹²; a double-bellied muscle⁶; and a distally placed anomalous muscle that may demonstrate a variety of attachments.^{1,6} The incidence of total absence or so-called agenesis is estimated at 15% of the global population.⁶ There have been numerous studies that have objectively assessed palmaris longus muscle presence, and the results showed that its absence ranges between 1.5% and 63.9% among different populations.^{2,13-19} Current evidence is conflicting, but there appears to be a trend that palmaris longus muscle absence is more common in women^{6,15-18,20} and on the left side.^{14,-16,18} Bilateral agenesis presents to be more common as compared with the absence of just one muscle,^{14,15,18,20} but evidence is contradictory.^{2,-13,19} One study showed a high correlation in individuals with palmaris longus agenesis to be left hand dominant.²¹ Palmaris longus agenesis is postulated to be inherited as a sex-linked dominant trait.⁶ Anomalies other than absence occur in approximately 9% of individuals.^{12,-22,23}

Palmaris longus muscle variations can contribute to painful syndromes of the forearm and wrist, including carpal tunnel syndrome and Guyon canal syndrome. Cases are infrequently reported, but when anomalies are discovered intraoperatively, they typically require surgical removal of the muscle to relieve patient's symptoms.

Several reports of patients having signs and symptoms consistent with Guyon canal syndrome were discovered during surgery to be due to having a hypertrophied accessory palmaris longus muscle.²⁴⁻²⁶ An anomalous reversed palmaris longus muscle that entered the Guyon canal has been observed in several patients,^{27,28} but it did not always cause symptoms related to overcrowding.²⁹

Multiple cases of what appeared to be carpal tunnel syndrome were found to have a variation of the palmaris longus muscle in which the tendon passed beneath, rather than above, the volar carpal ligament.^{30,31} A dual palmaris longus tendon, central muscle belly variant, was observed to cause median nerve compression in the mid-forearm.³² Three other cases proved to have anomalous distal bellies of the palmaris longus muscle that compressed the median nerve against the underlying tendons.³³ The surgical decompressions described all produced successful outcomes.³⁰⁻³³ A cross-sectional study examined the influence on the presence or absence of the palmaris longus tendon on median sensory nerve latencies across the wrist. Werner and Spiegelberg found the presence of a palmaris longus tendon did not influence the median nerve function across the wrist in 462 healthy subjects.³⁴

The palmaris longus muscle is considered an accessory muscle and is not essential for normal muscle function. Therefore, the palmaris longus tendon is commonly used for various reconstruction surgeries because of its lack of importance in function, low donor site morbidity, and easy accessibility for harvesting.^{35,36} Wehbe concluded that the palmaris longus tendon should be the prime choice for tendon grafts when a strong tendon is required.³⁶ Examples of its use vary to include ulnar collateral ligament reconstructive surgery in overhead athletes,³⁷ acromioclavicular joint reconstruction,³⁸ sternoclavicular joint reconstruction,³⁹ triangular fibrocartilage complex reconstruction,⁴⁰ interposition arthroplasty of the carpometacarpal joint,⁴¹ and facial palsy,⁴² among others.^{7,43}

2.1. Innervation and Vascularization

The median nerve supplies the palmaris longus muscle through a branch from spinal roots C6-C7,^{44,45} C7-C8 (the usual arrangement),^{1,46,47} or C7-T1.⁴⁸ The median nerve forms from the union of the lateral root (C6-C7) from the lateral cord, and the medial root (C8-T1) from the medial cord that meet anterior to the third part of the axillary artery. The median nerve branch to the palmaris longus muscle is variable; it may penetrate the flexor carpi radialis muscle⁴⁶ or the superficial fibers of the flexor digitorum superficialis muscle.⁴⁹

A small vascular branch from the anterior ulnar recurrent artery supplies the vascularization of the palmaris longus muscle.^{1,50} A contribution is sometimes made by the median artery (a branch of the anterior interosseous artery)¹ or brachial⁵⁰ artery. The arterial branches penetrate the muscle through the posterior aspect, either through the proximal third or middle third of the belly.⁵⁰

2.2. Function

The distinctive primary function of the palmaris longus muscle is to tense the palmar fascia and weakly flex the wrist.^{1,47,51} It also acts as an anchor for the skin and fascia of the hand, stabilizing the structures against shearing forces.^{1,-7,16} This muscle may also contribute to abduction of the thumb.^{4,20}

Functions of the palmaris longus muscle have been substantiated in the literature.

Duchenne,⁵² upon neuromuscular stimulation of the palmaris longus muscle, observed only wrist flexion without pronation or deviation of the hand to either side. Authors have consistently noted this flexor function.^{44, 47, 49, 51, 53} Historically, Beever⁵³ observed that the palmaris longus muscle contracted with the flexor carpi radialis muscle as the hand was pronated against resistance; others have agreed with this pronator function.^{49, 54} Pai and colleagues examined cadavers and concluded that the distal tendinous segments of the palmaris longus muscle appear to contribute to stabilizing the mobile end of the long axis, around which supination and pronation of the forearm occur.²² Because of the muscle's attachment to the medial epicondyle of the humerus, some authors propose a possible weak flexor action at the elbow.^{47, 49} Although several secondary functions of the palmaris longus muscle have been proposed, the literature is inconclusive and is based off weak evidence at best.

Generally, the palmaris longus muscle's role is negligible, which is why it is used in many reconstruction operations without any cost to the function of the forearm or the wrist.⁷ Absence of the palmaris longus muscle is not associated with a decrease in grip or pinch strength.⁵⁵ It has also been demonstrated that utilizing the ipsilateral palmaris longus tendon for ulnar collateral ligament reconstruction does not appear to compromise pitching mechanics in baseball players.^{56, 57}

2.3. Functional Unit

The functional unit to which a muscle belongs includes the muscles that reinforce and counter its actions as well as the joints that the muscle crosses. The interdependence of these structures is functionally reflected in the organization and neural connections of the sensory motor cortex. The functional unit is emphasized because the presence of a TrP in one muscle of the unit increases the likelihood that the other muscles of the unit will also develop TrPs. When inactivating TrPs in a muscle, one must be concerned about TrPs that may develop in muscles that are functionally interdependent. Box 37-1 grossly represents the functional unit of the palmaris longus muscle.⁵⁸

Box 37-1 Functional unit of the palmaris longus muscle

Action	Synergists	Antagonists
Wrist flexion	Flexor carpi radialis Flexor digitorum superficialis Flexor carpi ulnaris	Extensor carpi radialis longus Extensor carpi radialis brevis Extensor digitorum Extensor carpi ulnaris
Thumb abduction	Abductor pollicis longus and brevis	Adductor pollicis Extensors of the thumb

	Flexor pollicis brevis Opponens pollicis	
--	---	--

3. CLINICAL PRESENTATION

3.1. Referred Pain Pattern

The palmaris longus muscle can exhibit TrPs in any part of the muscle. Trigger points in the palmaris longus muscle refer a superficial, needle-like prickling pain rather than the deep-tissue aching pain of most other muscles. This is similar to the platysma, which also acts primarily on the cutaneous tissue. The referred pain pattern typically centers in the palm (Figure 37-2). It can extend to the base of the thumb and to the distal crease of the palm but not into the digits. The prickling sensation feels as if many fine needles are producing it. The pain may also spread to the distal volar forearm.

Figure 37-2. Patterns of the referred prickling sensation (dark red) arising from TrPs in a right palmaris longus muscle (light red) in its usual configuration. The referred sensation is described as a superficial painful prickle, rather than an aching pain. The belly of this variable muscle, and therefore its TrPs, may lie high or low in the forearm.

3.2. Symptoms

In addition to pain, patients with TrPs in the palmaris longus muscle may report difficulty in handling tools because of soreness and tenderness in the palm, and the soreness may call attention to tender nodules there. The pressure of working with the handle of a screwdriver or trowel in the palm can become intolerably painful. For instance, a construction worker may be unable to firmly grip tools to secure a bolt or screw.

Most manipulative activities involve thumb abduction. Patients may report overuse symptoms from TrPs in the palmaris longus muscle after performing repetitive activities (eg, when playing a musical instrument that requires a wide span of the hand, such as when repeatedly striking a key on a piano with the thumb, or when performing a recurring manual task in a factory or on a computer requires a similar movement).⁴ Overuse may be more pronounced when the activities are resisted.

3.3. Patient Examination

After a thorough subjective examination, the clinician should make a detailed drawing representing the pain pattern that the patient has described. This depiction will assist in planning the physical examination and can be useful in monitoring the progression of the patient as symptoms improve or change. For proper assessment and examination of the palmaris longus muscle, the clinician should first assess the general and resting hand posture, range of motion of the wrist and fingers, and the presence of the palmaris longus muscle. The palm and fingers should be palpated for nodules that may be associated with Dupuytren contracture (most commonly at the ring and little fingers) as a potential differential diagnosis.

To assess for the presence of the palmaris longus muscle, the patient should have his or her arm supported with the forearm supinated and elbow flexed before the patient cups the hand forcefully (Figure 37-3) abducting and opposing the thumb toward the little finger with the wrist partially flexed to make the tendon stand out at the wrist superficial to the transverse carpal ligament. The prominence of the tendon depends on the degree of wrist flexion or extension. This becomes evident when the strongly cupped hand is moved slowly from extension to flexion. Palpation of the muscle during contraction helps to identify variations of the usual structure. There are more than 10 different clinical tests that have been established and referred to in the literature to identify presence, absence, and variations in the palmaris longus muscle.^{2,13,20,59-61}

Figure 37-3. Identification that the individual has a palmaris longus muscle. Finger points to palmaris longus tendon in the right arm. Note its absence in the left forearm.

3.4. Trigger Point Examination

Currently, there are no reliability studies specific to the examination of the palmaris longus muscle for TrPs. However, in other muscles, Gerwin et al⁶² found that the most reliable examination criteria for making the diagnosis of TrPs were the identification of a taut band by palpation, the presence of spot tenderness in the band, the presence of referred pain, and reproduction of the patient's symptomatic pain. Although identification of a local twitch response by palpation was unreliable, it is a valuable objective confirmatory finding when present.

For examination of the palmaris longus muscle, the patient can be seated in a chair with his or her forearm relaxed and in contact with the armrest. Alternatively, a supine position with the shoulder slightly abducted and externally rotated and the forearm relaxed on a pillow (Figure 37-4) may be assumed. Cross-fiber flat palpation is utilized to locate a TrP in the palmaris longus muscle. The TrP usually responds with a local twitch response seen as wrist flexion. Stimulation of this TrP by pressure often elicits the projection of referred prickling pain into the volar forearm and up to the base of the thumb and distal crease of the palm (Figure 37-4).

Figure 37-4. Cross-fiber flat palpation for TrPs in the palmaris longus muscle.

No nerve entrapments have been observed because of TrPs in this muscle. However, anatomic variations may cause median nerve entrapment at the wrist^{30,32} or ulnar nerve entrapment in the region of the ulnar tunnel at the wrist.^{25–28,63} In addition, increased tension and nodular enlargement characteristic of TrPs in one of these variant muscle configurations could aggravate entrapment symptoms.

4. DIFFERENTIAL DIAGNOSIS

4.1. Activation and Perpetuation of Trigger Points

A posture or activity that activates a TrP, if not corrected, can also perpetuate it. Unaccustomed eccentric loading, eccentric exercise in an unconditioned muscle, or maximal or submaximal repetitive concentric loading can activate TrPs in any part of the palmaris longus muscle.⁶⁴ Trigger points may also be activated or aggravated when the muscle is placed in a shortened and/or lengthened position for an extended period of time.

In addition, TrPs in the palmaris longus muscle may also be activated by direct trauma, such as a fall on the outstretched hand. The use of a tool forcibly pressed or held firmly in the cupped palm can aggravate and possibly initiate TrP activity in the palmaris longus muscle. Examples include gardening and using a screwdriver or other carpenter's tools. Holding a tennis racquet with the end of the handle against the palm, and leaning on a cane with an angular, rather than a round handle pressing into the palm may also activate or perpetuate TrPs in this muscle. The novice worker or athlete is apt to maintain the palm in a more tightly cupped position for longer periods when holding equipment, whereas the skilled more experienced individual does not.

4.2. Associated Trigger Points

Associated TrPs can develop in the referred pain areas caused by primary TrPs. Therefore, musculature in the referred pain areas for each muscle should also be considered.⁶⁵ Muscles in the referred pain regions of the palmaris longus muscle are frequently associated with TrPs in the wrist and finger flexors. However, palmaris longus TrPs are rarely associated with TrPs in the muscles that refer pain to the elbow, as in “tennis elbow” or “golfer’s elbow.” Associated TrPs in the palmaris longus muscle may develop secondary to TrPs in the distal medial head of the triceps brachii muscle,⁶⁶ which can also refer pain to the region of the palmaris longus muscle.

4.3. Associated Pathology

Trigger points in this muscle are associated with or can mimic several different conditions; therefore, a thorough medical screening and examination are essential and a possible referral to another healthcare practitioner may be necessary.

The volar wrist and hand pain and tenderness may tempt some clinicians to diagnose the symptoms caused by palmaris longus TrPs as carpal tunnel syndrome. When the palmaris longus muscle anomalously extends under the carpal ligament, TrPs in it can cause a genuine carpal tunnel syndrome. Active TrPs in such a muscle would increase tendon tension and tend to aggravate the carpal tunnel symptoms.

In 2005, Wainner et al published a clinical prediction rule to aid clinicians in diagnosing carpal tunnel syndrome. The components include: (1) shaking hands for symptom relief; (2) wrist ratio index >0.67 ; (3) Symptom Severity Scale score >1.9 ; (4) reduced median sensory field of the first digit; and (5) age >45 years. The likelihood ratio was 18.3 when all five tests were positive and was 4.6 when at least four of the tests were positive.⁶⁷

Electrodiagnostic examination of the median nerve is commonly used as the reference standard, with separate guidelines established by the American Association of Electrodiagnosis, the American Academy of Neurology, and the American Physical Medicine and Rehabilitation Academy to classify patients as having minimal, moderate, or severe carpal tunnel syndrome.⁶⁸ Interestingly, positive electrodiagnostic findings do not necessarily correlate to symptom development,⁶⁹ severity, or clinical presentation.^{70,71} Therefore, diagnosis of carpal tunnel syndrome presents a clinical challenge that must incorporate clinical pain presentation and full clinical examination, and integrate imaging/electrodiagnostic studies as necessary. Because of its distinctive prickling pain, TrPs in the palmaris longus muscle are usually easily distinguished from carpal tunnel syndrome, but nonetheless, should still be examined in the event of a positive electrodiagnostic finding. Other painful conditions of the volar wrist and hand such as referred pain from TrPs in the flexor carpi radialis, pronator teres, and the brachialis muscles should also be assessed.

Patients with Dupuytren contracture may present with symptoms that could be

confused with active TrPs in the palmaris longus muscle. In the case of Dupuytren contracture, dimpling over the palmar crease on the ulnar side of the hand is evident along with digital flexion contractures, most typically involving the metacarpophalangeal and proximal interphalangeal joints of the ring or little finger. Palpation of the palm during the early development of Dupuytren contracture reveals discretely tender nodules and patient reports of diffuse referred palmar tenderness, typically responding as “soreness” to the applied pressure. In contrast, the TrP-referred sensation has a prickling quality. The presence of digital flexion contractures, discrete nodules, and diffuse tenderness rather than a cutaneous prickling sensation enables the practitioner to differentiate TrPs from Dupuytren contracture. Conservative rehab for Dupuytren contracture is not warranted.

5. CORRECTIVE ACTIONS

Correction of aggravating activities is an essential first step for anyone who experiences pain during manual labor. Using ill-fitted tools such as a screwdriver or jackhammer with the end of the handle held directly against the palm can activate TrPs in the palmaris longus muscle, especially when used repetitively. It is important to make ergonomic modifications such as increasing the girth of the handle (for wider dispersion of forces), wearing padded gloves, and alternating techniques to decrease direct pressure onto the palm from the tool. The same adjustments can be utilized in athletes who develop TrPs as a result of improper handling of equipment in sports such as tennis, hockey, and lacrosse, among others. It is important to assess how athletes grip equipment at a young age to ensure they do not develop poor habits that are generally more challenging to correct at an older playing age.

The patient should learn to self-stretch the palmar fascia and palmaris longus muscle in a warm bath or shower, using the stretch position shown in Figure 37-5. The patient may also sit with the forearm of the affected side supported on a padded surface. The fingers and hand are extended until the patient feels a moderate stretch. Extending the forearm at the elbow normally does not add to the passive stretch. Simultaneously extending the thumb may increase further gains. As always, it is important to avoid stretching muscles to full range of motion in hypermobile joints. Patients with osteoarthritis in any of the joints in the thumb likely will not be able to tolerate the addition of thumb extension.

Figure 37-5. Self-stretch position for the palmaris longus muscle. To fully stretch the muscle, the patient simultaneously extends his or her fingers and hand at the wrist. Adducting the thumb with his or her contralateral index finger can enhance the stretch of the muscle.

After stretching, the entire group of forearm flexor muscles, particularly the wrist and finger flexors, may then be stretched to eliminate any associated TrP involvement of parallel muscles (see Chapter 38). After inactivation of the palmaris longus TrPs, firmly extending the fingers and splaying the palm under warm water may stretch mild to moderate contractures of the palmar fascia.

Wrist and Finger Flexors in the Forearm

Flexor Carpi Radialis and Ulnaris Muscles; Flexor Digitorum Superficialis and Profundus Muscles; Flexor Pollicis Longus Pronator Teres, and Pronator Quadratus Muscles:

“Pseudo Golfer’s Elbow and Gripping Grippers”

Johnson McEvoy and Joseph M. Donnelly

1. INTRODUCTION

The wrist and finger flexor muscles and the pronator muscles of the forearm are important muscles in power gripping and in fine dexterous movements of the forearm, wrist, and hand. The synergy between the forearm extensor muscles and flexor muscles optimizes the wrist position and hand grip for efficient movement and function. These muscles are involved in pain syndromes of the elbow, forearm, wrist, hand, and fingers. Trigger points (TrPs) in these muscles may be primary pain generators or coexist with other diagnoses. Activation and perpetuation of TrPs in these muscles can occur with gripping and repetitive hand actions. Symptoms may include pain, paresthesias, and dysesthesias in the elbow, forearm, wrist, and hand. Differential diagnosis includes medial epicondylitis; ulnar neuropathy; carpal tunnel syndrome; osteoarthritis of the wrist; C5, C6, C7, C8, and T1 radicular pain or radiculopathy; and median and ulnar nerve entrapment syndromes. Corrective actions include modification of activities (especially those that require gripping), self-pressure TrP release, self-stretching, and strengthening.

2. ANATOMIC CONSIDERATIONS

Wrist Flexor Muscles

The flexor carpi radialis (FCR) muscle¹ is subcutaneous and nearly centered on the volar side of the forearm between the pronator teres muscle, which crosses the forearm above it on the radial side, and the palmaris longus muscle, which tends to overlap it on the ulnar side (Figure 38-1A). This radial wrist flexor muscle originates from the medial epicondyle via the common flexor tendon and to the intermuscular septa. The muscle belly extends

only to the mid-forearm. Its tendon inserts mainly onto the base of the 2nd metacarpal bone, with a slip extending to the base of the 3rd metacarpal bone.

Figure 38-1. Volar view of the right upper extremity showing the attachments of the wrist and finger flexor muscles in the forearm. A, Flexor carpi radialis and flexor carpi ulnaris muscles are dark red, other muscles including the pronator teres muscle are medium red. B, Flexor digitorum superficialis muscle (dark red). The ulnar head lies unseen beneath the humeral head. C, Flexor digitorum profundus and flexor pollicis longus muscle (dark red) and the cut end of the flexor digitorum superficialis muscle (light red).

The flexor carpi ulnaris (FCU) muscle¹ lies superficially along the volar side of the sharp edge of the ulna. It originates proximally by two heads: the humeral head attaches to the medial epicondyle of the humerus via the common flexor tendon, and the ulnar head attaches to the medial margin of the olecranon and to the proximal two-thirds of the dorsal border of the ulna through an aponeurosis shared in common with the extensor carpi ulnaris and flexor digitorum profundus (FDP) muscles, and to intermuscular septa. Distally, its tendon inserts onto the pisiform bone.

Finger Flexor Muscles

Proximally, the flexor digitorum superficialis (FDS) muscle¹ has three heads: humeral, ulnar, and radial (Figure 38-1B). The humeral head originates from the medial epicondyle of the humerus via the common flexor tendon and to the intermuscular septa. The ulnar head attaches to the medial side of the coronoid process of the ulna, proximal to the attachment of the pronator teres muscle, beneath the humeral head. The radial head attaches to the oblique line of the radius between the attachments of the biceps brachii and pronator teres muscles. The median nerve passes beneath the fibrous archway between the attachments of the ulnar and radial heads. This muscle covers most of the volar forearm, beneath the palmaris longus muscle and flexor carpi muscles (Figure 38-1B).

The tendons at the wrist, and to some extent the fibers of the FDS muscle, lie in a deep and superficial plane. The superficial plane carries tendons to the middle and ring fingers, and the deep plane carries tendons to the index and little fingers.¹

Distally, at the first phalanx, each tendon of the FDS muscle divides to pass around the deep tendon of the FDP muscle, as each superficialis tendon attaches to the sides of a middle phalanx.¹

The fibers of the FDP muscle¹ (Figure 38-1C) extend through the proximal half on the ulnar side of the forearm. The muscle originates from the proximal three-fourths of the volar, medial, and dorsal surfaces of the ulna to an aponeurosis shared by the flexor and extensor carpi ulnaris muscles, to the medial side of the coronoid process of the ulna, and to the ulnar half of the interosseous membrane. Each tendon inserts onto the base of the terminal phalanx of the respective finger.

The flexor pollicis longus (FPL) muscle¹ (Figure 38-1C) extends throughout the forearm under more superficial muscles, chiefly on the radial side. It originates proximally from the radius, the adjacent interosseous membrane, and by a slip to the humerus, and it inserts onto the base of the distal phalanx of the thumb. The belly of the FDS muscle

covers both the deep finger flexor and the long thumb flexor muscles.¹

Pronator Muscles

The pronator teres muscle¹ originates above and medially by two heads. The humeral head attaches proximally to the medial epicondyle and to the adjacent fascia. The ulnar head attaches to the medial side of the coronoid process of the ulna, and the median nerve enters the forearm between these two heads. The muscle travels distally and laterally and inserts onto the lateral surface of the radius at its midpoint in the forearm.

The pronator quadratus muscle is a deep flat muscle that covers the distal ends of the ulna and radius anteriorly. It originates from the anterior surface of the shaft of the distal ulna and by a strong aponeurosis that covers the medial one-third of the muscle. The muscle travels obliquely and downward to insert onto the distal aspect of the anterior surface of the radius.¹ Cadaveric studies have shown that the pronator quadratus muscle has a superficial head and a deep head.^{2–4} The superficial head has a transverse orientation from the distal anterior ulna to the distal anterior radius. The deep head has an oblique orientation arising from the anterior surface of the ulna and traveling downward and laterally to insert onto the anterior surface of the radius and onto the distal radioulnar joint.^{2–4} Sakamoto et al² describe two or more muscle fascicles with multiple arrangements both in the superficial and deep head in 80% of the forearms investigated. They also found a slip of muscle in 26 of 40 forearms that inserted onto the head of the ulna extending to the styloid process. They suspect that this slip of muscle would provide additional stabilization to the distal radioulnar joint.

Locations and Structure

The specific location of the bellies of the four digitations of the FDS muscle is described and illustrated.⁵ The muscle bellies for the 2nd and 5th digits are relatively distal and those of the 3rd and 4th digits are largely proximal to them.

The architectural arrangement of fibers in the FCR (see below for compartmentalization) and FCU muscles⁶ reveals similar fiber lengths (51 and 41 mm). However, the ulnar muscle is much more pennate (12°) than the radial one (3.1°). This is reflected in the ratios of the fiber length to the muscle length of 0.19 and 0.31, respectively. Extensor forearm muscles show a much larger range of length ratios.⁷ The FCU muscle favors force rather than speed and should have an endplate zone that would be nearly longitudinal from almost one end of the muscle to the other end. However, the FCR muscle is structured for speed rather than force and would be expected to have a diagonal endplate zone that would likely be broken by the three separate compartments of the muscle.⁸

The pronator teres muscle has a “strength” architecture similar to that of the FCU muscle (pennate angle 10° and a short fiber length/muscle length ratio of 0.28). The finger flexor and long thumb flexor muscles have intermediate architecture tending toward more

of the force configuration progressively from the FDS muscle through the FDP muscle to the FPL muscle.

As in most skeletal muscles, the fiber type in the FCR and FPL muscles was nearly evenly distributed between Type I and Type II fibers.⁹ Interestingly, there was a consistently lower percentage (about 6% difference) of type I (slow twitch) fibers on the dominant side when compared with the nondominant side.¹⁰

The FCR muscle shows evidence of three compartments, each innervated by a separate branch of the motor nerve. Fibers inserting along the midline of the tendon are longitudinally oriented. A medial and a lateral group of fibers attach along the sides of the tendon.⁸ It is characteristic for each of such compartments to have a separate endplate zone. The functional significance of these separately innervated compartments is not currently known.

2.1. Innervation and Vascularization

Wrist and Finger Flexor Muscles

Most of the flexor muscles in the forearm, including the FCR, FDS, and FPL muscles, are supplied by the median nerve.¹ However, the FCU muscle and half of the FDP muscle are supplied by the ulnar nerve, and the other half are supplied by the median nerve.¹

The FCR muscle derives its innervation from spinal nerves C6 and C7, the FDP muscle from C7 and C8, and the FCU, FDP, and FPL muscles from C8 and T1.¹ Thus, the most caudal of these spinal segments innervate the deepest flexor muscles and those on the ulnar side of the forearm.

Pronator Muscles

The pronator teres muscle is innervated by a branch of the median nerve through spinal nerves C6 and C7.¹ The pronator quadratus muscle is innervated by the anterior interosseous branch of the median nerve through spinal nerves C7 and C8. The deep head is innervated via branches of the anterior interosseous nerve that lie on the surface of the distal radius.^{1,2}

The radial artery supplies the anterolateral aspect of the FCR muscle, the lateral half of the FDS and FPL muscles, and the radial insertion of the pronator teres muscle.¹ The ulnar artery supplies the FCU, FDS, FDP, FPL, and pronator teres muscles.¹

2.2. Function

Wrist Flexor Muscles

The FCR muscle flexes the hand and assists abduction of the hand at the wrist.^{1,11,12} The FCU muscle flexes and strongly adducts the hand^{1,11} and is active during finger-flexion movements.¹³ An electromyographic study¹⁴ substantiated these functions.

Finger Flexor Muscles

The FDS muscle primarily flexes the middle phalanx of each finger,¹² flexes the proximal phalanx, as well as the hand at the wrist.^{1, 11}

The FDP muscle primarily flexes the terminal phalanx of each finger and also all the other phalanges and the hand.^{1, 11, 12} It is used not so much for wrist flexion, as for gross closure of the fist at all joints simultaneously.¹⁵

The FPL muscle initially flexes the terminal phalanx of the thumb, then the proximal phalanx with adduction of the metacarpal bone,¹ and eventually assists in flexion and radial deviation of the hand at the wrist.^{11, 12} Normal flexion of this prime mover requires coordinated activity of four other thumb muscles.¹⁶

Pronator Muscles

The pronator teres muscle assists the pronator quadratus muscle in fast pronatory movements and to overcome resistance.¹² The pronator teres muscle also assists flexion at the elbow¹² but only when resistance is offered.¹⁵

The pronator quadratus muscle's primary function is to pronate the forearm in all positions of elbow flexion.¹⁵ Ok et al¹⁷ investigated the cross-sectional area of the pronator quadratus muscle and hand grip strength in the dominant and nondominant forearms of 89 healthy volunteers. The results demonstrated a correlation between grip strength, hand dominance, and pronator quadratus muscle thickness in the dominant arm of all individuals whether they were right- or left-hand dominant. The pronator quadratus muscle plays a key role in most functional activities requiring arm dominance.¹⁷

2.3. Functional Unit

Wrist and Finger Flexor Muscles

The functional unit to which a muscle belongs includes the muscles that reinforce and counter its actions as well as the joints that the muscle crosses. The interdependence of these structures is functionally reflected in the organization and neural connections of the sensory motor cortex. The functional unit is emphasized because the presence of a TrP in one muscle of the unit increases the likelihood that the other muscles of the unit will also develop TrPs. When inactivating TrPs in a muscle, one must be concerned about TrPs that may develop in muscles that are functionally interdependent. Box 38-1 grossly represents the functional unit of the wrist flexor, finger flexor, and forearm pronator muscles.¹⁸

Box 38-1 Functional unit of the wrist flexor, finger flexor, and forearm pronator muscles

--	--	--

Action	Synergists	Antagonists
Wrist flexion	Flexor digitorum superficialis Flexor digitorum profundus Palmaris longus Flexor carpi radialis Flexor carpi ulnaris	Extensor carpi radialis
Finger flexion	Lumbricals Interossei Flexor pollicis brevis Flexor digiti minimi brevis Flexor pollicis longus	Extensor digitorum Extensor pollicis longus Lumbricals Interossei
Forearm pronation	Brachioradialis Pronator teres Pronator quadratus	Supinator Biceps brachii

All flexion movements of the fingers involve some activity of the extensor digitorum muscle. The antagonistic relationship between the extensor and flexor muscles is important for power grip.¹⁹ Extension of the wrist allows optimal length tension for wrist and finger flexor muscles to power grip.¹⁹ When the fingers are held in extension at the interphalangeal joints, only the interossei and lumbrical muscles produce metacarpophalangeal (MCP) flexion.¹⁵

The wrist and finger extensor muscles function as described in Chapters 34 and 35.

3. CLINICAL PRESENTATION

3.1. Referred Pain Pattern

Winter described TrPs in the flexor muscles of the wrist and fingers near their common attachment to the medial epicondyle as a frequent source of referred pain.²⁰ Good depicted the pain as projecting to the volar aspect of the wrist or to the corresponding digit.²¹ Good also attributed idiopathic myalgia (descriptions compatible with myofascial TrPs) of the elbow to referred pain from localized myalgic areas, some of which were in the flexor muscles of the wrist and fingers.²²

Wrist Flexor Muscles

Trigger points in the FCR muscle refer pain and tenderness that center in the radial aspect of the volar crease of the wrist, with some spillover into the adjacent forearm and palm²³ (Figure 38-2A, left).

Figure 38-2. Composite referred pain patterns (dark red) in the right wrist and finger flexor muscles (medium red) for all muscles. A, Flexor carpi radialis and flexor carpi ulnaris muscles. B, Flexor digitorum superficialis and profundus muscles: left—superficialis middle finger pattern; right—superficialis 4th and 5th digit pattern and profundus pattern. The index finger pattern, not shown, is comparable. C, Flexor pollicis longus muscle. D, Pronator teres muscle.²⁴

Trigger points in the FCU muscle refer pain and tenderness to the ulnar side of the volar aspect of the wrist with similar spillover (Figure 38-2A, right).

Finger Flexor Muscles

No distinction is made between the referred pain patterns of the FDS and FDP muscles. A TrP in these muscles refers pain to the same digit that the fibers activate. For example, a TrP in the fibers of the middle finger flexor muscle projects pain through the length of the middle finger (Figure 38-2B, left). Similarly, TrPs in fibers that flex the ring and little fingers project pain throughout those digits (Figure 38-2B, right). Simons et al reported

that the pain is frequently described by the patient as an explosive pain that “shoots out the end of the finger, like lightning.” However, clinically, the authors of this chapter have not noted this report of symptoms in patients. This description may be more related to neuropathic symptoms because of the close anatomic arrangement of these muscles with the median and ulnar nerves. More research into the nature of referred symptoms from TrPs in these muscles is warranted. This pattern differs from the pain referred from the finger extensor muscles that stops short of the end of the digit.

Kellgren reported that injection of 6% saline solution into the FDP muscle produced MCP joint pain that was indistinguishable from the pain caused by injecting 0.3 mL of the same solution directly into the same joint space of the opposite hand.²³ The similar nature of the joint pain due to these two sources causes confusion between the pain of an articular disease and that referred from TrPs in the finger muscles.

Pain referred to the hypothenar eminence and the 5th MCP joint, induced by injection of 0.2 mL of 6% salt solution into the FDP muscle, persisted despite total anesthesia of the painful structures by local anesthetic block of the ulnar nerve at the wrist.²³ The referred pain in this experiment was not dependent on impulses arising in the pain reference zone. A significant part of the afferent nerve discharges caused by the irritant saline solution in the muscle, and of those signals perceived as pain from the reference area, must have followed a common pathway in the central nervous system. One might describe this as a “phantom pain.” (The pain referred to the hypothenar eminence may have been due to inadvertent saline infiltration of the FCU muscle as well.)

Trigger points in the FPL muscle project pain throughout the volar aspect of the thumb to its tip (and possibly “beyond”) (Figure 38-2C).

Pronator Muscles

Pronator teres TrPs refer pain deep in the volar radial region of the wrist and the forearm (Figure 38-2D).

Trigger point referral pattern for the pronator quadratus muscle has not been previously described by Simons et al. Hwang and Kang²⁴ investigated the pain referral pattern of the pronator quadratus muscle in the nondominant arm of 35 healthy individuals using 0.3 mL of 6% hypertonic saline injection. They used electromyographic guidance for accurate placement of the injection solution into the pronator quadratus muscle. In 57% of the individuals, a pain referral pattern was reported from the injection site both proximally and distally along the medial aspect of the forearm. Fifty percent of these individuals reported that the pain spread as far proximally to the medial epicondyle of the humerus and distally to the 5th digit. Twenty-nine percent of the individuals described a pain referral pattern from the volar and dorsal aspect of the mid-distal forearm spreading to the 3rd and 4th digits, both volarly and dorsally to the distal interphalangeal joints. The referred pain patterns from the pronator quadratus muscle resemble the C8-T1 dermatomal pattern as well as the ulnar and medial nerve sensory distribution (Figure 38-2E).²⁴

In their illustrations of the referred pain patterns for all of these flexor muscles located

in the forearm, Bonica and Sola strongly emphasized local pain in the region of the TrP and minimized pain referred to the wrist and beyond.²⁵ Rachlin, however, emphasized the more distal pain pattern of the FDS muscle but did not include the other wrist and finger flexor muscles.²⁶

3.2. Symptoms

Patients with TrPs in the flexor muscles of the forearm report difficulty in using scissors for cutting heavy cloth, handling tools while gardening, or using tools that require stability and a forceful grasp. These symptoms are typically reported in the volar aspect of the forearm and/or fingers and may or may not be associated with lateral epicondylalgia because of the reciprocal role the extensor muscles play in grasp.

Patients with TrPs in the finger flexor muscles typically report increasing difficulty with fine motor skills such as writing, picking up coins from a flat surface, or other functional activities that require fine coordinated finger movements and grasping. When patients with TrPs in the finger flexor muscles are asked whether the pain is more on the top or underside of the finger, they may rub the volar aspect and reply, "I don't know." Where the patient rubs his or her fingers will lead the clinician to investigate either the finger flexor or extensor muscles.

Patients with TrPs in the pronator teres muscle are likely to be unable to supinate the cupped hand, as when coins are placed into it or when trying to use a screwdriver to loosen a screw or a jar in a right-hand dominant person. The combined motion of full supination, slight extension, and cupping of the hand becomes prohibitively painful because of the stretch and overload on the pronator teres muscle. These patients usually compensate by rotating the arm at the shoulder, thus overloading the shoulder muscles.

If a patient presents with signs and symptoms of a trigger finger, TrPs may be associated with but not be the primary cause of the presenting dysfunction. Pain produced by TrPs may be in the region of the trigger finger on the volar aspect of the thumb or first two digits.

3.3. Patient Examination

After a thorough subjective examination, the clinician should make a detailed drawing, representing the pain pattern that the patient has described. This depiction will assist in planning the physical examination and can be useful in monitoring the progression of the patient as symptoms improve or change.

Evaluation of the cervical and thoracic spine as well as neurodynamic testing of the median and ulnar nerves is also helpful in identifying any spinal contribution to symptoms felt in the forearm region. This assessment is important even if patients do not report symptoms that are directly related to the cervical or thoracic spine. Wainner et al²⁷ identified a test item cluster to determine the likelihood that a patient presents with a cervical radiculopathy. The following four predictor variables were identified: a positive Spurling sign, cervical rotation less than 60° to the same side, positive cervical compression

test, relief of symptoms with axial distraction, and a positive neurodynamic upper limb test. Patients presenting with four of these positive variables have a 90% posttest probability of cervical radiculopathy. Patients with three positive variables have a 65% posttest probability of cervical radiculopathy.

Active and passive range of motion of the elbow, wrist, forearm, and hand should be carefully examined. When testing for TrP dysfunction, painful restriction of the range of motion is a better indicator of TrPs than is weakness. All of the wrist and finger flexor muscles can be screened for restriction at one time by fully supinating the forearm with the fingers (including the distal phalanges) and wrist fully extended. The long thumb flexor can be tested by extending the wrist and thumb. Hand-held dynamometer can be employed to objectify wrist and hand power grip.^{28, 29}

The finger extension test can screen both hands at once by first placing the fingertips of the right and left hands together (Figure 38-3A), and then pushing the palms tightly against each other while bringing the forearms into as straight a line as possible (Figure 38-3B). If there are TrPs present in the flexor muscles, they are revealed by a feeling of tightness in the muscle and pain in the pain reference areas specific to the involved muscles as described in Section 3 (Figure 38-2A to E).

Figure 38-3. The finger extension test showing some tightness of the wrist and finger flexor muscles. A, Starting position. B, Nearly normal extension. The final position must have the palms together and both forearms in a horizontal line for a completely negative, normal test.

Involvement of individual finger flexor muscles can be tested by passive extension of each digit first by extending the wrist and just the middle phalanx, and then both the middle and distal phalanges are tested for painful limitation of extension.

If weakness is an issue, individual muscles can be tested as clearly described and illustrated by Kendall et al.¹²

Accessory joint motion should be examined in the proximal and distal radioulnar, radiocarpal, and intercarpal joints, and also the MCP and interphalangeal joints of all five digits. Loss in accessory motion in any of these joints may lead to wrist, finger, and pronator quadratus muscle overload.^{30,31}

3.4. Trigger Point Examination

Trigger points in the wrist flexor, finger flexor, and pronator muscles are easily examined with the patient side-lying on the affected side with the shoulder elevated, forearm fully supinated, and the wrist and hand in neutral position (Figure 38-4A). If full forearm supination is not tolerated, a towel roll can be used to place the forearm in a comfortable position. Trigger points in the flexor muscles are typically located in the mid-fiber portions of the muscle bellies; however, the entire muscle should be examined. Both the FCR and FCU muscles are sufficiently superficial, and their TrPs can be identified by cross-fiber flat palpation (Figure 38-4C and E). FDS and FDP TrPs are identified using a cross-fiber flat palpation (Figure 38-4D) and are typically palpated together. Depth and location of the referred pain pattern assist the clinician in identifying the affected muscle. A monofilament needle or injection needle may be utilized to differentiate and identify the FDP TrPs from FDS TrPs. FPL TrPs are identified by cross-fiber flat palpation against the proximal volar surface of the radius (Figure 38-4F).

Figure 38-4. Cross-fiber flat palpation for TrPs in the wrist and finger flexor muscles. A, Side-lying with the volar aspect of the forearm exposed. B, Pronator teres muscle. C, Flexor carpi radialis muscle. D, Flexor digitorum superficialis/profundus muscle. E, Flexor carpi ulnaris muscle. F, Flexor pollicis longus muscle.

Pronator teres TrPs are identified with cross-fiber flat palpation near its origin at the medial epicondyle of the humerus (Figure 38-4B) or near its insertion on the radius at the midpoint of the forearm. The pronator quadratus muscle cannot be reliably palpated. A trained clinician can use a monofilament needle or injection needle to identify TrPs in the pronator quadratus muscle. A dorsal approach is encouraged to avoid the anterior interosseous nerve on the volar aspect of the muscle.

4. DIFFERENTIAL DIAGNOSIS

4.1. Activation and Perpetuation of Trigger Points

A posture or activity that activates a TrP, if not corrected, can also perpetuate it. In any part of the wrist or finger flexors or pronator muscles, TrPs may be activated by unaccustomed eccentric loading, eccentric exercise in an unconditioned muscle, or maximal or submaximal concentric loading.³² Trigger points may also be activated or perpetuated when the muscle is placed in a shortened and/or lengthened position for an extended period of time.

Trigger points in the wrist and finger flexor muscles are not aggravated by the fine pincer movements that tend to activate TrPs in the intrinsic hand muscles but rather are aggravated by repetitive overload from gross gripping movements. The TrPs in the wrist and finger flexor muscles are activated and perpetuated by any functional or work-related activities that require excessive use through gripping, twisting, and pulling. The skier who grips ski poles hard for long periods and the carpenter who tightly grips small-handled tools are likely to activate TrPs in these muscles. Playing a musical instrument that requires grasp and fine finger movements such as the guitar, saxophone, or other wind instruments may also activate and perpetuate TrPs in these muscles.

The finger flexor muscles may develop TrPs as a result of driving a car with the fingers tightly gripping the steering wheel, especially when the hand grasps the top of the wheel so that the finger flexion is combined with wrist flexion. Symptoms are especially likely to occur after long, focused driving as is required in a rain or snowstorm. FDS and FDP TrPs may be specifically activated with sporting activities that require intense grasping such as tennis, golf, or rowing.

Activation of FPL TrPs causes symptoms that have been termed “weeder’s thumb.” These TrPs are activated by forceful rocking, twisting, and then pulling motions, all of which can strain the FPL and other thumb muscles.

The pronator teres TrP can be activated as a result of a fracture at the wrist or elbow. In addition, along with the pronator quadratus muscle, these TrPs can also be caused by rapid

forceful pronation movements, for example, a “top spin” forehand technique used by high-level recreational or professional tennis players. They can also be activated or perpetuated by loosening screws with a manual screwdriver for right-handed individuals, and tightening screws for left-handed individuals.

4.2. Associated Trigger Points

Associated TrPs can develop in the referred pain areas caused by primary TrPs.³³ Therefore, musculature in the referred pain areas for each muscle should also be considered. Trigger points tend to develop in the parallel FDS and FDP muscles together and in the FCR and FCU muscles together. However, TrPs may appear in the FCR muscle alone following an elbow fracture or comparable trauma. Associated TrPs may develop in the FCR muscle from active TrPs in the pectoralis minor muscle.³⁴ Associated TrPs may develop in the FCU muscle from TrPs in the pectoralis minor, latissimus dorsi, or serratus posterior superior muscles.^{33, 34}

Trigger points in the finger flexor muscles may develop as a result of TrPs in muscles of the shoulder and neck that refer pain into the volar forearm, most commonly the infraspinatus, scalene, and pectoralis minor muscles.

Trigger points in the FPL muscle tend to develop independently of TrPs in the other forearm flexor muscles.

4.3. Associated Pathology

Differential diagnoses that are commonly identified when TrPs in flexor muscles of the forearm are responsible for or contribute to the symptoms include medial epicondylitis, ulnar neuropathy, carpal tunnel syndrome, osteoarthritis of the wrist, C5 radicular pain or radiculopathy (when there are TrPs in the FPL muscle), C7 radicular pain or radiculopathy (with TrPs in the radial head of the FDS muscle), and C8 or T1 radicular pain or radiculopathy (with TrPs in the humeral head of the FDS muscle and/or the pronator quadratus muscle).²⁴ Erroneous diagnosis of thoracic outlet syndrome with active TrPs in the proximal part of the FDS or pronator quadratus muscles is possible, as some practitioners are prone to apply the term thoracic outlet syndrome to any disturbance of the 4th and 5th digits in the presence of a normal or nonfocal neurologic examination.

Medial common flexor tendinopathy (golfer’s elbow) is basically similar to lateral common extensor tendinopathy (tennis elbow), as discussed in Chapter 36 under Associated Pathology.

Adaptive shortening and/or TrPs in the muscles of this chapter can contribute to entrapment syndromes in both the ulnar and median nerves. The forearm muscles serve as a structural interface for the course of the nerves as it travels distally to innervate target tissues. Trigger points may cause localized tension and fascial restrictions where the nerve travels over, through, or under these muscles and fascial components. Box 38-2 lists, for each nerve, the muscles that may be a source of or contributing factor for the patient’s symptoms.

Box 38-2 Muscles of the forearm that may develop TrPs that cause entrapment of the ulnar or median nerve

Nerve	Muscles that may cause entrapment
Ulnar nerve	Flexor carpi ulnaris Flexor digitorum superficialis Flexor digitorum profundus
Median nerve	Pronator teres Flexor digitorum superficialis

Entrapments or compressions correlated with the ulnar nerve are typically associated with muscles in the forearm and are likely to begin immediately distal to the condylar groove (cubital tunnel) that the nerve fills going around the elbow. Any entrapment within the cubital tunnel is often called a cubital tunnel syndrome and is classified as neuropathic pain. Symptoms of entrapment or compression commonly begin with a disturbed sensation in the 4th and 5th digits, including dysesthesia, burning pain, and a feeling of numbness. Hypoesthesia may also be present. Motor involvement leads to clumsiness and weakness of the grip because of neuropraxia in half of the lumbrical and the interossei muscles. The diagnosis is confirmed by delayed nerve conduction velocity across, and to a lesser extent beyond, the point of entrapment.³⁵ The region of entrapment can usually be identified in this way as somewhere beyond the distal end of the condylar groove and within the first third of the forearm. Electromyographic data that show neuropathic changes may further localize the lesion.

The ulnar nerve exits the upper arm through the medial intermuscular septum, to pass through a groove behind the medial epicondyle (Figure 38-5A). The nerve is held in this groove by a fibrous expansion of the common flexor tendon that forms the roof of the cubital tunnel. From there, it enters the forearm beneath an aponeurotic arch formed by the humeral and ulnar heads of the FCU muscle,³⁶ commonly called the humeroulnar arcade. In 130 cadaver elbows, the arcade was identified 3 to 20 mm distal to the medial epicondyle, and the nerve then coursed through the FCU muscle for 18 to 70 mm.³⁷ The ulnar nerve then occupies the triangular space bounded by three flexor muscles: the FCU muscle covers the space superficially toward the ulnar side of the forearm, the FDS muscle is located superficially and radially, and the FDP muscles lies beneath, deep to the nerve.³⁸ The ulnar nerve continues through the proximal half of the forearm between the FCU muscle above it and the FDP muscle beneath it (Figure 38-5B).

Figure 38-5. Dorsal view of the normal relation between the right ulnar nerve and the FCU muscle (dark red). A, The tendinous arch between the muscle's humeral and ulnar heads, through which the ulnar nerve passes, is called the cubital tunnel. B, Cross-section showing the relation of the ulnar nerve to the FCU muscle (dark red), and the flexor digitorum superficialis and profundus muscles (light red). The section is several centimeters below the elbow in the region of TrPs that may cause the nerve entrapment.

Trigger points in the FCU muscle are most likely to be associated with entrapment or compression of the ulnar nerve. This entrapment may be caused by adaptive muscle shortening, myofascial tension pulling the humeroulnar arcade tight against the nerve, or by compressing the nerve where the nerve penetrates the muscle.

Clinically, TrPs in the FDP muscle also seem to contribute to ulnar nerve entrapment symptoms; however, the specifics of this mechanism are not clear. Symptoms related to TrP and localized tension leading to entrapment or compression causing symptoms of neuropathic pain are relieved by inactivating all contributing TrPs.

Median nerve entrapment or compression below the elbow will typically cause paresthesias, dysesthesia, and hyperesthesia of the 3rd and 4th digits, and occasionally the adjacent digits, and it is commonly called pronator teres syndrome.^{39, 40} The median nerve generally passes between the humeral and ulnar heads of the pronator teres muscle beneath the fibrous arch between the two heads but sometimes pierces the humeral head.⁴⁰ The nerve then passes beneath the aponeurotic arch of the FDS muscle that bridges between its radial and humeroulnar heads and clings to the underside of that muscle.⁴¹ Adaptive shortening of fascial structures and/or local tension caused by TrPs might promote entrapment or compression of the median nerve in the pronator teres or FDS muscles through increased tension of the aponeurotic arch against the nerve or by direct compression of the nerve, where the nerve penetrates the humeral head of the pronator teres muscle.

Although clinical experience indicates TrPs can cause some of these entrapments, well-planned case studies of these conditions that include full electrodiagnostic documentation and adequate pre- and posttreatment outcome measures are sorely needed.

The presence of an anomalous FDS indicis muscle caused an acute carpal tunnel syndrome that was relieved by freeing the muscle from the median nerve.⁴²

The carpal tunnel syndrome is likely to be diagnosed when the patient has TrPs in the pronator teres, FCR, and/or brachialis muscles. The referred pain from even more distant TrPs in trapezius and infraspinatus muscles can mimic a carpal tunnel syndrome diagnosis.^{43, 44} Trigger points in the respective muscles that evoked a tingling sensation in the hand in order of frequency were: infraspinatus, 65.4%; upper trapezius, 57.7%; FCR, 38.5%; rhomboids, 15.4%; and FPL, 11.5%.⁴⁴ Infraspinatus TrPs were 13 times more prevalent than carpal tunnel syndrome in the cohort studied.⁴⁴

A median nerve conduction study and examination of the muscles for TrPs establish if one or both of the diagnoses are appropriate.

The presence of an anomalous FCR brevis muscle originating in the proximal radial aspect of the forearm and inserting at the base of the 2nd or 3rd metacarpal has been implicated in anterior interosseous nerve compression.⁴⁵

The painless phenomenon of a trigger finger,¹⁹ a “trick” or “locking” finger, consists of the finger sticking in the flexed position until it is extended by an external force. This condition responds to cortisone injection into the fascial sheath that is responsible for the constriction of the flexor tendon near the MCP joint. The constriction may ensnare a knot-like enlargement of the tendon itself. Such a fascial band that might anchor the tendon is described just short of the end of the distal palmar synovial sheath for digits 2, 3, and 4.³⁶

Several techniques are available for noninvasive treatment of the trigger finger. Blocking or splinting the MCP joint of the affected finger in extension will typically eliminate or reduce the triggering. With the finger in the MCP extended position, the patient should flex and extend the interphalangeal joints while maintaining the MCP joint extended position. This maneuver mechanically limits the nodule from exiting the finger pulley system and often will eliminate “locking” of the finger.

Amirfeyz et al⁴⁶ report in a systematic review that there is moderate evidence to support the use of a cortisone injection early on in treatment; however, there is strong evidence that cortisone injection is associated with recurrence and ongoing symptoms at 6 months following injection. There is weak evidence to support conservative interventions or splinting for management of adult trigger finger. There is also strong evidence to support the management of trigger finger through percutaneous surgical intervention. They conclude that a cortisone injection may be the first line of intervention, but if symptoms recur, surgical intervention is the best option.⁴⁶

5. CORRECTIVE ACTIONS

When prolonged gripping is required, as in tightly holding a ski pole or a steering wheel, lifting weights, or climbing, the patient should learn to relax the grip frequently. They should also be taught alternative strategies such as gripping with the palm down versus the palm up and stretching the flexor muscles at frequent intervals. Taking micro breaks or rotating activities can also be a useful strategy. Relaxation is aided by occasionally performing the finger-flutter exercise with a gentle shaking motion of the hands with the arms hanging down at the side to release tension. Grasping the sides of the steering wheel at the 9 and 3 position of a clock places the wrist in a more neutral position and is the recommended position for holding the steering wheel while driving by the National Highway Traffic Administration.

If the patient rows on a crew or paddles a canoe, he or she should fully open the fingers on the return stroke while holding the oar or paddle between the thumb and palm to relieve tension and to stretch the flexor muscles. For those playing racquet games, the wrist should be held in a neutral or slightly “cock-up” position and should not allow the head of the racquet to tilt downward (see Figure 36-5A). A patient with TrPs in the flexor muscles should learn to keep the wrist, as well as the forearm, supported on the armrest while sitting

and not to let the wrist dangle over the end, thus avoiding leaving the wrist and finger flexor muscles in a shortened position.

Individuals who are required to work at the computer should take frequent breaks, especially with prolonged mouse or touch screen work as these activities keep the finger flexor muscles in a shortened position. Frequent breaks will prevent overload of the muscles that may activate and perpetuate TrPs.

Self-pressure release for TrPs in the wrist flexor, finger flexor, and pronator muscles can be performed in a sitting position by placing the forearm on the armrest of a chair or on a table with the palm up, using manual pressure (Figure 38-6A) or a TrP release tool (Figure 38-6B). For any self-pressure release techniques, the sensitive spot in your forearm is identified with the fingers, light pressure (no more than 4/10 pain) is applied and held for 15 to 30 seconds, or until pain reduces. This technique can be repeated five times, several times per day.

Figure 38-6. Self-pressure release technique for pronator teres, wrist and finger flexor muscles. A, Manual. B, Trigger point release tool. flexor muscle stretch. D, Finger flexor muscle stretch. E, Thumb flexor muscle stretch. position with elbow supported. B, Pronator teres muscles stretch into supination. C, Wrist

The patient can easily perform self-stretch techniques as part of self-management for TrPs located in the wrist flexor, finger flexor, or pronator muscles. Stretching of the pronator teres and pronator quadratus muscles should be performed with the elbow straightened and bent, respectively, with the palm facing up. The patient grasps the forearm above the wrist and gently turns the forearm into more supination (palm up) (Figure 38-7B). To stretch the wrist flexor muscles, the elbow is supported on the armrest and the opposite hand pushes the wrist down into extension with pressure on the palm of the hand (Figure 38-7C). To stretch the finger flexor muscles, the same procedure is used as in the wrist flexor muscles, but the pressure is applied into extension across the four fingers of the hand (Figure 38-7D). This technique can also be performed one finger at a time. The same procedure may be followed with the elbow straight to thoroughly stretch the wrist flexor and finger flexor muscles that have a humeral attachment. To stretch the long flexor muscle of the thumb, the same procedure is used as in stretching of the finger flexor muscles with the addition of the thumb being pushed out and down with the index finger of the

unaffected hand (Figure 38-7E). These self-stretches should be carried out gently, and attention to the reproduction of pain versus stretch is paramount. These stretches should not be painful, nor should they cause tingling or numbness in the hand or forearm.

Adductor and Opponens Pollicis Muscles

“Clumsy Thumb”

Johnson McEvoy and Joseph M. Donnelly

1. INTRODUCTION

The adductor pollicis and opponens pollicis muscles are intrinsic muscles of the hand and along with the flexor pollicis brevis and abductor pollicis brevis muscles make up the thenar muscle group. The adductor pollicis and opponens pollicis muscles are important for gripping and fine dexterous movements between the thumb and fingers. The synergy between the thumb and fingers is important in human hand function, fine motor skills, power and pincer gripping. It is also a vital component of activities of daily living and of occupational, recreational, and sporting activities. Pain from trigger points (TrPs) is referred over the distal radial wrist and hand. In addition to pain, patients will report a feeling of clumsiness and difficulty with fine motor movements of the thumb and hand. Activation and perpetuation of TrPs in these muscles can result from repetitive or forceful gripping actions and fine motor activities such as typing, moussing, or phone usage. Differential diagnosis includes cervical radicular pain or radiculopathy, local wrist and thumb joint dysfunction, and osteoarthritis. Corrective actions include modification of activities, ergonomics assessment and training, TrP self-pressure release, self-stretch, and strengthening of the upper extremity and hand muscles.

2. ANATOMIC CONSIDERATIONS

Adductor Pollicis

The adductor pollicis muscle is the largest and most powerful of the intrinsic hand muscles.¹ The adductor pollicis muscle spans the web space between the thumb and index finger. Both the oblique and transverse heads lie beneath (dorsal to) the tendon of the flexor pollicis longus muscle and originate laterally to the ulnar side of the base of the proximal phalanx of the thumb (Figure 39-1A) along with the flexor pollicis brevis and

abductor pollicis brevis muscles (Figure 39-2B). Medially, the oblique head of the adductor pollicis muscle inserts into the bases of the 2nd and 3rd metacarpals and to the capitate bone. The transverse head inserts medially onto the distal two-thirds of the palmar surface of the 3rd metacarpal bone (Figure 39-2A).¹

Opponens Pollicis

The opponens pollicis muscle originates medially to a tubercle of the trapezium bone of the wrist and to the flexor retinaculum, and it inserts laterally and distally along the whole length of the radial side and the adjoining lateral half of the palmar surface of the 1st metacarpal bone (Figure 39-1A).¹

Figure 39-1. Attachments of thumb muscles. A, The adductor pollicis and opponens pollicis (dark red) muscles after removal of the flexor pollicis brevis and abductor pollicis brevis muscles. B, Course of the tendon of the flexor pollicis longus muscle with restraining fascial sheath at the head of the 1st metacarpal close to the metacarpophalangeal joint, and the cut attachments of the overlying (light red) flexor pollicis brevis and abductor pollicis brevis muscles.

This muscle lies partly under the abductor pollicis brevis muscle and between the superficial and deep heads of the flexor pollicis brevis muscle (Figure 39-1B).¹ It is not easy to distinguish from the other two muscles that may contain TrPs that are attributed to the opponens pollicis muscle.

A bulbous enlargement of the flexor pollicis longus tendon may become ensnared by a

restricted flexor sheath at the head of the 1st metacarpal bone, where the tendon becomes firmly attached to the thumb after it has passed over the adductor pollicis muscle and between the two heads of the flexor pollicis brevis muscle (Figure 39-1B).¹ This “triggering” phenomenon is similar to that described for the tendons of the finger flexors (see Chapter 38).

2.1. Innervation and Vascularization

Adductor Pollicis

The adductor pollicis muscle is innervated by the deep palmar branch of the ulnar nerve via the medial cord and lower trunk of the brachial plexus from spinal nerves C8 and T1.¹

Opponens Pollicis

The opponens pollicis muscle is innervated by a branch of the median nerve via the lateral cord and upper and middle trunks from spinal nerves C6 and C7.¹

The adductor and opponens pollicis muscles receive their vascularization by the superficial palmar branches of the radial artery.¹

2.2. Function

The meaning of terms used to describe the direction of movement of the thumb is specific and requires definition. Flexion and extension movement at the metacarpophalangeal (MCP) and interphalangeal (IP) joints is perpendicular to the thumb nail and in the plane of the palm. Flexion is in the ulnar direction and extension in the radial direction. Abduction and adduction are movements perpendicular to the plane of the palm, away from and toward the palm, respectively. Opposition brings the palmar surfaces of the thumb and fifth finger in direct contact (not just fingertip contact).¹⁻⁵

Adductor Pollicis

This muscle adducts the thumb. It also assists in flexion at the MCP joint of the thumb.

The adductor pollicis muscle has been shown to be electromyographically active during any adduction, opposition, and MCP flexion movements⁶ and especially during forceful opposition of the thumb, which rotates the thumb to face the other fingers.^{2,4}

Opponens Pollicis

The opponens pollicis muscle of the thumb abducts,² flexes,^{2,3} and rotates the metacarpal bone of the thumb into a position of opposition.^{1-5,7}

Electromyographically, the opponens pollicis muscle is consistently active during opposition of the thumb and, surprisingly, is moderately active during extension, and markedly active during abduction of the thumb.²

2.3. Functional Unit

The functional unit to which a muscle belongs includes the muscles that reinforce and counter its actions as well as the joints that the muscle crosses. The interdependence of these structures is functionally reflected in the organization and neural connections of the sensory motor cortex. The functional unit is emphasized because the presence of a TrP in one muscle of the unit increases the likelihood that the other muscles of the unit will also develop TrPs. When inactivating TrPs in a muscle, one must be concerned about TrPs that may develop in muscles that are functionally interdependent. Box 39-1 grossly represents the functional unit of the adductor pollicis and opponens pollicis muscles.⁸

Box 39-1 Functional unit of the adductor pollicis and opponens pollicis muscles

Action	Synergists	Antagonists
Thumb adduction	First dorsal interosseous	Abductor pollicis longus Abductor pollicis brevis
Thumb opposition	Abductor pollicis brevis Flexor pollicis brevis	Adductor pollicis Extensor pollicis longus Extensor pollicis brevis

Functionally, the opponens pollicis muscle and its synergists, along with the adductor pollicis muscle, act in conjunction with the first dorsal interosseous and extrinsic finger muscles for forceful index-finger pinch, and with the opponens digiti minimi muscle for forceful opposition. This synergy acts to allow power and fine dexterous movement associated with the functional nuances of the human hand.

3. CLINICAL PRESENTATION

3.1. Referred Pain Pattern

Adductor Pollicis

Pain from TrPs in the adductor pollicis muscle causes aching pain along the lateral aspect of the thumb and hand at the base of the thumb distal to the wrist crease (Figure 39-2A). Pain may spread as far lateral and posterior as the scaphoid bone in the vicinity of the anatomical snuffbox. The pain may also spread over the palmar surface of the 1st MCP joint, and it may include most of the thumb, thenar eminence, and dorsal web space.^{9,10}

Opponens Pollicis

Pain from TrPs in the opponens pollicis muscle refers to the palmar surface of most of the

thumb and also to a spot on the radial side of the palmar aspect of the wrist, where the patient is likely to place a finger to locate the pain (Figure 39-2B). This area of pain may be diffuse and located in the vicinity of the attachment of the flexor carpi radialis tendon insertion into the base of the 2nd metacarpal on the palmar aspect of the wrist.

3.2. Symptoms

In addition to pain, patients with TrPs in these thumb muscles may complain that the hand and thumb is “clumsy.” They may report fatigue with thumb muscle gripping or continued fine dexterous movements. Their handwriting may often become poor or even illegible because of difficulty holding a pen. They may have trouble with the fine manipulations necessary for the activities of daily living or occupational or recreational activities such as buttoning clothing, sewing, drafting, and painting that require the prehensile pincer grip provided by the thumb. In athletes, gripping and squeezing a water bottle may be painful or difficult. Smartphone and tablets create new challenges for the hand and thumb in terms of fine repeated dexterous movements, often over extended periods of time. Adductor pollicis myofascial pain is commonly seen in patients who frequently use handheld devices.¹¹ See Chapter 41 for further discussion.

3.3. Patient Examination

After a thorough subjective examination, the clinician should make a detailed drawing representing the pain pattern that the patient has described. This depiction will assist in planning the physical examination and can be useful in monitoring the progression of the patient as symptoms improve or change.

Evaluation of the cervical and thoracic spine (as well as neurodynamic testing of the median, radial, and ulnar nerves) is also helpful in identifying any spinal or peripheral nerve contribution to symptoms felt in the wrist and hand region. This assessment is important even if patients don’t report symptoms that are directly related to the cervical or thoracic spine. When ulnar nerve compression or entrapment is suspected, special tests for motor integrity of the adductor pollicis muscle should be conducted.

Because deep tenderness in the web space of the thumb may be referred from other muscles such as the scalene, brachialis, supinator, extensor carpi radialis longus, or brachioradialis muscles, these muscles should be examined for TrPs as well. The infraspinatus is another muscle that can refer sensory phenomena to the hand. If these muscles are involved, they should be treated before attempting to inactivate TrPs in the thumb muscles; the tenderness in the region of the thumb, if referred, may disappear following inactivation of TrPs in the distant forearm and arm muscles. In “weeder’s thumb” syndrome, for example, TrPs in the first dorsal interosseous muscle usually respond to treatment immediately, leaving the more complex thumb muscles still causing symptoms (see Chapter 40).

Active and passive range of motion of the elbow, wrist, forearm, and hand should be carefully examined. Flexion, adduction, and abduction movements of the thumb often

demonstrate inhibition weakness on the affected side when one of these muscles is involved, even when considering differences due to hand dominance. The strength of the adductor pollicis muscle is easily tested by the ability to hold a piece of paper tightly between the thumb and the 2nd metacarpal bone. A pinch strength gauge can be employed to objectify strength and compare to the contralateral side and normative values and to measure change over the course of treatment. Abduction, and especially extension, of the thumb are often painful. Objective strength assessment of pinch and hand power grip of the thumb can be measured by a pinch and handheld dynamometer.

Accessory joint motion should be examined in the 1st carpometacarpal (CMC), and the proximal and distal IP joints. Articular dysfunctions that can coexist with TrPs in the adductor pollicis and opponens pollicis muscles are those at a CMC joint, the most likely being volar subluxation of a metacarpal bone on a carpal bone, especially at the 1st CMC joint. Hypomobility in these joints could lead to overload on the adductor and opponens pollicis muscles. Injuries may lead to joint instability or hypermobility. Joint hypermobility may be associated with benign hypermobility syndrome.^{12, 13}

3.4. Trigger Point Examination

Adductor Pollicis

With the patient seated comfortably and the hand pronated and relaxed, the web space of the thumb is examined by cross-fiber pincer palpation (Figure 39-3A). The first dorsal interosseous muscle, which lies superficial to the transversely oriented adductor fibers, is pushed aside to improve access to the adductor pollicis muscle.

Figure 39-2. Referred pain patterns (dark red) for two thumb muscles (medium red), right hand. A, Adductor pollicis muscle. B, Opponens pollicis muscle.

Opponens Pollicis

With the patient seated as noted for the examination of the adductor pollicis muscle, TrPs in this muscle are identified by cross-fiber flat palpation over the thenar eminence (Figure 39-3B).

4. DIFFERENTIAL DIAGNOSIS

4.1. Activation and Perpetuation of Trigger Points

A posture or activity that activates a TrP, if not corrected, can also perpetuate it. In any part of the adductor and opponens pollicis muscles, TrPs may be activated by unaccustomed eccentric loading, eccentric exercise in an unconditioned muscle, or maximal or submaximal concentric loading.¹⁴ Trigger points may also be activated or aggravated when the muscle is placed in a shortened and/or lengthened position for an extended period of time. Common activities associated with the activation of TrPs in these muscles include repetitive fine motor movements such as smartphone or keyboard usage and gripping actions such as lifting weights or rowing. Hair stylists or barbers manipulating scissors repetitively often present with thumb pain. Physical therapists and other body work specialists who perform manual and soft tissue treatments often experience occupational hand and thumb pain.

Weeder's thumb is a common syndrome that results from repetitive hand activities, such as pulling weeds, that can activate TrPs in these muscles. The trouble arises when the patient repeatedly firmly grasps the base of the weed in a strong pincer grip, twists the weed to loosen the root, and then exerts an even stronger pincer grip to pull it. Similarly, sustained, unrelieved tension and muscle fatigue can activate TrPs when using a fine paintbrush, sewing, or writing—especially if writing requires pressing firmly with a ball-point pen held perpendicular to the paper.

When TrPs result from the muscle's response to the fracture of a bone in the hand, a patient may say, "Of course it hurts, I had a fracture there years ago." They do not realize that the hand should be pain-free after the bone has healed. They are unaware that the continuing pain and dysfunction may be due to residual TrPs in the hand muscles.

Psychophysiologic patterns during text messaging revealed that subjects showed significant increases in respiration rate, heart rate, skin conductance, and shoulder and thumb surface electromyography (EMG) when compared with baseline measures.¹⁵ Eighty-three percent of subjects reported hand and neck pain during texting and held their breath and experienced increased arousal when receiving text messages. Most participants were unaware of these changes. The study suggests that frequent triggering of these physiologic patterns may increase muscle discomfort symptoms. This study may have implications with

patients presenting with hand and thumb pain and who regularly use handheld devices.¹⁵

4.2. Associated Trigger Points

Associated TrPs can develop in the referred pain areas caused by primary TrPs.¹⁶ Therefore, musculature in the referred pain areas for each muscle should also be considered. Trigger points are nearly always found in the first dorsal interosseous muscle when they are present in the adductor and opponens pollicis muscles. Clinically, it appears that the thumb muscles are involved primarily, and the first dorsal interosseous muscle is affected secondarily because of its synergistic function. The flexor pollicis brevis and abductor pollicis brevis muscles eventually are also likely to become involved.

These muscles may also develop associated TrPs from the scalene, brachialis, supinator, infraspinatus, extensor carpi radialis longus, or brachioradialis muscles as they are located within the pain referral pattern of these muscles.

4.3. Associated Pathology

The symptoms produced by TrPs in the adductor and opponens pollicis muscles are most commonly mistakenly for carpal tunnel syndrome, DeQuervain's stenosing tenosynovitis, and CMC osteoarthritis. These conditions can exist in isolation but more commonly they coexist with TrPs in the thumb muscles and must be differentially diagnosed for effective treatment. An accessory flexor pollicis longus muscle, when present, can cause compression neuropathy of the anterior interosseous nerve.¹⁷

Osteoarthrosis of the CMC or MCP of the thumb is common in patients over age 55 and especially in individuals with thumb trauma. It is estimated that greater than 90% of people will have CMC osteoarthritis after 80 years of age.¹⁸ Trigger points are often present in this condition, and treatment can assist with pain management and movement impairment.

Hand pain and weakness can be associated with neuropathic mechanisms such as nerve root compression, radiculopathy, and other neurologic disorders. Assessment with EMG, nerve conduction studies, and imaging may be required to assist in differential diagnosis. Guyon's canal syndrome may lead to weakness of the adductor pollicis muscle, resulting in diminished grip strength (refer to Chapter 40).¹⁹

Pain and tenderness referred to the 1st MCP joint from TrPs in the adductor pollicis muscle are easily mistaken for evidence of joint disease if the myofascial origin of the symptoms is not recognized.²⁰ On the other hand, pain and dysfunction of the MCP and IP joints may be due to loss of accessory joint motion, which should be identified and corrected.²¹

Heberden's nodes have been observed on the ulnar side of the thumb. When a node is present there, an associated TrP can sometimes be found in the adductor pollicis muscle.

The phenomenon of "trigger thumb" is identified by the patient's inability to extend the thumb without external assistance after flexing it; the thumb "locks" in flexion. The corresponding phenomenon, trigger finger, is considered in detail in Chapter 38.

Trigger thumb may be associated with a TrP located lateral to the tendon of the flexor pollicis longus muscle, possibly in the flexor pollicis brevis muscle. To locate this TrP, the patient supinates the forearm, fully extends the MCP joint of the thumb (Figure 39-4A), and then alternately flexes and extends the distal phalanx, while the clinician identifies the tendon and corresponding TrP (Figure 39-4B). To identify the tendon of the flexor pollicis longus muscle, the clinician places a finger against the bulge of the MCP joint, pressing on the space between the flexor pollicis brevis and adductor pollicis muscles where the tendon of the flexor pollicis longus muscle enters the fascial sheath of the thumb (Figure 39-1B). As the patient moves the distal phalanx back and forth, the cord of the subcutaneous tendon is located proximal to where it enters the securing arch of fibers at the head of the 1st metacarpal bone in the region of the “trigger” phenomenon. The TrP is usually located several millimeters lateral (radial) to the tendon, just proximal to the bony bulge of the MCP joint.

Figure 39-3. Palpation for TrPs in thumb muscles. A, Cross-fiber pincer palpation of the adductor pollicis muscle. B, Cross-fiber flat palpation of the opponens pollicis muscle.

Locking of the IP joint of the thumb may be caused by a sesamoid bone of that joint.²² Of 30 patients presenting with trigger thumb, 25 were followed to spontaneous resolution without treatment. Five demanded treatment. The average duration of symptoms to spontaneous recovery was 6.8 months (range 2-15 months).²³

5. CORRECTIVE ACTIONS

An attempt should be made to identify and correct the causative and/or contributing factors of the patient's symptoms. Ergonomic aids for activities of daily living and occupational activities may be required. Ergonomic assessment may play an important role in the adaptation of habitual tasks.¹⁹

Modification of activities that require forceful gripping are necessary to reduce activation and perpetuation of TrPs in the adductor and opponens pollicis muscles. As an example, in weeder's thumb, the patient should avoid persistent, vigorous weeding by limiting the time spent, by alternating hands in this activity, or by loosening the dirt with a spading fork before pulling the weeds out. Switching to a soft felt-tip pen, which requires

much less pressure on the paper than does a ball-point pen, may also be helpful.

Habits around smartphone and computer use may need to be modified. Voice activation or text to speech software may assist in reducing load in keyboard operators. Progressive graded exposure to activities, coupled with micro-breaks and rotation of activities, may be required to build tolerance. Patient education should include mindfulness of patterns of increased psychophysiologic arousal and muscle tension during smartphone use.¹⁵ Time away from devices, relaxation exercises, and general aerobic exercises may also be helpful treatment strategies.

Self-pressure release for TrPs in the adductor and opponens pollicis muscles can be performed in sitting by placing the forearm on the arm rest of a chair or on a table with the palm up. Manual pressure is the best method for performing self-pressure release of the adductor pollicis (Figure 39-5A) and opponens pollicis muscles (Figure 39-5B). As with any self-pressure release technique, the sensitive spot in the web space of the hand or the front of the thumb is identified with the fingers; light pressure (no more than 4/10 pain) is applied and held for 15 to 30 seconds, or until pain reduces. This technique can be repeated five times, several times per day.

Figure 39-4. Technique for palpating the TrP of a “trigger thumb.” The distal phalanx is wiggled back and forth to help identify the flexor pollicis longus tendon. Pressure against the head of the metacarpal bone, radial (lateral) to the tendon, elicits spot tenderness.

The patient can easily perform self-stretch techniques as part of self-management for TrPs located in the adductor or opponens pollicis muscles. Stretching of the adductor and opponens pollicis muscles is performed with the patient seated, forearm supported with the palm up (Figure 39-6). To stretch the adductor pollicis muscle, the patient spreads the thumb away from the first finger using the unaffected thumb and index finger. Pressure is applied on the bone just below the finger and the base of the thumb (Figure 39-6A). To

stretch the opponens pollicis muscle, the patient pushes the thumb down so the stretch is felt in the pad of the thumb (Figure 39-6B). These self-stretches should be carried out gently, and attention to the reproduction of pain versus stretch is paramount. These stretches should not be painful.

Interosseous, Lumbrical, and Abductor Digiti Minimi Muscles

“Hand Crampers”

Johnson McEvoy and Joseph M. Donnelly

1. INTRODUCTION

The interosseous, lumbrical, and abductor digiti minimi muscles are intrinsic muscles of the hand involved in specific dexterous fine-hand motor movements, including gripping and pinching motions. Pain and dysfunctions, such as contracture and strength deficits, can significantly impact hand function. Symptoms from trigger points (TrPs) in the intrinsic hand muscles include a deep boney ache in the fingers, finger stiffness that produces impairments in hand dexterity, strength, and function. Activities such as buttoning a shirt, writing, and grasping may be impaired. Pain referral from TrPs in these muscles is primarily to the digits. Activation and perpetuation of TrPs in these muscles is commonly caused by gripping actions and fine motor activities such as typing, smartphone usage, and sporting activities such as boxing. Differential diagnosis includes cervical radicular pain or radiculopathy, local wrist and hand joint dysfunction, and osteoarthritis. Corrective actions include modification of activities, ergonomic assessment and training, TrP self-pressure release, self-stretch, and strengthening exercises.

2. ANATOMIC CONSIDERATIONS

Interossei

As the name denotes, the interosseous muscles lie between adjacent metacarpal bones. The interosseous muscles are divided into two groups: palmar and dorsal interossei muscles.¹ The dorsal interosseous muscles are larger and more expansive. Each dorsal interosseous muscle originates proximally by two heads (Figure 40-1A) with significantly different structures that may be important to know when examining for injection of TrPs. The attachment of the head on the side nearest the middle finger covers nearly three-fourths of

that metacarpal bone,² giving it a pennate structure, as clearly illustrated for the first dorsal interosseous muscle.³ The other head has a much shorter attachment to its metacarpal bone² and more parallel arrangement of fibers.³ This structure indicates that the head on the side nearest the middle finger (designed for strength) has a long endplate zone running nearly the length of the muscle belly, whereas the other head (designed for speed and large range of motion) has a nearly transverse endplate zone near the middle of the muscle belly. Each bipennate muscle inserts distally at the base of the proximal phalanx of the related finger and to that finger's extensor aponeurosis. Each muscle attaches on the side of the phalanx away from the midline of the hand.¹

The first dorsal interosseous muscle is larger than the other interosseous muscles, but it follows the same attachment pattern (Figure 40-1A). One head originates proximally from the ulnar border of the metacarpal bone of the thumb, and the other head originates from almost the entire length of the radial border of the 2nd metacarpal bone. Both heads insert distally to the proximal phalanx of the index finger on the radial side (and to the extensor aponeurosis). This muscle fills the dorsal web space of the thumb.

Dorsal interossei

Palmar interossei

Figure 40-1. Attachments of the right interossei muscle. A, Dorsal view of the dorsal interosseous muscles (dark red), which move the fingers away from the midline of the middle finger, and of the abductor digiti minimi muscle (light red). B, Palmar view of all (the first, second, and third) palmar interossei (dark red) muscles. C, Cross-sectional view through the metacarpal bones showing the relationship between the dorsal (D1, D2, D3, and D4, dark red) and the palmar (P1, P2, and P3, medium red) interossei muscles. The lumbrical muscles are the light red muscle masses on the radial side of the four flexor digitorum profundus tendons. D, Appearance of Heberden's nodes on the sides of the distal interphalangeal joints.

Each of the three palmar interosseous muscles originates proximally from the palmar

interosseous surface of one metacarpal bone (Figure 40-1B) and lies palmar to the related dorsal interosseous muscle (Figure 40-1C). Each then inserts distally to that finger's extensor aponeurosis and to the base of the proximal phalanx on the side closest to the midline of the hand (center of the middle finger).

Lumbricals

The four lumbrical muscles are worm-shaped muscles that originate proximally from the four tendons of the flexor digitorum profundus muscle in mid-palm and insert distally to the radial side of the extensor aponeurosis on each of the four fingers.¹ The first and second lumbrical muscles lie palmar to the first and second dorsal interosseous muscles, but the transverse head of the adductor pollicis muscle is interposed between these two lumbrical muscles and the dorsal interosseous muscles. The third and fourth lumbrical muscles lie palmar and adjacent to the second and third palmar interosseous muscles (Figure 40-1C).

Abductor Digiti Minimi

The abductor digiti minimi muscle provides half of what would be the next dorsal interosseous muscle and exhibits a parallel fiber arrangement³ that has a transverse endplate zone in mid-muscle (light red, Figure 40-1A and B). The muscle originates proximally from the pisiform bone, and it inserts distally onto the ulnar side of the base of the first phalanx of the fifth finger and to its associated extensor aponeurosis.¹

2.1. Innervation and Vascularization

All of the interosseous muscles and the abductor digiti minimi muscle are innervated by branches of the ulnar nerve, through the medial cord and lower trunk of the brachial plexus from spinal nerves C8 and T1.¹ The first and second lumbrical muscles are innervated by the median nerve, and the 3rd and 4th are innervated by the ulnar nerve.¹

The dorsal interosseous muscles receive vascularization through the dorsal and palmar metacarpal arteries. The dorsal metacarpal arteries arise from the dorsal carpal arch of the anastomosis of the dorsal carpal branch of the radial and ulnar arteries. The palmar metacarpal arteries arise from the deep palmar arch formed by the radial and ulnar arteries.¹

Vascularization of the palmar interosseous muscles is provided via the palmar metacarpal artery that arises from the deep palmar arch. The deep palmar arch is formed by the radial and ulnar arteries.¹

The lumbrical muscles receive their vascularization through the superficial palmar arch, the common palmar digital artery, the deep palmar arch, and the dorsal digital artery.¹

The abductor digiti minimi muscle receives its vascularization through the ulnar artery.¹

2.2. Function

The interosseous and lumbrical muscles are important intrinsic muscles of the hand that

assist in fine dexterous movement, stability, and function. To understand the actions of these intrinsic hand muscles, it is important to remember that the extensor digitorum muscle strongly extends the proximal phalanx of each finger but only weakly extends the middle and distal phalanges. The flexor digitorum superficialis muscle attaches to the center of the middle phalanx, thus acting to flex the proximal and middle phalanges. The flexor digitorum profundus muscle attaches to the distal phalanx, flexing it and the more proximal phalanges.

The four dorsal and three palmar interosseous muscles have opposing actions in abduction and adduction, respectively, and rotation. Both groups of interosseous, along with the lumbrical muscles, flex the fingers at the metacarpophalangeal (MCP) joints and extend the middle and distal phalanges.^{1,4-7} It is the interosseous and lumbrical muscles that extend the middle and distal phalanges when any degree of flexion of the proximal phalanx is present. The flexion or extension of the latter is controlled by the flexor digitorum superficialis and extensor digitorum muscles, working as antagonists. The Dorsal interosseous muscles *abduct* (mnemonic—DAB), and the *palmar* interosseous muscles *adduct* (mnemonic—PAD) with reference to the midline of the middle finger.^{1,4,5,7,8} Electromyographic (EMG) studies have shown that the interosseous hand muscles act as flexors of the MCP joints only when this function does *not* conflict with their extensor function at the interphalangeal joints (IP) joints.⁴

The flexion–extension function of the interosseous muscles requires considerably less force than the lateral motions of abduction and adduction. Therefore, in disease, the lateral motions are lost earlier and recover more slowly than flexion–extension. The abduction–adduction functions of the interosseous muscles must be tested with the fingers extended at the MCP joints. Spreading the fingers apart is normally significantly limited when the fingers are flexed at the MCP joint.⁸

The first dorsal interosseous muscle rotates the proximal phalanx to make the index finger pad face the ulnar side of the hand, whereas the first palmar interosseous muscle rotates it in the opposite direction. The first dorsal and first palmar interosseous muscles counter-balance their rotational movements while combining their flexion–extension actions. In precision handling of objects, the interosseous muscles function mainly as abductors and adductors of the fingers. In spherical grip, their rotational forces were found to position the proximal phalanges for best finger pad contact.⁹

Weakness of the interosseous muscles may lead to loss of pinch and grasp grip strength and muscle balance associated with claw hand dysfunction.⁶

The lumbrical muscles are unusual in that they don't attach to bone but to the tendons of other muscles.¹ Thus, the lumbrical muscles function as the equivalent of an adjustable physiologic tendon transplant. Contraction of these muscles converts the distal phalanx flexion action of the flexor digitorum profundus muscle to extension of the distal phalanges. The lumbrical muscles specifically permit the flexor digitorum superficialis muscle to strongly grip with the proximal and middle phalanges, yet release the distal phalanx grip in the presence of flexor digitorum profundus muscle activity. The usual test of the intrinsic muscles' flexion–extension function, by resisting IP joint extension with the

MCP joint flexed, tests both the interosseous and lumbrical muscles.⁷ The lumbrical muscles' function is most important when a strong grip is required in the absence of fingertip pressure.

Isolated weakness of the lumbrical muscles is unusual and hard to identify. It may, with combined weakness of the interosseous muscles, contribute to claw hand deformity.⁶

2.3. Functional Unit

The dorsal and palmar interosseous muscles are synergistic for flexion at the metacarpophalangeal joint and extension of the two most distal phalanges. They are antagonistic for adduction–abduction and for rotation of the proximal phalanges.

The interosseous and lumbrical muscles are synergistic. Full effectiveness of these intrinsic muscles for grip, holding, and grasping objects also requires the assistance of the thumb muscles in the thenar eminence.

3. CLINICAL PRESENTATION

3.1. Referred Pain Pattern

Interossei

First dorsal interosseous TrPs refer pain strongly down the same (radial) side of the index finger and deeply in the dorsum and through the palm of the hand (Figure 40-2A). The referred pain may also extend along the dorsal and ulnar sides of the fifth finger.^{10,11} Generally, patients experience the most intense pain at the distal IP joint where a Heberden's node may be noted.

First dorsal interosseous TrPs are the second most frequent source of referred pain in the palm, exceeded only by TrPs in the palmaris longus muscle. Some patients have difficulty in deciding whether the pain referred from first dorsal interosseous TrPs is more prominent on the palmar or on the dorsal aspect of the hand.¹²

Trigger points in the remaining dorsal and palmar interosseous muscles refer pain along the side of the finger to which that interosseous muscle attaches (Figure 40-2C). No distinction is made between the patterns of pain referred from the dorsal interosseous, palmar interosseous, and lumbrical muscles. Pain extends as far as the distal IP joint. The exact pain pattern varies somewhat, depending on the location of the TrP in the interosseous muscle. A TrP in an interosseous muscle may be associated with a Heberden's node located within the TrP zone of referred pain and tenderness.

Experimental injection of hypertonic saline solution into the third dorsal interosseous of one subject referred pain to the ulnar aspect of both the dorsal and palmar surfaces of the hand¹³ but not to the fingers.¹⁴

Abductor Digiti Minimi

The abductor digiti minimi muscle refers pain similarly along the outer aspect of the fifth finger to which it attaches (Figure 40-2B).

3.2. Symptoms

Patients with TrPs in an interosseous muscle characteristically report an achy “arthritis pain in my finger.” The pain is often described as a deep boney ache. They may also report finger stiffness that produces impairments in hand dexterity and strength and in functions such as buttoning a shirt, writing, and grasping. Numbness and paresthesia is not expected to accompany these TrPs unless there was involvement of the sensory digital nerves. Some patients will identify and describe the Heberden’s node as a “sore inflamed joint.” Careful examination indicates a tender Heberden’s node but, as a rule, no true synovial or bony swelling. In time, the Heberden’s node becomes less tender. Clinically, it appears that TrPs in muscles can be associated with joint disease,¹⁵ but there is little quality research on this association.

3.3. Patient Examination

After a thorough subjective examination, the clinician should make a detailed drawing representing the pain pattern that the patient has described. This depiction will assist in planning the physical examination and can be useful in monitoring the progression of the patient as symptoms improve or change.

Evaluation of the cervical and thoracic spine, as well as neurodynamic testing of the median, radial, and ulnar nerves is also helpful in identifying any spinal or neurogenic contribution to symptoms felt in the wrist and hand region. This assessment is important even if patients don’t report symptoms that are directly related to the cervical or thoracic spine.

Active and passive range of motion of the elbow, wrist, forearm, and hand should be carefully examined. Kendall et al⁷ describe and illustrate clearly the effect of shortening of the interosseous and lumbrical muscles. Adaptive shortening or local TrP tension of the palmar interosseous muscles that produce adduction of the fingers (PAD) compromises the ability to fully spread the extended fingers. Shortening, pain, or dysfunction of the dorsal interosseous muscles, which produce abduction of the fingers (DAB), interferes with the ability to bring the extended fingers close together. If the fifth finger rests in abduction, the abductor digiti minimi muscle is shortened. If the index finger rests in abduction, a shortened first dorsal interosseous muscle is likely the cause.

Testing for shortening of the lumbrical muscles is a bit more complicated. For example, holding a hand of cards or holding up a newspaper to read it⁷ by pressing the middle phalanx of the middle finger against the thumb but avoiding finger-tip pressure overloads the second lumbrical. When it becomes shortened, it will tend to hyperextend the distal phalanx of the middle finger when the fingers are extended and prevent full closure of the middle finger when attempting a claw position (fingers flexed with the MCP joint extended).

The muscles with TrPs may exhibit some weakness, especially when tested in a lengthened position. Tests of interosseous muscle strength are well described and illustrated by Kendall et al.⁷

Accessory joint motion should be examined in the MCP, proximal IP, and distal IP joints of all five fingers. Articular dysfunctions of the MCP joints often coexist with TrPs in the interosseous, lumbrical, and abductor digiti minimi muscles, especially in rotation, which is typically not examined. Hypomobility in these joints could lead to overload on the interosseous, lumbrical, and abductor digiti minimi muscles, especially during forceful grasping.

3.4. Trigger Point Examination

Trigger points in the interosseous or lumbrical muscles are difficult to palpate. The first dorsal interosseous muscle can be palpated with the forearm supported and in a neutral position. Cross-fiber flat palpation is used to identify TrPs in this muscle (Figure 40-3A). Separating the fingers widely moves the metacarpal bones apart and permits pincer palpation of the other interosseous and lumbrical muscles between the metacarpal bones. A counter-pressure is produced with a finger against the palm, beneath the muscle to be palpated (Figure 40-3B). Deep tenderness can be localized in the interosseous and lumbrical muscles but, except for the first dorsal interosseous muscle, referred pain and local twitch responses are rarely induced unless a monofilament or injection needle penetrates the TrPs.

Figure 40-2. Referred pain patterns (dark red) for selected intrinsic muscles of the right hand.

Essential zones are solid red, spillover zones are stippled red. A, The first dorsal interosseous muscle (medium red). B, The abductor digiti minimi muscle (medium red). C, The second dorsal interosseous muscle (medium red) and the third and fourth dorsal interosseous muscles (light red). Trigger points may be found anywhere in the interossei muscles, proximally or distally. This is to be expected because the two heads converge in a bipenniform manner and have endplate zones running in the shape of a horse-shoe the length of the muscles. Note the small Heberden's nodes in the essential pain reference zones.

To examine the abductor digiti minimi muscle, the patient's forearm and hand is supported with the palm facing up, and the TrPs are identified using cross-fiber pincer palpation (Figure 40-3C).

Cutaneous hypoesthesia may be noted along one side of a finger where the patient reports a sensation of numbness when an active TrP lies in the corresponding interosseous muscle. This apparent neurologic phenomenon may disappear following inactivation of the TrP, suggesting that the median or ulnar digital nerve had been affected by the increased tension of the involved interosseous muscle. However, this symptom could be sensory referred phenomena related to the presence of TrPs. It should be noted that no evidence exists to support this hypothesis, and more research is warranted.

On their way through the palm to the digits, the median and ulnar nerves lie next to the lumbrical and palmar interosseous muscles. The deep (motor) branch of the ulnar nerve pierces the opponens digiti minimi muscle before supplying all the interosseous muscles, the third and fourth lumbrical muscles, the adductor pollicis muscle, and the deep head of the flexor pollicis brevis muscle.¹ Trigger points in the opponens digiti minimi muscle can be responsible for weakness of these ulnarly innervated muscles, and if weakness is present, the opponens digiti minimi muscle should be examined for TrPs.

4. DIFFERENTIAL DIAGNOSIS

4.1. Activation and Perpetuation of Trigger Points

A posture or activity that activates a TrP, if not corrected, can also perpetuate it. In any part of the interosseous, lumbrical, and abductor digiti minimi muscles, TrPs may be activated by unaccustomed eccentric loading, eccentric exercise in an unconditioned muscle, or maximal or submaximal concentric loading.¹⁶ Trigger points may also be activated or aggravated when the muscle is placed in a shortened and/or lengthened position for an extended period of time.

Trigger points in the interosseous muscles are activated by sustained or repetitive pincer grasp, as performed by a tailor, hair stylist, painter, sculptor, mechanic, or wind instrument player. Balancing and sustaining a smartphone between the index finger and thumb may fatigue intrinsic muscles of the hand. Text message-related injuries are a relatively new phenomenon, with myofascial pain syndrome of the adductor pollicis muscle, first

interosseous muscle, and extensor digitorum muscle being common (70%).¹⁷ Activities requiring sustained forceful finger movements, such as pulling weeds, manipulation of hand muscles by a physical or massage therapist, or the actions of an aesthetician, can initiate interosseous TrPs. “Golf hands” have been associated with constant tight grip on the handle of the golf club, especially when the handle has a very small diameter.

Clinically, “boxer’s fractures” of the 2nd and 5th metacarpal have been seen to activate TrPs in patient’s first interosseous (2nd metacarpal) muscle or abductor digiti minimi (5th metacarpal) muscle, causing persistent pain and impairment. Trigger point dry needling into the muscle with several local twitch responses rapidly reduced pain and improved function. In several cases, recognized pain to the related digit was elicited. One patient, who presented with suspected complex regional pain syndrome of 5 months’ duration after surgical pinning of a 2nd metacarpal fracture, rapidly achieved long-term relief of pain after two sessions of TrP dry needling. Strength gains were significant and seen within several days of relief of pain. Subsequent graded return to sport was achieved within 2 weeks of the amelioration of the pain in the first interosseous muscle and a return of grip strength. The boxer continued to box for years without return of pain or recurrence.

4.2. Associated Trigger Points

Associated TrPs can develop in the referred pain areas caused by primary TrPs.¹⁸ Therefore, musculature in the referred pain areas for each muscle should also be considered. When the interosseous muscles are involved, the intrinsic thumb muscles should be examined for associated TrPs. Other TrPs that may refer pain into the fingers include the long flexors and extensors of the fingers, the infraspinatus muscle, the latissimus dorsi muscle, the pectoralis major muscle, the scalene muscles, and either the lateral or medial head of the triceps brachii muscle.

Trigger points in the pronator quadratus muscle may cause associated TrPs in the abductor digiti minimi muscle because it is located in the pain referral zone of the pronator quadratus muscle.

4.3. Associated Pathology

The distal IP joints of the fingers preferentially develop Heberden’s nodes. This phenomenon can be evidence of an osteoarthritic process¹⁹ and is most common in the finger joint that has the highest load per unit area of joint surface and in those individuals who commonly load that joint.²⁰ The increased strain on the interosseous muscles caused by abnormal hand mechanics associated with the distorted joint function of arthritis may activate and perpetuate these TrPs. Vice versa, TrPs may also contribute to the pain of arthritis,¹⁵ potentially through peripheral and central pain mechanisms. Inactivating the related TrPs and the elimination or management of their perpetuating factors may be important in rehabilitation and management of patients with osteoarthritis of the fingers and hand.

Heberden’s nodes are often identified with osteoarthritis,^{19,21} particularly with the

primary idiopathic form, rather than the traumatic secondary form.²² The node is an enlargement of soft tissue, sometimes partly bony, on the dorsal surface on either side of the terminal phalanx at the distal IP joint (Figure 40-2D). A positive association between Heberden's and radiographic evidence of osteoarthritis has been demonstrated ($n = 1939$; mean age 68 years, 54% women).¹⁹ The patient may eventually develop a flexion deformity with lateral or medial deviation of the distal phalanx.²³ Similar nodes located at the proximal IP joints are called Bouchard's nodes, but they are seen in only 25% of individuals with Heberden's nodes.²⁴

Not all swollen painful distal IP joints of the hands should be assumed to be Heberden's nodes as, for example, the prevalence of distal IP joint rheumatoid arthritic involvement is estimated at 10%.^{25,26}

The presence of Heberden's nodes is a common finding in patients with TrPs in the interosseous muscles. A node is palpable as an excrescence on the dorsal margin of the distal phalanx or the distal end of the middle phalanx on either side, always near the distal IP joint (Figure 40-2D). A Heberden's node may also appear on the thumb, usually on its ulnar side, in conjunction with TrPs in the adductor pollicis muscle. Idiopathic Heberden's nodes are most commonly seen on the index and middle fingers.⁵ They may appear on the side of the interosseous muscle attachment to the finger. A well-designed research study is needed to study the relationship between TrPs and Heberden's nodes and the efficacy of TrP treatment.

The diagnoses most likely to be confused with interosseous TrPs include C6 radicular pain or radiculopathy, ulnar neuropathy, C8 or T1 radicular pain or radiculopathy, and when the TrPs are primarily in the abductor digiti minimi muscle, thoracic outlet syndrome. Rarely, one may see the pain misdiagnosed as an isolated digital nerve entrapment when, in fact, it is associated with TrPs in one of the dorsal interosseous muscles. When the TrP is inactivated, this finger pain resolves completely. Finger pain and numbness may also result from neuropathy of the brachial plexus including compression from the scalene muscles (scalene syndrome) or compression as the plexus passes beneath the scapular attachment of the pectoralis minor muscle (see Figure 44-2B). The infraspinatus muscle has been associated with hand symptoms similar to those of carpal tunnel syndrome²⁷ and in one study was 12 times more likely than true carpal tunnel syndrome.²⁸

Guyon's canal is a passageway on the medial palmar aspect of the wrist that allows the ulnar nerve and artery to enter the hand.^{29,30} The canal is created between the hook of the hamate bone and the pisiform bone and the transverse carpal ligament proximally and the aponeurotic arch of the hypothenar muscles distally with the roof of the canal covered by the flexor retinaculum.^{1,30} Entrapment or irritation of the ulnar nerve in the canal is termed Guyon's canal syndrome after the French surgeon who first described it in 1861.^{29,30} Entrapment can lead to sensory and motor deficits as well as significant disability of hand function. Sensory deficits can affect the palmar ulnar aspect of the hand, both sides of the fifth finger, and the ulnar aspect of the ring finger.³⁰ Motor effects include

loss of strength and potential wasting of the ulnar innervated muscles of the hand including the hypothenar muscles (abductor, opponens, and flexor digiti minimi muscles), the interosseous muscles, the third and fourth lumbrical muscles, the adductor pollicis muscle, and the flexor pollicis muscle.^{1,30} Functional loss of normal grip is demonstrated by claw hand and weakness or loss of pinch grip strength.³⁰ Clinical examination, along with nerve conduction and EMG studies, assists in the differential diagnosis.^{30,31}

Intrinsic contracture of the hand may also result from trauma, spasticity, ischemia, rheumatoid arthritis (RA) disorders, or iatrogenic causes. A diagnosis is usually made by history and physical examination; however, imaging, EMG, and blood testing may be required.³²

Articular dysfunctions, including the loss of joint play, that are associated with interosseous TrPs can occur at either the level of the carpometacarpal joint or at the level of the MCP joint, and any of these joint dysfunctions need to be treated concurrently with the associated interosseous TrPs.

Diseases such as RA and disorders of the skin, vascular, and musculoskeletal systems may influence the hand, making differential diagnosis even more important.³³ Imaging of the hand may prove useful for differential diagnosis in hand trauma or persistent hand pain. The occurrence of hand stress fractures in athletes is not uncommon, and imaging plays an integral role in timely diagnosis and management.³⁴ The complex nature of the hand may require consultation with specialists in the diagnosis and treatment of orthopedic hand disorders for optimal medical and/or surgical management to maximize functional and occupational outcomes.

5. CORRECTIVE ACTIONS

The patient should learn to reduce the force and duration of pincer grip activities in order to lessen strain on the interosseous muscles. Patients who use ballpoint pens should, if their work permits, write with a more freely flowing felt-tip pen that needs a much lighter touch. Reducing texting through habit modification, alternate modes of communication, or speech-to-text applications can lessen intrinsic hand muscle fatigue and overload. Patient education should also include mindfulness of patterns of increased psychophysiologic arousal and muscle tension during smartphone use.³⁵ Time away from devices, relaxation exercises, and general aerobic exercises may be helpful treatment strategies.

The patient should interrupt prolonged fine manual activity with the finger-flutter exercise to lessen tension of the intrinsic muscles of the hand. With the arms and hands by the side, the patient gently shakes the hands and arms to release tension. Ergonomic aids for activities of daily living and occupational activities may be required. Ergonomic assessment may play an important role in the adaptation of habitual tasks. Splinting may be helpful in managing specific hand dysfunctions.³⁰

Self-pressure release for TrPs in the interosseous, lumbrical, and abductor digiti minimi muscles can be performed in sitting by placing the forearm on the arm rest of a chair or on a table with the thumb pointed up toward the ceiling for the first dorsal interosseous

muscle (Figure 40-4A) as well as the other interosseous and lumbrical muscles (Figure 40-4B). Manual pressure is the best method for performing self-pressure release of these muscles. With the palm facing up, a pincer grasp can be used for manual release of TrPs in the abductor digiti minimi muscle (Figure 40-4C). As with any self-pressure release technique, the sensitive spot on the pinky finger side of the hand or in the palm is identified with the fingers, light pressure (no more than 4/10 pain) is applied and held for 15 to 30 seconds or until pain reduces. This technique can be repeated five times several times per day.

Figure 40-3. Palpation for TrPs in intrinsic hand muscles. A, Cross-fiber flat palpation of the first dorsal interosseous muscle. B, Cross-fiber pincer palpation of interossei and lumbrical muscles. C, Cross-fiber pincer palpation of the abductor digiti minimi muscle.

When indicated, the patient should perform the interosseous self-stretch exercise, illustrated in Figure 40-5. In doing this exercise, it is important that the forearms form a straight line. When active TrPs are present in the first dorsal interosseous muscle, regular use of the adductor pollicis self-stretch exercise (see Figure 39-6A) may also help ensure continued recovery. These self-stretches should be carried out gently, and attention to the reproduction of pain versus stretch is paramount. These stretches should not be painful.

Figure 40-4. Self-pressure release of hand muscle TrPs. A, First dorsal interosseous muscle. B, Interossei and lumbrical muscles. C, Abductor digiti minimi muscle.

Strengthening of the upper limb, wrist, thumb, and hand is an important component of upper extremity rehabilitation. Strength deficits identified from a professional assessment can be addressed with the use of hand putty, hand grippers, and weights. The restoration of strength and grip function is an important component of rehabilitation.

Figure 40-5. Two views of the interosseous-stretch exercise. Both hand positions are effective. The forearms are held in a straight line with the arms abducted. A, An effort is made to firmly oppose the palmar aspects of the metacarpal heads and the fingers, whereas the fingers and thumbs are spread apart. B, Only the finger pads contact each other while the fingers and thumbs are spread apart, with the uninvolved fingers assisting the stretch of the involved interossei muscle.

Clinical Considerations of Elbow, Wrist, and Hand Pain

Ann M. Lucado, Gustavo Plaza-Manzano, and César Fernández de Las Peñas

1. INTRODUCTION

Potential competing diagnoses are abundant in nontraumatic distal upper extremity pain-producing conditions. A thorough medical history, an upper quarter regional examination, and a detailed assessment of local anatomic structures are required in the clinical diagnosis of conditions causing elbow, wrist, and/or hand pain symptoms. The tight confines in which multiple anatomic structures function in the distal upper extremity make it particularly challenging to isolate pathologic disorders; in fact, symptoms are often attributable to multiple sources. Moreover, movement strategies that an individual may use to avoid or compensate for pain from a primary diagnosis may result in altered motor patterns and overload of muscles. These compensatory movement strategies may result in trigger point (TrP) development in the distal upper extremity musculature, further complicating the isolation of a clinical diagnosis. Nonetheless, it is important to address faulty or compensatory movement patterns along with the primary condition(s). Recent or past trauma to the region can directly or indirectly impact current symptoms. Soft-tissue tumors, other space-occupying lesions, vascular compromise or occlusion, and proximal pathology are all known to mimic painful local musculoskeletal conditions in this region. Systemic disorders such as endocrine dysfunction including diabetes, autoimmune diseases, rheumatologic and neurologic conditions directly impact clinical presentation and must be ruled out or taken into account, if present, as potential contributors to symptoms in the upper extremity. Appropriate medical management is essential for successful outcomes; yet, its comprehensive discussion is beyond the scope of this text. This chapter provides an overview of the most common nontraumatic musculoskeletal clinical considerations of elbow, wrist, and hand pain.

2. LATERAL EPICONDYLALGIA

2.1. Overview

The presence of symptoms in the lateral aspect of the elbow may be primarily associated with local tendinopathy, joint pathology (arthritis, radiocapitellar pathology, posterolateral rotatory instability), or nerve compression (radial tunnel syndrome, posterior interosseous nerve entrapment). Any of these diagnoses may occur in isolation or in combination and do not preclude the presence of referred pain from TrPs in the associated muscles.

Lateral epicondylalgia is commonly considered a tendinopathy of the common wrist extensor tendon at the lateral epicondyle. Although a diagnosis of lateral epicondylalgia may be an accurate term for the patient presenting with pain over the lateral epicondyle, it provides little information about the underlying pathology. In fact, multiple, essentially synonymous, names are associated with this disorder, including, tennis elbow, lateral elbow pain, and lateral epicondylitis. Additionally, several derivations of the term related to tendinopathy have been used to describe the pathophysiology thought to accompany the condition, including tendinitis and tendinosis. Symptoms typically arise in middle-aged active adults.¹ Although it has been commonly associated with tennis players, lateral epicondylalgia also develops in individuals who repetitively use their arms at work or in other sporting activities. The annual incidence of lateral epicondylalgia is less than 10% in the general population,² but it continues to be highly prevalent in tennis players, particularly those who are less skilled and play recreationally.³

Loading of the wrist extensor muscles in a forceful or repetitive manner, especially in extreme positions of the wrist or elbow, is associated with an onset of lateral epicondylalgia⁴; although symptoms develop gradually. Extrinsic reaction forces from using tools, such as a hammer or tennis racquet, or internal forces generated to manipulate a mouse or type on a keyboard can contribute to the overload of the wrist extensor muscle-tendon unit. Over time, the excessive loading results in a cascade of pathophysiologic events within the tendon, leading to pain. Nirschl⁵ and Kraushaar⁶ first described tendinopathy in stages that ranged in severity symptoms and tendon pathology. The earliest stage consists of a peritendinous inflammation, whereas later and more severe stages are characterized by angiofibroblastic degeneration and ultimately fibrosis of the tendon.⁵ Nevertheless, most histologic studies on lateral epicondylalgia have not found clear evidence of an inflammatory process,⁷ and it is likely that individuals may experience acute on chronic aggravation of symptoms after loading an inferior quality tendon. The presence of neuropeptides, substance P, and calcitonin gene-related peptide in local sensory nerve fibers implicates neurogenic inflammation as a possible mediator of pain in patients with lateral epicondylalgia.⁸⁻¹⁰ Neurochemical and tissue changes associated with chronic tendinopathy can also result in central sensitization, compounding the potential complexity of this diagnosis.¹¹ In an effort to adequately explain different clinical presentations, Cook and Purdam¹² proposed a clinical model of histopathologic changes across a continuum from (a) reactive tendinopathy, (b) tendon disrepair to (c) degenerative tendinopathy.

Ultrasonography has been extensively used for the identification of grey-scale hypoechoic lesions that imply dysfunction in the connective tissues; however, hypoechoic lesions identified in the wrist extensor common tendon in patients with lateral

epicondylalgia are not linked to pain in the tendon.^{12–14} This discrepancy between imaging and clinical pain symptoms has led to some authors claiming that there is a relevant role of nociceptive pain mechanisms in lateral epicondylalgia and other tendinopathies.¹⁵ Today, there is strong evidence implicating the central nervous system in the symptoms experienced in patients with lateral epicondylalgia, which could explain why several patients with unilateral symptoms, if they are not properly treated, develop bilateral symptoms.

Several conservative treatments, such as medication, exercise, and manual therapy, are advocated for the management of lateral epicondylalgia. Therapeutic exercise is probably the physical therapy strategy with the highest evidence for lateral epicondylalgia,^{16,17} but eccentric exercise is not necessarily better than concentric exercise.¹⁸ The exercise program should be graduated and progressive from isometric to isotonic contractions of the wrist and forearm muscles, culminating in pragmatic exercises that replicate the patient's required function. This functional management supports a role of the wrist extensor muscles, and hence the presence of TrPs, in lateral epicondylalgia.

2.2. Initial Evaluation of a Patient With Lateral Epicondylalgia

Lateral epicondylalgia is by definition a clinical entity; therefore, imaging studies for confirmatory diagnosis are not usually required. The diagnosis of lateral epicondylalgia can be achieved most easily in the early stages of its onset. Focal pain is located directly over, or immediately distal to, the lateral epicondyle. With time, most patients report pain spreading to the forearm and the wrist. The pain is aggravated with palpation, contractile unit testing of the wrist, and occasionally the finger extensors, and any activity that loads the wrist extensor muscles, including lifting in a pronated position or gripping made worse when the elbow is in an extended position. Stretching of the wrist extensor muscles may also reproduce symptoms. Although muscular tightness may be detected, passive and active elbow, forearm, wrist, and hand range of motion are generally unaffected.^{19–21} Patients presenting with lateral epicondylalgia will have pain and weakness with tests that challenge the wrist extensor muscles. Pain-free grip strength is a commonly used outcome measure and has been shown to be more sensitive to change than maximal grip strength in patients with lateral epicondylalgia.²² Grip strength deficits are generally greater when tested in an elbow extended position than when tested with the elbow at 90° of flexion.²³ Cozen test (resisted wrist radial deviation), Mill stretch maneuver (long extensor stretch), and pain with palpation to the lateral epicondyle are all special tests associated with making this clinical diagnosis; however, the diagnostic utility of these tests has not been established. Because each of these tests stresses other soft tissue located in the region, it is important to interpret the results of the special tests in the context of the entire clinical examination considering the role of muscle tissue instead of just the tendon. The assessment should include examination for TrPs in the wrist extensor muscles including the brachioradialis²⁴ that may be the source or a contributing factor to the symptoms. In fact, a recent study has reported that the identification of TrPs in the wrist extensor muscles is reliable.²⁵ Similarly, TrPs in the antagonist muscles, ie wrist flexor muscles, should also be explored.

A detailed clinical examination that systematically rules out other potential causes of lateral elbow pain is essential to improving the confidence in making this differential diagnosis.

3. RADIOCAPITELLAR JOINT PATHOLOGY

3.1. Overview

Patients with arthritic changes at the radiocapitellar joint are typically middle-aged to older adults who present with gradual increasing stiffness and pain in the lateral elbow.²⁶ Stiffness due to osteoarthritis will be most noticeable in the morning or after periods of rest. If arthritis is due to an inflammatory condition, like rheumatoid arthritis, visible generalized joint effusion may be present. Noninflammatory arthritic conditions can be degenerative in nature or post-traumatic; eg, post-traumatic arthritis may present years following a radial head fracture because of structural changes to the joint causing pain and loss of motion. Articular cartilage tears, loose bodies, and bone spurs can develop and potentially cause mechanical blocks to motion, particularly loss of full elbow extension.

In younger, more athletic, individuals, richly innervated synovial plica at the humeroradial joint may become inflamed, hypertrophied, and symptomatic.^{27–29} Although plica, also known as synovial folds, in the elbow are normal, pathologic changes in the lateral synovial fold associated with repetitive elbow motion will cause a vague posterolateral elbow pain and often a palpable “snapping” when the elbow is moved passively or actively.²⁸

Posterolateral rotatory instability is most commonly seen in subjects who sustained a traumatic injury to the elbow, particularly a fall on an outstretched arm.³⁰ The traumatic event tears the lateral collateral ligamentous complex. This will result in gross instability or subluxation of the radial head and ulna from the humerus in a posterolateral direction. In other cases, individuals may present with a slower onset of symptoms because of a gradual attenuation of the lateral collateral ligament complex. The subluxation may be subtle in cases of gradual onset. Assuming that obvious signs of gross instability are not present, a painful click or clunk with motion may be noted, particularly when a person is using the arm to push up to standing from a seated position. Patients will typically report vague, lateral-sided elbow pain. Camp et al³⁰ hypothesize that repeated cortisone injections commonly used for lateral epicondylalgia may contribute to posterolateral rotatory instability in certain patients because of the steroid’s damaging effects on the ligamentous tissue. As in other joint instabilities, it is possible that overactivity of muscles in the region that provide dynamic stability to the joint may lead to TrP formation.

3.2. Initial Evaluation of a Patient With Radiocapitellar Joint Pathology

If radial joint pathology is suspected, clinicians must differentiate between radiocapitellar arthritis, hypertrophied and inflamed synovial plica, and posterolateral rotatory instability. All may produce mechanical limits in passive as well as active range of motion of the elbow

and forearm rotation. They may be associated with audible crepitus, clicking, or clunks with motion and will likely present with vague lateral elbow pain.²⁶ Contractile unit testing is typically normal and not painful in these joint conditions. If associated muscular symptoms are present, the examination should include examination for TrPs in regional muscles that could be contributing to symptoms concurrently, particularly the supinator and pronator teres muscles, among others.³¹

It may be difficult to differentiate between radiocapitellar joint pathologies using clinical evaluation alone. Plain radiographs are useful in confirming the presence of arthritis in the radiocapitellar joint, whereas magnetic resonance imaging is better at identifying hypertrophied and inflamed synovial plica. Provocation of posterolateral rotary instability is difficult without anesthesia because of muscle guarding and pain. The chair push-up or prone push-up tests with the forearm in a supinated position are the most convenient clinical special tests to attempt to provoke subluxation in the elbow. Lateral elbow pain, posterior subluxation of the radial head (as evidenced by dimpling of the skin between the radial head and the capitellum), and a clunk as the subluxed joint reduces are signs of a positive test. The chair and push-up tests are specific for detecting posterolateral rotatory instability but may produce a high percentage of false-negative results. Special tests such as the lateral pivot-shift test or posterolateral rotatory drawer test provide more accurate results, especially when the individual can be fully relaxed under anesthesia.³⁰

4. RADIAL (CERVICAL) NERVE ENTRAPMENT

4.1. Overview

The incidence of cervical pathology ranges from 10% to 20% in the general population; it is more common in women than in men, and its onset increases in middle age.³² In fact, patients with elbow pain and concomitant neck pain typically experience a poorer outcome.³³ Further, several studies show the benefits of adding treatment of the cervical spine to elbow local treatment.^{34,35} Cervical radiculopathy is characterized by pain that radiates into the arm that can be associated with loss of sensation and/or weakness. Irritation of the C7 (or occasionally of the C6) nerve root refers symptoms into the lateral elbow region, may mimic symptoms of lateral epicondylalgia, and should be ruled out as a potential proximal cause of elbow pain.³⁶ Refer to Chapter 33 for further information on cervical radicular pain.

Compression of the posterior interosseous branch of the radial nerve at the dorsal forearm is called radial tunnel syndrome when lateral elbow pain is the primary symptom.³⁷ The condition referred to as posterior interosseous nerve compression occurs when a pain-free weakness or paresis is present in the finger and thumb extensors, while the wrist extensor muscle strength essentially appears intact. Compression of the posterior interosseous nerve has an estimated annual incidence of 0.03% and is less common than other upper extremity compression syndromes.³⁸ The nerve can be entrapped within thickened fascial layers close to the radiocapitellar joint, along fibrous bands associated with

the extensor carpi radialis brevis muscle, the proximal (arcade of Frohse) or distal borders of the supinator muscle, or can be compressed by abnormalities within the radial recurrent blood vessels in the region referred to as the leash of Henry. Fibro-fatty tumors in the region may also compress the nerve. Characterized by the absence of motor deficits, radial tunnel syndrome is often differentiated from lateral epicondylalgia by the location of pain which is typically located over the supinator muscle belly approximately 5 cm distal to the lateral epicondyle. Although individuals with pathology in the musculotendinous unit of contractile structures tend to have pain associated with activity, individuals with radial tunnel syndrome often report pain at night and may have trouble sleeping.³⁸

4.2. Initial Evaluation of a Patient With Cervical or Radial Nerve Entrapment

When radial nerve entrapment is suspected, clinicians must differentiate between more proximal sources of nerve compression in the cervical spine versus compression of the posterior interosseous branch of the radial nerve in the forearm. All individuals with lateral elbow pain should undergo a cervical spine screening. Any reproduction of lateral elbow pain with neck movement, palpation, or during assessment of accessory mobility of the cervical vertebrae will implicate the cervical spine as a potential contributor to lateral elbow pain.¹⁷ Individuals with cervical radiculopathy will likely have associated neck pain and may report paresthesias and/or weakness in the upper extremity. A positive neurodynamic test of the median nerve may also implicate cervical radiculopathy.³²

Local examination of the elbow is necessary and should include a history and physical examination. Individuals with either posterior interosseous nerve compression or radial tunnel syndrome will report no sensory deficits because of the lack of cutaneous sensory fibers in this deep branch of the radial nerve. Sensation testing may reveal deficits along the C7 or C6 dermatomes in cervical radiculopathy, including the dorsal arm and hand or thumb. In true posterior interosseous nerve compression, the absence of pain and the presence of defined weakness or complete paralysis in the extensor digitorum, extensor indicis, extensor digiti minimi, extensor pollicis longus and brevis, and abductor pollicis longus muscles as well as possibly the extensor carpi ulnaris muscle is evident. Testing procedures will confirm the diagnosis. It is likely that individuals with posterior interosseous nerve compression will demonstrate incomplete or no active digit and thumb extension range of motion, and wrist extension may deviate toward the radial side because of weakness of the extensor carpi ulnaris muscle, while the strength of the radial wrist extensor muscles is spared.

Range-of-motion deficits in the upper extremity are not common in either cervical radiculopathy or radial tunnel syndrome. Strength deficits associated with cervical radiculopathy, if present, are not as clearly defined as in posterior interosseous nerve compression. Palpation over the course of the posterior interosseous nerve in the forearm is generally not painful in individuals with cervical radiculopathy or with posterior interosseous nerve compression; however, the nerve will typically be exquisitely tender in those with radial tunnel syndrome. A positive neurodynamic test of the radial nerve is

typical in radial tunnel syndrome but not necessarily in cervical radiculopathy.³²

Special tests for radial tunnel syndrome may be positive for pain in the region of the supinator muscle, approximately 5 cm distal to the lateral epicondyle. Resisted supination, resisted wrist extension, and resisted middle-finger extension can all load the musculature that forms the roof of the radial tunnel; theoretically, these tests will all potentially cause irritation of the posterior interosseous nerve and replicate symptoms of pain by loading the roof of the tunnel.³⁸ However, the diagnostic utility of these tests in accurately identifying radial tunnel syndrome have not been clearly established. Peripheral nerve conduction velocity and electromyographic (EMG) testing can also produce false-negative results and are therefore not considered to be useful in many cases of radial tunnel syndrome.³⁸

4.3. Trigger Points and Lateral Elbow Pain

Several studies have reported a high prevalence of active TrPs in the wrist extensor muscles, particularly the extensor carpi radialis brevis and longus muscles, in subjects with lateral epicondylalgia^{24,39} and blue-collar and white-collar workers.⁴⁰ Obviously, any wrist extensor muscle, and potentially the brachioradialis, can be affected (Chapters 34 and 35). It is still unclear as to whether TrPs predispose individuals to lateral epicondylalgia or if they coexist.⁴¹

The role of TrPs in lateral epicondylalgia is also supported by preliminary evidence showing that myofascial release and dry needling have been found to be effective for reducing symptoms related to lateral epicondylalgia.⁴² However, soft-tissue mobilization and manual myofascial release techniques plus ultrasound were no more effective than no treatment or laser for elbow pain.⁴³ Shmushkevich and Kalichman⁴¹ have called for more research examining the effectiveness of myofascial techniques on reducing symptoms of lateral elbow pain and advocate the use of manual myofascial techniques in the treatment of lateral epicondylalgia. Krey et al⁴⁴ conducted a systematic review examining the effectiveness of dry needling alone in the treatment of tendinopathy and concluded that dry needling seems to have a positive effect on self-reported function in the midterm in these patients. Because dry needling is still an emerging intervention for the treatment of TrPs in the treatment of lateral elbow pain, more clinical trials are clearly needed.

Trigger points in other neck and shoulder muscles, such as the scalenes or infraspinatus muscles, and elbow muscles, such as the triceps brachii or anconeus muscles, can also refer pain to the lateral area of the elbow and contribute to symptoms compatible with lateral epicondylalgia; however, limited evidence is available. Clinically, TrPs within the triceps brachii, supinator, and anconeus muscles are more related to individuals with localized elbow pain, whereas TrPs in the wrist extensor muscles are more related to individuals with symptoms spreading throughout the forearm.

Pain in peripheral nerve compression syndromes can be replicated/provoked by maneuvers that either stretch the irritated nerve or exacerbate compressive forces. Because neural tissues are pain-sensitive and are relatively mobile within the musculoskeletal system under normal conditions, nerves have the potential to be responsible for painful movement

and dysfunction. However, compression neuropathy often results from a nerve that is chronically compressed by some adjacent anatomic structure. In many cases this structure may be a muscle with taut bands from TrPs or overactivity. Therefore, examination of muscles adjacent to the nerve for TrPs should be conducted in patients with suspected nerve compression syndromes. A clear example of the close association of myofascial pain syndrome and radial tunnel syndrome is seen in patients with symptoms of radial tunnel syndrome who exhibit TrPs in the supinator muscle (Chapter 36).

5. MEDIAL EPICONDYLALGIA

5.1. Overview

Medial epicondylalgia is a condition that causes medial elbow pain that may result from tendinopathy of the common flexor tendon at the medial epicondyle.⁴⁵ It is considered analogous to lateral epicondylalgia in terms of its pathophysiology⁸; however, medial epicondylalgia is less prevalent and less often studied than lateral epicondylalgia. Medial epicondylalgia is said to occur more often in golfers than in tennis players, but any activity that cyclically loads the wrist flexor muscles and forearm pronators in a forceful or repetitive manner can cause symptoms.⁴⁶

Management of medial epicondylalgia is more limited than that for lateral epicondylalgia and generally includes a combination of activity modification, ice, oral analgesics, anti-inflammatory medications, physical therapy, iontophoresis, and dry needling. Similar to lateral epicondylalgia, therapeutic exercise would probably lead to positive outcomes in medial epicondylalgia; however, no clinical trials exist on this topic.⁴⁷

5.2. Initial Evaluation of a Patient With Medial Epicondylalgia

Similar to lateral epicondylalgia, a definitive diagnosis is easier to establish early in the onset of its development. Pain is generally localized to the medial epicondyle or just distal to it. The focal pain is aggravated with palpation, contractile unit testing of wrist flexion, and possibly pronation, and with any activity that loads the wrist flexor muscles or pronators. Strength of the wrist flexor muscles and pronators may be inhibited by pain. Stretching of the wrist flexor muscles may also replicate symptoms; although muscular tightness may be detected, passive and active elbow, forearm, wrist, and hand range of motion are generally unaffected.⁴⁵ Similarly, as with lateral epicondylalgia, most clinical tests stress other soft tissue located in the region; therefore, it is important to interpret their results in the context of the entire clinical examination and to consider the role of muscle tissue and of the tendon. The assessment should include examination for TrPs in the wrist flexor muscles and forearm pronators that may be the source or a contributing factor to the symptoms. A thorough differential examination should be conducted to rule out other sources of medial elbow pain.

6. HUMEROULNAR JOINT PATHOLOGY

6.1. Overview

Patients with arthritic changes at the humeroulnar joint are typically middle-aged or older adults who present with gradually increasing stiffness and pain in the medial elbow region. Stiffness due to osteoarthritis will be most noticeable in the morning or after periods of rest.²⁶ If arthritis is due to an inflammatory condition, such as rheumatoid arthritis, visible joint effusion and olecranon bursitis may be present, and oftentimes, the swollen bursa is apparent to visual inspection. Noninflammatory arthritic conditions can be degenerative in nature or post-traumatic, following elbow dislocation and/or fracture. Articular cartilage tears, loose bodies, and bone spurs can develop and potentially cause mechanical blocks to motion, particularly loss of full elbow extension.

In overhead throwing athletes, such as baseball pitchers, javelin throwers, and other athletes who repeatedly use a throwing motion, ulnar collateral ligament (UCL) injuries are common.⁴⁸ The ligament originates from the medial epicondyle and runs distally to insert on the ulna. It is the main restraint of the elbow joint to valgus stresses. The valgus stresses on the medial elbow can overload the UCL in time, causing a gradual over-lengthening resulting in ligamentous insufficiency or a tear that could cause joint instability. Both UCL insufficiency and instability are typically associated with medial elbow pain with activity that subsides with rest. Additionally, the athlete may report loss of throwing speed or accuracy.⁴⁸ Late stages of UCL insufficiency as a result of repetitive throwing activities is called valgus extension overload syndrome and can be associated with posteromedial osteophyte formation, loose bodies, and flexor-pronator muscle injury.⁴⁵

6.2. Initial Evaluation of a Patient With Humeroulnar Joint Pathology

When medial elbow joint pathology is suspected, it is fairly easy to differentiate between humeroulnar arthritis and UCL/medial joint instability. To start with, the history and the behavior of symptoms are quite different, as outlined above; although both conditions present with vague medial elbow pain. Humeroulnar arthritis may produce mechanical limits in passive as well as active flexion/extension of the elbow because of bone spurs or loose bodies in the joint associated with the arthritic condition. Movement may be associated with audible crepitus or clicking. In contrast, elbow motion is typically full and smooth in individuals with UCL insufficiency or instability.⁴⁸

Pain and stiffness with motion is typically worse in the morning for individuals with arthritic changes at the medial elbow, whereas with UCL injury, motion without resistance is typically pain free. Contractile unit testing is typically normal and not painful in either of these joint conditions. Also, plain radiographs are useful in confirming the presence of arthritis in the humeroulnar joint. Special tests to assess medial elbow joint stability have demonstrated acceptable diagnostic utility in detecting UCL injuries. The moving valgus stress test has demonstrated a superior estimated positive likelihood ratio of 4.0 (95% CI

0.73, 21.8) and a negative likelihood ratio of 0.04 (95% CI 0.00, 0.72) over valgus stress tests to the elbow at varying degrees of elbow flexion. It is important to compare the results of these tests with the contralateral extremity and assess for both pain and instability.⁴⁹

7. POTENTIAL NERVE ENTRAPMENTS CAUSING MEDIAL ELBOW PAIN

7.1. Overview

Thoracic outlet syndrome, as discussed in detail in Chapter 33, is a potential cause of medial elbow pain when the lower trunk of the brachial plexus is affected. Symptoms aside from medial elbow pain may also include neurologic and/or vascular components. Neurologic symptoms are evidenced by sensory disturbance, or even strength deficits in severe cases, in the ulnar nerve distribution. Vascular symptoms may present as arterial compromise associated with a coldness and whitish hue to the hand, venous congestion associated with a purplish hue to the hand, or vasospasm resulting in Raynaud phenomenon characterized by cold insensitivity.

Cubital tunnel syndrome is a condition that results from ulnar nerve compression, stretching or friction irritation anywhere along the medial elbow region. Irritation of the ulnar nerve in the region of the elbow is a potential source of medial elbow pain. Cubital tunnel syndrome is the second most common upper extremity nerve entrapment after carpal tunnel syndrome (CTS).⁵⁰ Its prevalence ranges from 0.6% to 0.8% in the general population but may be even more prevalent in individuals with certain occupations. Individuals with high occupational force requirements have a worse prognosis for complete symptom resolution.⁵⁰

Along the course of the ulnar nerve, multiple potential compression sites exist. In the upper extremity, the ulnar nerve pierces the medial intermuscular septum, travels along the posterior aspect of the humerus, and passes through a deep fascial band in the distal arm, called the arcade of Struthers, before it crosses the elbow in the cubital tunnel, posterior to the medial epicondyle, leading into the forearm.⁵¹ The medial intermuscular septum and the arcade of Struthers are potential sites of compression of the ulnar nerve if these fascial bands become thickened, if the muscular attachments become hypertrophied, or through a friction irritation of the nerve associated with repetitive flexion and extension of the elbow.⁵² The cubital tunnel itself can be a source of compression as the tunnel floor is formed by the rigid ulna and roof is formed by an unyielding retinaculum that keeps the nerve in place. An attenuation of the cubital tunnel retinaculum can allow the ulnar nerve to sublux anteriorly. Repetitive elbow flexion and extension movements can cause a friction irritation of the ulnar nerve that is compounded if the ulnar nerve is not firmly situated in the ulnar groove. In many subjects, the subluxation may be asymptomatic, but if the ulnar nerve should become symptomatic, the repeated friction irritation from the nerve subluxing anteriorly out of the cubital tunnel perpetuates symptoms and may require surgical intervention in advanced cases.⁵³ The ulnar nerve can also be compressed as it travels distal

to the cubital tunnel into the forearm. An aponeurosis between the humeral and ulnar heads of the flexor carpi ulnaris (FCU) muscle can be a source of ulnar nerve irritation.⁵¹ Forearm flexor muscle hypertrophy can exacerbate irritating forces along the ulnar nerve.⁵⁴

Because there is little subcutaneous tissue protecting the nerve at the elbow, the ulnar nerve is also susceptible to direct pressure from leaning the elbow region on a table or arm rest. Because the nerve courses posterior to the axis of rotation of the elbow, when the joint is flexed, the nerve is stretched. If the elbow is held in a flexed position and tension is placed on the ulnar nerve for prolonged periods of time, symptoms of cubital tunnel syndrome are evoked. Holding a phone up to the ear for a prolonged period of time can cause ulnar nerve irritation at the elbow, as can a sleeping posture of acute elbow flexion. Cubital tunnel syndrome is typically associated with paresthesias and sensory disturbance, and in the long term can result in weakness in muscles innervated by the ulnar nerve including the FCU muscle, the flexor digitorum profundus muscle to the fourth and fifth digits, and most of the intrinsic muscles of the hand. Muscle strength deficits are often associated with reports of clumsiness and the inability to grip tightly.⁴⁵

The median nerve also travels in the medial arm and forearm and can be a potential source of medial elbow pain, although in a lesser extent than the ulnar nerve. Entrapment of the median nerve in the elbow region is referred to as pronator syndrome. It has been reported to be more common in women and occurs primarily in middle-aged adults.⁵⁵ Pronator syndrome is associated with variations in local muscular architecture and is characterized by vague medial elbow pain and sensory disturbance in the median nerve distribution at the hand.⁵⁶ The sensory symptoms may be similar to those of CTS; however, sensation in the palm is impaired in pronator syndrome and spared in CTS because the anterior cutaneous branch splits from the median nerve proximal to the carpal canal. Symptoms are aggravated with repetitive forearm rotational tasks in occupations requiring assembly-line work.⁵⁵ Anecdotally, it is also seen in active individuals who are avid rock climbers. Finally, compression of the anterior interosseous nerve is referred to as anterior interosseous nerve compression syndrome, and it is mainly differentiated from pronator syndrome by its characteristic nonpainful weakness or paresis of the muscles it innervates. No sensory disturbance is noted in anterior interosseous nerve compression.⁵⁶

7.2. Initial Evaluation of a Patient With Potential Nerve Entrapments Causing Medial Elbow Pain

The examination for identifying thoracic outlet syndrome has been described in detail in Chapter 33. When examining individuals suspected of having either ulnar or median nerve entrapment associated with medial elbow pain, common symptoms denoting a nerve compression issue will include sensory disturbance and possible weakness in the peripheral nerve distribution of the involved nerve. Therefore, in addition to the history, visual inspection, and general orthopedic examination assessing range of motion and contractile unit testing, a full sensory examination and manual muscle test may be required to fully differentiate the source and location of nerve compression. Results of the examination will

vary greatly depending on the extent and severity of nerve entrapment. Severe cases of entrapment can be easy to identify, but the subtle signs of either cubital tunnel or pronator syndrome may be more difficult to discern early in the stages of compression. Provocative maneuvers include Tinel test over the involved nerve, neurodynamic testing of the ulnar or median nerve, and muscle length tests (which may irritate the nerve if taut). All muscles related to each particular nerve should be examined for the presence of TrPs, including, the flexor digitorum profundus and FCU muscles in patients with a potential involvement of the ulnar nerve. Electrodiagnostic tests for compromise of ulnar nerve function have demonstrated excellent diagnostic utility in cubital tunnel syndrome but not for pronator syndrome. This difference may be related to the depth at which the median nerve travels compared with the more superficial ulnar nerve.

Multiple nerve entrapments may occur simultaneously and are commonly referred to as a “double crush” phenomenon. One compression site on a nerve will lower its threshold for occurrence of a second neuropathy along the same nerve, by blocking the axonal transport mechanism by which the nerve cell body provides nutrition and removes breakdown products. This block makes a nerve that has a more proximal (or distal) entrapment more susceptible to a second location of entrapment. It is therefore important to examine the structures along the entire path of the nerve. It is common to see multiple neuropathy situations occur along the median nerve at the level of the cervical spine, the pronator teres, and the carpal canal and along the ulnar nerve at the thoracic outlet, the elbow, and the wrist.

7.3. Trigger Points and Medial Elbow Pain

Trigger points in the wrist flexor muscles or forearm pronator muscles could lead to symptoms associated to medial epicondylalgia; however, there is no epidemiologic study in the literature investigating this topic. In all nerve entrapment syndromes that are associated with medial elbow pain, muscle hypertrophy and/or overactivity due to taut bands resulting from TrPs are potential contributors to the irritation of the involved peripheral nerve. For instance, in thoracic outlet syndrome, overactivity of the scalene muscles related to excessive use of these muscles for breathing, or of the pectoralis musculature in weight lifters due to excessive training of the anterior chest muscles, can cause compression of the lower portion of the brachial plexus; hypertrophy of the FCU muscle can cause entrapment of the ulnar nerve; pronator teres hypertrophy, such as in rock climbers, can result in the compression of the median nerve of the elbow. Although there is a scarcity of studies examining the relationship, it stands to reason that abnormal tone related to taut bands resulting from TrP in musculature adjacent to these nerves may also be related to nerve compression syndromes. Therefore, all muscles related to a particular peripheral nerve should be evaluated for TrPs and managed appropriately. Trigger points in the proximal upper quarter musculature that also contribute to medial elbow pain may include the scalene, pectoralis major, latissimus dorsi, teres major, and subscapularis muscles.

8. RADIAL WRIST/THUMB PAIN

8.1. Overview

The presence of symptoms in the radial area of the wrist and thumb may be primarily associated with local tendinopathy (DeQuervain tenosynovitis, intersection syndrome, extensor pollicis longus muscle irritation), joint pathology (carpometacarpal joint [CMCJ] arthritis, ganglion cyst), or local nerve compression (Wartenburg syndrome, CTS). Any of these diagnoses may occur in isolation or in combination.

DeQuervain tenosynovitis, intersection syndrome, and irritation of the extensor pollicis longus tendon are all tendinopathies that can contribute to radial wrist pain. DeQuervain tenosynovitis refers to a painful tendonitis of the first dorsal compartment tendons including the abductor pollicis longus and extensor pollicis brevis muscles. Repetitive movements of the thumb and loading of the involved tendons are thought to be causative factors. The meta-analysis conducted by Stahl et al⁵⁷ found 2.89 (95% CI 1.4-5.97) increased odds of developing DeQuervain tenosynovitis with repetitive, forceful, or ergonomically stressful manual work. It is also a common condition in new mothers that seems to be related to lifting a newborn or toddler child and in people who do needle work, use a computer mouse, and in phlebotomists. Pain along the thumb that increases with activity or lifting with the forearms in a neutral position is typical in people with DeQuervain tenosynovitis.

Intersection syndrome refers to tendonitis at the intersection site where the abductor pollicis longus and extensor pollicis brevis muscles cross over the extensor carpi radialis longus and brevis tendons in the distal radial forearm.⁵⁸ Hypertrophy of the abductor pollicis longus and extensor pollicis brevis muscles at the dorsal distal forearm can be often visually appreciated. Extensor pollicis longus tendon irritation can occur where the tendon is redirected at Lister tubercle on the distal radius. Attenuation and eventually rupture of the extensor pollicis longus tendon is known to occur in subjects with rheumatoid arthritis. The onset of each of these tendinopathies at the radial wrist is associated with repetitive thumb and/or wrist movements.

The most common nontraumatic joint pathologies causing radial wrist pain include CMCJ or metacarpal phalangeal (MCP) joint osteoarthritis of the thumb and development of a dorsal wrist ganglion. As in other osteoarthritic conditions, the onset typically occurs in middle-aged adults and may have a genetic component, or it may be associated with previous trauma to the joint. Osteoarthritis in any joint of the hand is characterized by pain, stiffness, and deformity. In the thumb CMCJ, a visible bump represents the dorsal subluxation of the 1st metacarpal on the trapezium. Nodules can also develop in the finger joints causing generalized hand pain: the proximal interphalangeal (PIP) joint nodules are referred to as Bouchard nodes and those at the distal interphalangeal (IP) joint are called Heberden nodes. Activities including opening jars, turning keys, and writing are often reported to be painful in patients with CMCJ or hand arthritis.

Ganglion cysts are fluid-filled lumps that occur commonly at the dorsal wrist and

sometimes the fingers.⁵⁹ The cause of ganglion cysts is unknown, although they seem to occur in subjects who use the wrist in repetitively or in extreme positions and may be associated with tendon or joint irritation or mechanical changes. They occur in patients of all ages, genders, and ethnic backgrounds. Ganglion cysts vary in size, location, and may or not cause pain. They may cause sensory disturbance if located in the region of a nerve. A common site for ganglion cyst formation is at the scapholunate joint and therefore can be the cause of radial wrist/thumb pain. Ganglions can also form at other joints and can therefore be the cause of pain anywhere in the hand depending on its location. Because ganglion cysts are known to resolve naturally in time with no intervention, many times no treatment is offered. If the ganglion cyst is causing symptoms of pain, loss of motion, or causing nerve compression, the cyst can be aspirated or surgically removed.

Irritation of the radial nerve can also cause radial wrist/thumb pain. Wartenburg syndrome is a radial nerve irritation at wrist level where the superficial branch of the radial nerve emerges between the brachioradialis and extensor carpi radialis longus tendons. Pronation of the forearm causes these two tendons to come together and compress the radial nerve. Repetitive pronation and supination may cause irritation at this site secondary to the creation of a scissoring effect between the brachioradialis and extensor carpi radialis longus muscles. Blunt local trauma, a wrist watch applied too tightly, or a surgical incision in the region can also cause the nerve irritation. The annual incidence rate for Wartenburg syndrome is 0.003%.³⁸ This condition may affect cutaneous sensation to the radial thenar area and the dorsal hand and wrist and can cause extreme hypersensitivity in the cutaneous nerve distribution including the dorsum of the 1st and 2nd metacarpals. In some cases, pain may extend proximally and radially into the forearm and is typically described as sharp and shooting.

8.2. Initial Evaluation of Patients With Radial Wrist/Thumb Pain

A detailed history is imperative to allow the clinician to obtain as much information as possible regarding the causes of the patient's symptoms. Information must be gathered regarding the physical demands and postural requirements of the patient at work, at home, and at play. In addition, what activities exacerbate and relieve the symptoms must be noted. This knowledge will be critical for the recommendation and implementation of activity modifications.

Patients with DeQuervain tenosynovitis and intersection syndrome will report no sensory deficits, and Tinel test will be negative in both conditions. Pain reports are local to the anatomic snuffbox and thumb in DeQuervain tenosynovitis and are located in the distal third of the dorsal forearm (approximately 4-6 cm proximal to the first dorsal compartment) in intersection syndrome. Application of resistance to the affected tendons will aggravate the pain; abductor pollicis longus and extensor pollicis brevis–resisted testing may produce pain in both conditions, but resisted wrist extension is typically painful in intersection syndrome as well. Crepitus is often palpated at the intersection site with wrist range of motion, and swelling in the area may be visible; these findings are absent in

DeQuervain tenosynovitis. Finkelstein test is a highly sensitive test that results in many positive, including false-positive, results. It can be positive in patients with intersection syndrome, but pain is usually located over the intersection site. If Finkelstein test is negative, it is likely that the patient does not have DeQuervain tenosynovitis.⁶⁰

The evaluation of patients with CMCJ arthritis should include a close visual inspection of the region. The appearance of the thumb is distinct because of the arthritic changes, but may not be fully appreciated in early stages. Dorsal subluxation of the 1st metacarpal on the trapezium is evident as a dorsal bump at the base of the thumb. In advanced cases, a thumb CMCJ adduction contracture and MCP joint extension contracture can develop. Sensory deficits are not typical, but pain can be elicited with palpation directly of the CMCJ and with resisted or sustained pinch activities that compound the dorsally directed forces of the 1st metacarpal on the trapezium. Other resisted tests may be variably uncomfortable but not associated with specific tendon loading. Tinel tests over regional nerves are typically negative. Approximation and rotation of the 1st metacarpal on the trapezium through the grind test may elicit pain, especially earlier in the disease process, and joint surface changes may be appreciated as crepitus type sensation by the clinician.

Visual inspection is also an important component when a ganglion cyst is suspected. A visible discrete bump located at the dorsal wrist is the most typical presentation. Although palpation may reveal a soft fluid or gel filled nodule that becomes more noticeable with wrist flexion, the presentation of ganglion cysts is quite variable in the hand. Referral to a hand specialist is recommended for definitive medical treatment if it is highly symptomatic.

As it has been previously mentioned, a screen of the cervical spine is necessary for all patients who are thought to have a peripheral nerve compression, because of the potential of a multiple neuropathy syndrome along the nerve segment or referred pain from a cervical radiculopathy. A proximal origin of symptoms should be suspected if pain is radiating into the chest wall or posteriorly along the medial border of the scapula. A cervical radiculopathy or radicular pain may present if symptoms increase with a Valsalva maneuver, coughing, or sneezing. The examination may include the assessment of motor weakness in the C6 distribution (elbow flexion or wrist extension) or C7 distribution (elbow extension, finger extension, and flexion).

The examination of patients with Wartenburg syndrome will demonstrate symptoms consistent with an isolated neuritis of the superficial radial nerve including loss of cutaneous sensation to the radial thenar area and the dorsal hand and wrist, and it is often associated with extreme hypersensitivity including the dorsum of the 1st and 2nd metacarpals. Range of motion and strength are typically intact, although movements of the forearm or wrist may aggravate pain. Provocative tests for Wartenburg syndrome will produce tingling or an “electric” type pain along the course of the superficial radial nerve when positive including the Tinel test over the superficial radial nerve. Placing the proximal portions of the superficial radial nerve in a stretched position (extended elbow, pronated forearm, and ulnarly deviated wrist) will likely increase symptoms as will the Finkelstein position, because the simultaneous thumb flexion and wrist ulnar deviation places the distal portion of the superficial radial nerve on stretch.

8.3. Trigger Points and Radial Wrist and Thumb Pain

The role of forearm musculature in radial wrist and thumb pain may be lower than in other pain syndromes of the forearm. Obviously, tension induced by taut bands resulting from TrPs in these muscles could lead to an increased load in the respective tendon and therefore be a contributing or perpetuating factor for the pain symptoms. There is no study investing this topic.⁶¹

9. ULNAR WRIST PAIN

9.1. Overview

The presence of symptoms in the ulnar area of the wrist may be primarily associated with local tendinopathy (FCU or extensor carpi ulnaris tendinopathy), joint pathology (triangular fibrocartilage complex [TFCC] degeneration, distal radial ulnar joint instability, or ulnar impaction syndrome), or local nerve compression (Guyon tunnel syndrome).

Pain at the ulnar aspect of the wrist can be challenging to diagnose because of the multiple interrelated anatomic structures on the ulnar side that contribute to wrist joint stability as well as to its mobility and are required to place the hand in numerous positions for function.⁶² There are multiple causes of ulnar wrist pain that all have similar symptoms.⁶³ Activities that require repeated forearm rotation, radial/ulnar deviation of the wrist, and/or sudden impact involving the forearm, wrist, or hand can result in overload of the ulnar wrist structures and may result in ulnar wrist injury and pain. It is common in athletes such as golfers, baseball players, lacrosse players, and many others who use equipment to aggressively impact or throw a ball or puck.⁶⁴ Gymnasts and weight lifters who bear high loads of weight on the wrist are also susceptible to ulnar-sided wrist injuries. Occupations that have similar force requirements can also result in workers who sustain ulnar-sided wrist injury and subsequent pain.

It is the intricate connections between the tendons, ligaments, and joints at the ulnar wrist that make it difficult to differentiate involved tissues in patients with ulnar-sided wrist pain. The TFCC is an arrangement of ligamentous and cartilaginous tissue at the ulnar wrist joint that acts as a cushion in the space between the ulna and ulnar carpal bones preventing ulnocarpal abutment. This complex acts as a major stabilizing structure for the distal radioulnar joint. It distributes loads at the ulnar wrist and contributes to the complex, fine movements of the wrist and forearm. The TFCC consists of the articular disc structures, UCL, dorsal and palmar radioulnar ligaments, floor of extensor carpi ulnaris sub-sheath, and the ulnolunate and ulnotriquetral ligaments.⁵¹ These structures provide anatomic links connecting the joint structures to the stabilizing ligaments and to the movers of the joint through the tendons. Injury to one of these structures can impact the function of the other structures.

In patients with suspected tendon pathology, extensor carpi ulnaris irritation or subluxation is more common and potentially problematic than irritation to the FCU

muscle.⁶² Injury to the extensor carpi ulnaris complex is common in elite male (76%) over female tennis players (45%) as well as other elite athletes.⁶⁵ The location of the extensor carpi ulnaris tendon within the sixth dorsal compartment of the wrist is recognized as the second most common location of stenosing tenosynovitis. The spectrum of extensor carpi ulnaris injury ranges from a painful tenosynovitis, subluxation of the extensor carpi ulnaris with corresponding irritation to the tendon, to complete rupture of the extensor carpi ulnaris tendon.⁶⁵ Dynamic instability of the extensor carpi ulnaris tendon is associated with a shallow ulna groove, a weakened sheath due to repetitive impact, or an acute injury. Subluxation will not present in static situations; therefore, it is important to palpate the tendon for shifting during forearm rotation.⁶⁵

If joint or ligamentous pathology is suspected, a TFCC tear should be ruled out as a potential source of pathology. In the absence of a traumatic incident, this ulnar stabilizing complex may have been exposed to stresses over time causing degenerative changes to the TFCC complex. Compressive loading of the TFCC or repetitive forearm rotation stresses can result in TFCC injury and is a cause of ulnar wrist pain, and in severe cases, instability of the distal radial ulnar joint.⁶⁴

Normally, the TFCC absorbs approximately 20% of compressive loads of the wrist, with the radiocarpal joint taking the rest of the load.⁶⁴ However, alterations in ulnar variance, referring to the relative position of the articular surfaces of the radius and ulna at the wrist, will change this load distribution. A positive ulnar variance refers to a situation where the ulna projects more distally than normal. Ulnar impaction syndrome may result in positive ulnar variance leading to excessive loads on the ulnar aspect of the wrist and the TFCC. Over time, the excessive ulnar forces can lead to TFCC degeneration and tears. Ulnar impaction syndrome most commonly presents in middle-aged patients and may be associated with a previous wrist or forearm fracture or simply repetitive use in a person whose normal wrist architecture presents with positive ulnar variance. Conversely, Kienbock disease is associated with negative ulnar variance and excessive loading of the radius on the carpus, and results in avascular necrosis of the lunate and in mid-dorsal wrist pain. Local pain with palpation directly over the lunate and wrist radiographs can confirm the diagnosis. The etiology of Kienbock disease is unknown.

Guyon tunnel syndrome is a neuropathy of the ulnar nerve at the wrist level that causes ulnar-sided symptoms at the wrist and hand. It is associated with either external compression (handlebar palsy in cyclists, using the hand as a hammer) or a space-occupying lesion (ulnar artery thrombosis, ganglion). It can be easily confused with cubital tunnel syndrome and should also be differentiated from thoracic outlet syndrome and cervical radiculopathy affecting the C8/T1 segments.

9.2. Initial Evaluation of Patients With Ulnar Wrist Pain

When evaluating a patient with tendinopathy, resisted or muscle length testing will reproduce pain in the involved tendon in either the extensor carpi ulnaris or FCU muscles. Palpation along the distal portion of the tendon will also elicit pain. Range of motion will

typically demonstrate no restrictions; however, the dorsal ulnar wrist should be palpated and visualized during forearm rotation to identify subluxation of the extensor carpi ulnaris tendon. A painful snapping or clicking sensation over the dorsoulnar side of the wrist is a typical finding in a patient who has an unstable extensor carpi ulnaris tendon. The extensor carpi ulnaris synergy test is positive if bowstringing is visible and/or pain is replicated when the patient radially abducts the thumb against resistance with the forearm in supination and wrist in neutral (causing a synergistic co-contraction of the extensor carpi ulnaris muscle).⁶⁶

The FCU muscle has no tendon sheath and is not physically attached to the TFCC and is therefore more straightforward to evaluate its contribution to ulnar wrist pain.⁶² Range of motion and sensation are typically without restriction in FCU tendinopathy. Contractile unit testing in wrist flexion and ulnar deviation and sometimes palpation will result in volar ulnar wrist pain approximately 3 cm proximal to the pisiform along the FCU tendon.⁶²

A click or pop may also be noticeable with forearm rotation in patients with TFCC injury, although joint motion is typically full. Visual inspection will often reveal a more prominent ulnar styloid compared with the uninvolved extremity. Pain or distal radioulnar joint instability may be detected with special tests. The ulnomeniscotriquetral dorsal glide test (piano key test) may reveal distal radioulnar joint instability because of a TFCC tear. Testing in various degrees of pronation and supination may elicit pain, tenderness, and increased mobility compared with the contralateral side, and all may suggest distal radioulnar joint injury/instability.⁶⁷ Tenderness with palpation immediately distal to the distal radioulnar joint and between the head of the ulna and triquetrum may indicate a TFCC problem or an ulnocarpal abutment. The TFCC can also be loaded axially while ulnarly deviating the wrist and moving the wrist into flexion and extension. Any crepitus and/or reproduction of symptoms may indicate a TFCC tear or ulnocarpal abutment or impaction.²⁸ Forearm pronation or ulnar deviation of the wrist effectively increases positive ulnar variance; therefore, grip testing in a pronated position compared with a supinated position will accentuate symptoms when ulnar impaction and/or TFCC injury is present.

Sensory examination helps differentiate neural compression that may be contributing to ulnar-sided wrist pain. In local ulnar nerve compression, referred to as “Guyon tunnel syndrome,” sensation on the volar ulnar aspect of the hand is affected, but the dorsoulnar hand sensation is spared. If the compression is more proximal, as in cubital tunnel syndrome, dorsoulnar hand sensation deficits will be apparent. Symptoms of Guyon syndrome include pain along the ulnar side of palm as well as the fourth and fifth digits, sensation deficits in the same distribution, and weakness of the ulnar innervated intrinsic muscles. Muscle testing will reveal compression of superficial branch leading to possible weakness/atrophy of the hypothenar muscle group, most notably the first dorsal interosseous muscles and the third/fourth lumbrical muscles. In advanced cases, complete paralysis will present as a clawed hand in the fourth and fifth digits. Compression of the deep branch of the ulnar nerve is more common in chronic compression and may also lead to weakness of the flexor pollicis brevis and adductor pollicis muscles. Motor involvement will grossly impact grip and pinch strength of the hand; therefore, weakness in both may be detected. Froment sign may be positive. With attempts to perform lateral pinch against

resistance, the IP joint of the thumb flexes, indicating weakness of the abductor pollicis muscle and the deep head of the flexor pollicis brevis muscle. Wartenberg sign may be seen where the fifth digit is held in an abducted position from the fourth digit secondary to weakness of the volar interosseous muscle. These tests may also be positive in cubital tunnel syndrome; therefore, location of pain, Tinel test, and sensory examination may be helpful in differentiating the location of ulnar nerve compression. In cubital tunnel syndrome, motor weakness to the FCU muscle and the flexor digitorum profundus muscle to the fourth and fifth digit may be present and can result in less of a clawed position of the ulnar digits secondary to lack of strength in the flexor digitorum profundus muscle which is no longer pulling unopposed to the lumbrical muscles.⁶⁸ The examination should also include differential tests to rule out the cervical spine (C8, T1) or thoracic outlet as being the cause of ulnar nerve symptoms. Tinel and Phalen tests at the wrist will often times be positive over the ulnar nerve at the wrist in Guyon tunnel syndrome, but is negative in the more proximal nerve compressions.

9.3. Trigger Points and Ulnar Wrist Pain

The role of forearm musculature in ulnar wrist pain may be lower than in other pain syndromes of the forearm. Again, tension induced by TrP taut bands in these muscles could lead to an increased load in the respective tendon and therefore becomes a contributing or perpetuating factor for the pain symptoms. Experimentally induced pain through saline injections in the extensor carpi ulnaris muscle results in pain spreading distally on the ulnar side of the forearm toward the hand, although no changes in motor activity are found when mechanical circumstances remain the same.⁶⁹ Because of the complexity of the anatomy and differential diagnosis at the ulnar wrist, examining TrPs in the extensor carpi ulnaris or FCU muscles should not be neglected.

10. CARPAL TUNNEL SYNDROME

10.1. Overview

CTS is a compression of the median nerve at the wrist under the transverse carpal ligament, which extends from the tuberosity of the scaphoid and part of trapezium to the pisiform and hook of the hamate. It is the most common nerve compression syndrome in the upper extremity and is characterized by pain and paresthesia in the median nerve distribution of the hand usually including the thumb, index finger, middle finger, and radial aspect of the ring finger. Dale et al⁷⁰ pooled the epidemiologic data of CTS and reported an overall prevalence rate of 7.8% and an incidence rate of 2.3/100 persons/year. Symptoms increase with repetitive hand or wrist movements. Patients report clumsiness and weakness in the hand. Paresthesia and pain tend to be worse at night. Some studies have observed that patients with CTS also exhibit symptoms throughout the upper extremity.⁷¹

The underlying causes of CTS are highly variable, but are associated with several conditions that cause increased pressure within the carpal tunnel, including pregnancy or

thyroid disorders that may cause fluid retention. Repetitive movements of the wrist and/or fingers or use of the wrist in extreme positions can cause swelling around the wrist flexor muscle tendons, referred to as tenosynovitis, which imparts increased pressure in the carpal tunnel. Trauma resulting in carpal joint dislocations, fractures in the region, or arthritic conditions can increase pressure in the canal resulting in symptoms of CTS.^{72,73}

Potential compression sites of the median nerve include those at the ligament of Struthers (a ligament that links the supracondylar ridge and medial epicondyle of the humerus) in the distal arm, under the lacertus fibrosus of the biceps brachii tendon (if present), where the median nerve passes between the aponeurotic arch linking the humeral and ulnar heads of the pronator teres, and where it travels under the arch of the flexor digitorum superficialis muscle between the radial and humeral heads of that muscle.⁵¹

Management of CTS is still controversial because some authors propose a conservative approach, whereas others suggest surgery. It is interesting to note that conservative treatments applied just locally to the carpal tunnel have shown limited results.^{74,75} Similarly, outcomes are not clearly different between conservative and surgical treatments. Current theories propose that treatment of patients with CTS should include soft-tissue treatment of those areas anatomically related to the median nerve, ie, muscles, and neural mobilization interventions, suggesting a role for TrPs.

10.2. Initial Evaluation of a Patient With Carpal Tunnel Syndrome

Reports of transient symptoms as well as nocturnal pain and paresthesia within the hand are extremely common in patients with CTS; therefore, an assessment of the behavior of symptoms should be obtained. The gold standard for a diagnosis of CTS is the following clinical presentation: paresthesia, pain, swelling, weakness, or clumsiness of the hand provoked or worsened by sleep, sustained hand or arm positions, repetitive action of the hand or wrist that is mitigated by changing postures or by shaking of the hand, sensory deficits in the median-innervated region of the hand, and motor deficit or hypotrophy of the median-innervated thenar muscles. Provocative tests may replicate patient's symptoms or cause a tingling or "electric" type pain along the course of the median nerve when positive. Phalen test, reverse Phalen test, Tinel test, carpal compression test, and neurodynamic testing have been studied for their diagnostic utility and have shown variable results; however, the majority of tests demonstrate positive and negative likelihood ratios close to one and/or nonsignificant results, indicating that none of these tests alone are particularly consistently useful in confirming the diagnosis of CTS. The presence of clusters of factors improves the diagnostic accuracy of CTS. The presence of four of the following factors increases the probability of having CTS by over four times (+LR = 4.6): shaking hands for symptom relief, wrist-ratio index greater than 0.67, symptom severity scale score > 1.9 points, reduced median sensory field of the first digit, and age greater than 45 years.³⁶

Another gold standard for the confirmation of CTS diagnosis is the EMG. In fact, some studies have identified the relationship between the distribution of sensory pain

symptoms and the severity of CTS, according to the neurophysiologic classification. Patients with lower severity of pathology report sensory symptoms with a glove distribution, whereas patients with a higher severity of pathology report sensory symptoms with the “classical” median distribution, suggesting that affectation of the median nerve depends on its compression. Sensitivity testing reveals reduced light touch, pain, and temperature detection in the distal median nerve distribution. The palmar cutaneous branch of the median nerve distribution at the palm of the hand will demonstrate intact sensation in CTS but may be impaired in more proximal nerve compressions. Two-point discrimination tests (sensor receptor density) may be normal in CTS; therefore, the more sensitive Semmes Weinstein Monofilament test (threshold sensory examination) is preferred when attempting to detect sensory changes in CTS. Stress testing along with, before, and after volumetric and sensory measurements can objectify increases in hand volume and sensory changes after provoking activities.

Motor dysfunction may be noted in severe or more chronic cases; weakness and atrophy may be present in the median-innervated musculature including the abductor pollicis brevis, opponens pollicis, and first and second lumbrical muscles. Grip and pinch strength may be reduced secondary to weakness of these intrinsic muscles.

Cervical radicular pain or radiculopathy involving the C6 and C7 nerve roots may mimic CTS symptoms including mild to moderate aching in the forearm, and if symptoms are associated with neck or shoulder pain, one should suspect more proximal compression at the level of the pronator teres, cervical spine, or a multiple neuropathy syndrome at either of those locations. Therefore, examination of the cervical spine should be included in CTS.

Finally, clinicians should examine all muscles anatomically related to the median nerve for TrPs, particularly the scalene, pectoralis minor, biceps brachii, pronator teres, flexor digitorum, and lumbrical muscles.

10.3. Trigger Points and Carpal Tunnel Syndrome

Chapter 38 outlines the association of TrPs in the pronator teres muscle with symptoms of CTS. Cervical radicular pain or radiculopathy involving the C6 or C7 nerve roots is known to appear symptomatically similar to CTS, but symptoms may be aggravated by TrPs in muscles innervated by the affected nerve root. Active TrPs in infraspinatus or upper trapezius muscles proximally and in the pronator teres, flexor carpi radialis, palmaris longus, and/or biceps brachii muscles are potential sources of referred pain that cause symptoms that can be confused with CTS or other conditions causing radial hand pain. Qerama et al⁷⁶ found that one-third of patients referred with clinical symptoms compatible with CTS, but EMG negative, exhibited active TrPs in the infraspinatus muscle reproducing their symptoms. Nevertheless, local neuropathy of the median nerve could also activate TrPs. In such scenarios, Azadeh et al⁷⁷ observed that 70% of patients with clinical and electrophysiologic evidence of CTS showed TrPs in the upper trapezius muscle, probably related to nerve irritation. Therefore, an assessment of upper extremity muscles

for the presence of TrPs is imperative in the differential diagnosis of CTS.

11. OTHER CAUSES OF HAND PAIN

11.1. Overview

Other causes of symptoms in the hand may be associated with Dupuytren contracture or trigger finger (stenosing tenosynovitis of the flexor tendons). Dupuytren contracture is an abnormal thickening of the tissue just beneath the skin. This thickening occurs in the palm and can extend into the fingers. Firm pits, bumps, and firm cords can develop in the palm, and occasionally at the dorsal PIP joints, resulting in flexion contractures of the fingers, primarily at the MCP and PIP joints. The cause of Dupuytren contracture is unknown. This condition is more common in men, people over age 40, and people of Caucasian/European descent.⁷⁸ There is no evidence that hand injuries or specific jobs lead to a higher risk of developing Dupuytren contracture. In the case of Dupuytren, dimpling over the palmar crease on the ulnar side of the hand is evident along with digital flexion contractures, most typically involving the MCP and PIP joints of the ring or little finger. Palpation of the palm in early development of Dupuytren contracture reveals discretely tender nodules and patient reports of diffuse palmar tenderness.⁷⁹ The presence of digital flexion contractures, discrete nodules, and diffuse tenderness are typical findings of Dupuytren contracture. Estimations of the prevalence of the disease vary considerably, depending on where monitoring occurs, as it is more common in Europe.⁷⁸

Although uncomfortable in some people, Dupuytren contracture is not typically painful. As the fingers contract into the palm, it may be more difficult to wash hands, wear gloves, shake hands, and get hands into pockets. It is difficult to predict how the disease will progress. Some people have only small lumps or cords, whereas others will develop severe contractures.

Trigger finger is a stenosing tenosynovitis of the flexor tendons at the fingers or thumb. Changes, including thickening or a nodule formation, around the digital pulley system or to the flexor tendons cause snapping or locking of the finger in a flexed position, both of which can cause pain in some patients. The prevalence of trigger digit is 2% to 3% in the general population. Its etiology is unknown, but individuals with diabetes or rheumatoid arthritis have a much higher prevalence of the condition compared with the general population.⁸⁰ Repeated use of the hand seems to be associated with symptoms. Patients typically present with a painful nodule at the volar MCP corresponding with the level of the A1 pulley and a noticeable catching or locking of the finger with active flexion or extension. In severe cases, the finger can become locked in a flexed position and may resemble and ultimately result in a PIP joint flexion contracture. It can interfere with most activities that require grasping.⁸⁰ A concern is that repeated triggering of the tendon can result in tendon fraying and ultimately tendon rupture over time; therefore, proper and early management is important.

11.2. Initial Evaluation of a Patient With Hand Pain

Visual observations for deformity such as nodules, cords, or joint contractures at the hand can help differentiate some local causes of hand pain. Enlargement of joints or node formation at the joints, as described for radial hand pain previously, can implicate an arthritic condition; in osteoarthritis, these changes often occur at the IP joints of the fingers or at the CMC joint of the thumb. Nodules at the dorsal PIP joints, thick cord formations in the palm, dimpling of the skin in the palm, and flexion contractures of the MCPs and proximal phalangeal joints are consistent with Dupuytren contracture. Range-of-motion assessment will often reveal specific deficits. End-range motion deficits may be noted in osteoarthritic hands, and if it affects the CMC joint of the thumb, passive adduction and flexion contracture may be noted in advanced cases. Patients with Dupuytren contracture demonstrate incomplete digit extension, both passively and actively. Attempts to passively extend the affected fingers will be met with unyielding resistance, and the tight cords in the palm may be more visible. Patients with Dupuytren contracture may present with symptoms that could be confused with active TrPs in the palmaris longus muscle.

Active motion assessment in patients with trigger finger will reveal the characteristic triggering with flexion and extension. In advanced cases, the finger may get stuck in flexion, unable to extend without an external passive force applied by the patient or clinician. Passive motion is generally full with trigger finger. Strength will be variably affected in each of these conditions, depending on symptom severity.

11.3. Trigger Points and Hand Pain

Intrinsic muscles of the hand can develop TrPs that cause pain and replicate symptoms of common hand diagnoses. Chapter 39 overviews TrPs in the adductor and opponens pollicis muscles mimicking pain conditions, such as trigger thumb, CMCJ arthritis, CTS, and DeQuervain tenosynovitis. The symptoms may be aggravated with gross grasping activities or using the thumbs for smart phone use and texting. As adduction contractures form in advanced stages of CMCJ arthritis, self-release techniques and stretching will help alleviate associated TrPs and may slow or halt the progression of contracture development at the thumb index web space. The interosseous, lumbrical, and hypothenar muscles may emulate arthritic conditions in the hand. Following trauma or after conditions that result in considerable swelling in the hand, it is important to assess the intrinsic musculature. Tightness and local TrPs may cause difficulty in making a full fist and may lead to generalized or local hand pain, depending on the extent the intrinsic muscles are involved. Being such small muscles, they are often disregarded once swelling has subsided. Yet, intrinsic muscles can become adaptively shortened and result in an inability to make a complete fist.

Trigger points in the flexor pollicis longus, flexor digitorum superficialis, or flexor digitorum profundus muscles may result in pain reports similar to trigger finger or an arthritic condition in the corresponding digit. Trigger points in the palmaris longus muscle can result in volar hand pain that may associated with the fascial changes corresponding

with Dupuytren contracture, as outlined in Chapter 37.

Section 5

Trunk and Pelvis Pain

Pectoralis Major and Subclavius Muscles

“Chest and Shoulder Nuisance”

Joseph M. Donnelly and Deanna Hortman Camilo

1. INTRODUCTION

The pectoralis major muscle is a broad, multipennate muscle comprising of two distinct divisions. Its unique shape and large size allow the pectoralis major muscle to have an influence on three different joints in the upper quarter (sternoclavicular, acromioclavicular, and glenohumeral joints) in addition to participating in the gliding movement of the scapula over the ribs. Both divisions may act separately to achieve different glenohumeral joint motions, but the primary role of the pectoralis major muscle as a whole is to adduct and internally rotate the humerus. Trigger points (TrPs) within the pectoralis major muscle will generate referred pain over the anterior deltoid muscle, the chest region, and the medial aspect of the arm. Pain from pectoralis major TrPs may also extend toward the volar aspect of the forearm and ulnar side of the hand, including the last two or two-and-a-half digits. Symptoms may be exacerbated by rounded shoulder posture, heavy lifting, overhead sporting activities, weight training, and sustained lifting in a fixed position. Differential diagnosis should include pectoralis major muscle tear, angina pectoris, medial and lateral epicondylalgia, C5-C6 and C7-C8 radicular symptoms, and thoracic outlet syndrome (TOS). Corrective actions to prevent perpetuation and/or recurrence of pectoralis major TrPs should include techniques to address postural imbalances, work place ergonomics, and sleeping positions, as well as self-pressure release and self-stretching.

The subclavius is a small muscle that lies between the clavicle and first rib and indirectly assists in protraction of the shoulder. TrPs within the subclavius muscle commonly refer pain ipsilaterally into the anterior aspect of the shoulder area and arm, extending to the radial side of the forearm and hand. Differential diagnosis for subclavius TrPs should include vascular TOS. Access to this muscle is limited; therefore, indirect treatments can be used for management of TrPs in this muscle.

2. ANATOMIC CONSIDERATIONS

Pectoralis Major

The pectoralis major muscle is a multipennate fan-shaped muscle commonly described as having clavicular, sternal, costal, and abdominal heads with a complex morphologic arrangement. The most superior division of the pectoralis major muscle, the clavicular head, originates from the sternal half of the clavicle.^{1,2} The sternal head has been described as consisting of six to seven muscle segments³; other researchers have found as few as two segments.⁴ Regardless of the number of segments, muscle fibers that comprise the sternal head originate from the manubrium, the sternum, the costal cartilage of the upper six ribs, and the external oblique aponeurosis (abdominal head) (Figure 42-1). The clavicular and sternal heads come to form a bilaminar flat tendon, approximately 5 cm wide, and travel laterally to insert into the lateral lip of the intertubercular groove of the humerus and the glenohumeral joint capsule.^{1-3,5} The tendon comprises a thicker anterior tendon lamina and a posterior tendon lamina.¹⁻⁴ The anterior tendon lamina is composed of the entire clavicular head, fibers from the manubrium, and the upper segments of the sternal head (second to fifth costal cartilage). The most inferior segments of the sternal head and fibers from the aponeurosis of the external oblique (abdominal head) create the posterior tendon lamina.¹⁻⁴

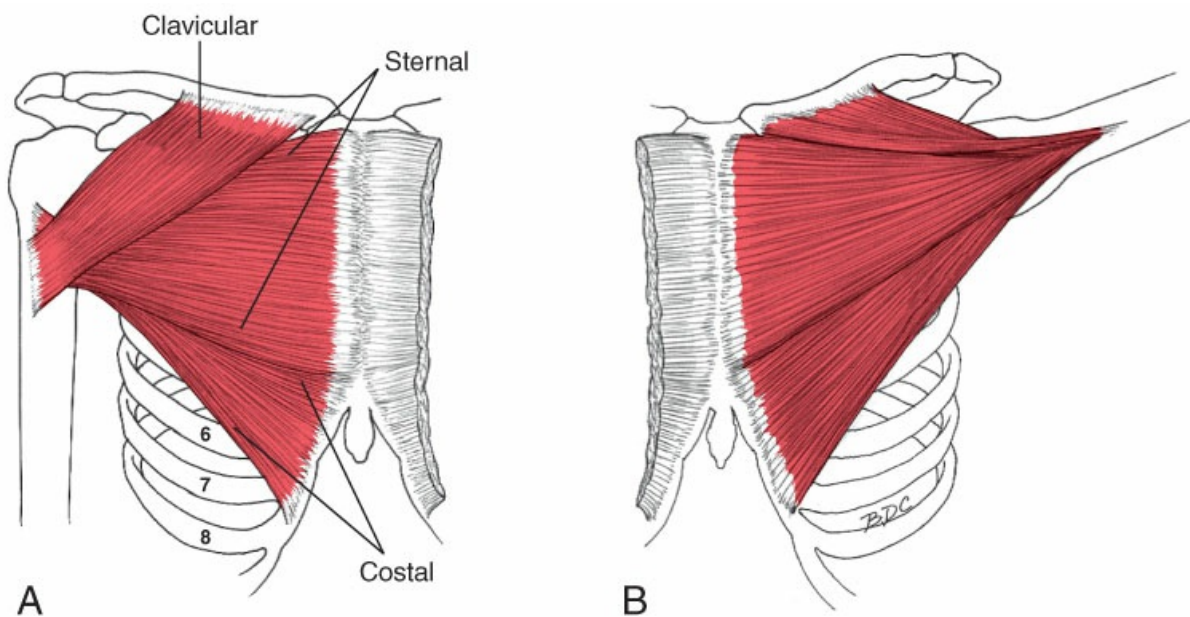

Figure 42-1. Attachments of the pectoralis major muscle (red), anterior (ventral) view. A, Fibers of the uppermost clavicular section overlap fibers of the sternal section to form part of the ventral layer at the humeral attachment. B, Costal fibers curl around the lateral border (anterior axillary fold) to form most of the dorsal layer at the humerus.

Petillon et al¹ described the fibers from the sternal and clavicular heads as rotating or folding around each other before insertion so that the clavicular head inserts anteriorly and inferiorly to the sternal head. The abdominal head of the muscle originates from the lower

ribs and abdominal (external oblique) fascia and twists upon itself as it courses to insert on the lateral lip of the intertubercular groove of the humerus. The lowest fibers of this portion insert most superiorly on the humerus and the uppermost fibers insert most inferiorly on the humerus.⁵ In addition, there is a fascial expansion from this tendon referred to as the falciform ligament, which encases the tendon of the long head of the biceps brachii muscle. This ligamentous expansion attaches to both the lateral and medial lips of the intertubercular groove of the humerus, which aids to stabilize both the tendon of the long head of the biceps brachii muscle and glenohumeral joint capsule.⁵

Ashley⁶ further illustrates the anatomic complexity of the pectoralis major muscle; he dissected 60 adult cadavers and presented schematics of his findings. The arrangement of most of the pectoralis major fibers can be clearly seen from the dorsal (under) side of the muscle, a view not found in most anatomy texts. Ashley's drawings were followed closely in the preparation of Figure 42-2, which is a semi-schematic presentation of the muscle's fiber arrangement. However, terminology has been modified to clarify the description.

Figure 42-2. Semi-schematic drawings of the fiber arrangement in the pectoralis major

muscle. A, Usual ventral view. B, Ventral view with the superficial dorsal-layer fibers retracted to show the seldom seen deep lamina of the ventral layer (light red). C, Muscle reflected laterally to show the seldom seen dorsal aspect that reveals the playing card arrangement of the deep lamina of the ventral layer. The dorsal layer (dark red) swings around the other fibers to attach on the humerus dorsal to them. Adapted from Ashley GT. The manner of insertion of the pectoralis major muscle in man. *Anat Rec.* 1952;113:301-307.

Ashley⁶ found that the tendinous pectoralis major muscle insertion to the humerus has two layers (Figure 42-2), each one made up of laminae as noted previously. The ventral layer (named by its attachment at the humerus) was previously described by Eisler as early as 1921 and is composed of six or more overlapping laminae splayed in the manner of playing cards. These six laminae attach medially to the clavicle, sternum, and ribs. The lower sternal and costal laminae of this ventral (superficial) layer at the humerus attach medially as underlying, but unfolded, deep fibers.

As seen from the usual anterior view, however, these deep lower laminae are hidden by a more superficial lamina of lower sternal, costal, and abdominal fibers that wrap or fold around the caudal end of the deeper laminae to attach on the humerus and to comprise most, if not all, of the dorsal (deep) layer at that location. The folded arrangement reverses the order of attachment of these fibers. They wrap around an unfolded lamina that usually attaches to the sixth rib, and sometimes to the fifth and seventh ribs.⁶

The semi-schematic version of the usual anterior view of the undisturbed pectoralis major muscle (Figure 42-2A) clearly shows the first two overlapping laminae of the ventral layer that are the fibers of the clavicular section and the manubrial portion of the sternal head. The remaining sternal, costal, and abdominal fibers visible in Figure 42-2A are superficial at their medial attachments but fold under the ventral layer fibers to form the bulk of the dorsal layer at their insertion into the humerus.

A glimpse of the remaining lamina of the ventral layer at the humerus is revealed in Figure 42-2B by retraction of the folded lamina. These remaining laminae are clearly seen in the reflected dorsal view of the fibers in Figure 42-2C. The ventral layer fibers attach medially to the sternum and ribs, deep to the more superficial folded lamina. Because of this arrangement, the lowermost medial fibers have the most proximal attachment to the humerus and uppermost fibers have the most distal attachment as previously noted. Standring² has also described this anatomic arrangement (Figure 42-2A to C).

Knowledge of this arrangement is important to interpret accurately the direction of the fibers palpated for TrPs and the direction of contraction when a local twitch response is elicited. Each lamina very likely has its own nerve branch and mid-fiber endplate zone.

Subclavius

The subclavius muscle is a long triangular muscle that lies beneath the clavicle over the first rib (see Figure 42-5A). It originates on the junction of the first rib with its costal cartilage

and inserts onto a groove on the underside of the middle third of the clavicle just anterior to the costoclavicular ligament.² The subclavius muscle may also independently or additionally insert into the coracoid process or the superior portion of the scapula.² The subclavius muscle is separated from the first rib posteriorly by a neurovascular bundle comprising the subclavian vessels and brachial plexus.² Anteriorly, it is separated from the pectoralis major muscle by the clavipectoral fascia.²

2.1. Innervation/Vascularization

Pectoralis Major

The medial and lateral pectoral nerves innervate the pectoralis major muscle.² The lateral pectoral nerve arises from the spinal nerves C5 through C7.² This nerve branches from, or just above, the lateral cord of the brachial plexus to supply the clavicular and sternal sections of the pectoralis major muscle.²

The medial pectoral nerve arises from spinal nerves C8 and T1 and passes via the medial cord of the brachial plexus to supply the lateral and inferior portions of the sternal head.^{1,2,4} This nerve may skirt the lateral border of, but usually pierces, the pectoralis minor muscle that it supplies en route to the pectoralis major muscle.²

The innervation of the pectoralis major fibers progresses segmentally from above downward. The clavicular section is supplied chiefly by spinal segments C5-C6; the sternal section is mainly innervated by segments C7, C8, and T1; the costal section innervation is usually a transition zone between the two nerves by segments C7 and C8; and the costal and abdominal sections are supplied by segments C8 and T1 through the medial pectoral nerve.²

The vascular supply of the pectoralis major muscle is primarily through the pectoral branch of the thoracoacromial artery by small branches from the clavicular and deltoid branches of the thoracoacromial artery and by branches of the internal thoracic artery, superior, and lateral thoracic arteries.² Entrapment of lymphatic vessels within the pectoralis major muscle may occur. Lymphatic drainage from the breast usually travels in front of, and around, the pectoralis major muscle to the axillary lymph nodes. A lymph vessel from the superior portion of the breast may pierce the pectoralis major muscle and terminate in the subclavicular lymph nodes.² Entrapment of this lymph duct at the passage between tense fibers of an involved pectoralis major muscle may cause edema of the breast.

Subclavius

The nerve to the subclavius muscle, supplied by C5 and C6 spinal nerves, innervates the subclavius muscle.² The vascular supply to the subclavius muscle is through the clavicular branch of the thoracoacromial artery and the suprascapular arteries.²

2.2. Function

Pectoralis Major

The pectoralis major muscle has many functions because of its expansive anatomic arrangement, and its function is dependent on the starting position of the shoulder girdle and thorax.⁵ The pectoralis major muscle influences three joints: the sternoclavicular, acromioclavicular, and glenohumeral joints. It also assists in providing the gliding movement of the scapula over the rib cage during shoulder girdle function.

The pectoralis major muscle, as a whole, acts to horizontally adduct, internally rotate, and adduct the glenohumeral joint.^{7,8} Internal rotation is a much stronger motion than external rotation because of influences from the latissimus dorsi, teres major, and anterior deltoid muscles. The pectoralis major muscle cannot bring the arm far enough across the chest for the hand to touch the opposite ear but only to reach the opposite side of the chest, and the movement is completed with assistance from the anterior deltoid muscle.^{7,8}

In addition, the clavicular portion elevates the glenohumeral joint in the sagittal plane when the movement is started with the arm at the side.^{7,8} Wattanaprakornkul et al,⁹ utilizing fine wire and surface electromyography (EMG), investigated shoulder girdle muscle activity during flexion with increasing external loads from no load (0%) up to 60% maximum voluntary contraction (MVC). Their results demonstrated moderate MVC of the pectoralis major muscle similar to that of the deltoid, infraspinatus, and supraspinatus muscles under heavy loads (60% MVC). They also reported that pectoralis major MVC decreased in upper limits of shoulder elevation because of its reverse action with the arms overhead.⁹

Alternatively, when the humerus is fixed overhead, the sternocostal and abdominal heads pull the arm back toward adduction and extension.⁵ The lower sternal and abdominal fibers can depress the shoulder girdle and downwardly rotate the scapula through their pull on the humerus. All fibers assist forced protraction of the shoulder.^{7,8}

Wickham et al,¹⁰ using fine wire EMG on 15 muscles of the shoulder girdle, found that during shoulder elevation in the coronal plane with an external load of 25% of MVC, the pectoralis major muscle was activated last at approximately 26° of shoulder abduction reaching peak MVC at approximately 120° and was deactivated first with the descent of the arm to the start position. The infraspinatus, supraspinatus, and middle trapezius muscles were activated before upper extremity movement.¹⁰

Decker et al¹¹ investigated muscle activation during seven shoulder strengthening exercises utilizing indwelling EMG. The pectoralis major muscle had a range of 18% MVC to 132% MVC. The push-up plus and diagonal exercises (ie, horizontal flexion, adduction, internal rotation) elicited a greater average and peak muscle activation for the pectoralis major muscle. The forward punch and internal rotation at 90° of elevation produced the lowest average and peak amplitudes (18%–25% MVC).¹¹

Among 13 professional right-handed golfers, the greatest pectoralis major muscle activity occurred during the acceleration and early follow-through phases of the swing.¹² The left side showed more activity than the right, and men showed higher activity than did women. The power in the shoulder for the drive came first from the latissimus dorsi muscle

and then the pectoralis major muscle, which showed more activity than any of the other seven tested muscles.¹² This activity provided the powerful arm adduction and internal rotation required.¹³

Electromyographic analysis of shoulder girdle muscle activity during functional movements is well documented. Jobe et al¹² and Gowan et al¹⁴ investigated muscle activation patterns and activity during throwing movements. They identified maximum activity of the supraspinatus, infraspinatus, and deltoid muscles during early and late cocking phases of the throw; whereas the pectoralis major, subscapularis, and latissimus dorsi muscles were more active during the arm cocking and acceleration phase of the throw. They also identified that amateurs tend to utilize more of the rotator cuff muscles during the acceleration phase.^{12, 14} This notion is further supported in a study of healthy, skilled throwers where EMG activity of the pectoralis major muscle increased dramatically with arm cocking and remained high during arm acceleration (56% of MVC) tapering to 30% during follow-through.^{15, 16} During a tennis serve, the pectoralis major muscle is the most heavily recruited during acceleration.¹⁷

Bankoff et al¹⁸ performed an EMG study of the pectoralis major (sternocostal portion) and the middle deltoid muscles in volleyball sequential actions. They found the pectoralis major muscle to have its peak activity during the spike and serve between 180° and 90° flexion. Peak activity was achieved during interaction with the ball versus movement without the ball.¹⁸ This conclusion is consistent with the findings reported by Rokito et al.¹⁹

During freestyle swimming, the clavicular section of the pectoralis major muscle in normal subjects was active during the pull-through phase, with peaks of activity during early and late pull-through as internal rotation of the arm progressed.²⁰ During the butterfly stroke, the pectoralis major muscle is the first muscle recruited, and it reaches peak activity rapidly during the pulling phase of the stroke during which it is considered to be a primary propulsive muscle.²¹

During simulated driving, the clavicular section showed more activity bilaterally during left turns than during right turns, and the clavicular section showed more activity than the sternocostal section.²² Other investigators found that the pectoralis major muscle reached the peak MVC during a pushing activity.²³

Subclavius

The subclavius muscle assists with protraction of the shoulder indirectly by approximating the clavicle and the first rib.^{7, 8} It is also thought that the subclavius muscle resists elevation and rotation of the clavicle during activities that require rapid elevation of the shoulder girdle.²

2.3. Functional Unit

The functional unit to which a muscle belongs includes the muscles that reinforce and

counter its actions as well as the joints that the muscle crosses. The interdependence of these structures is functionally reflected in the organization and neural connections of the sensory motor cortex. The functional unit is emphasized because the presence of a TrP in one muscle of the unit increases the likelihood that the other muscles of the unit will also develop TrPs. When inactivating TrPs in a muscle, one must be concerned about TrPs that may develop in muscles that are functionally interdependent. Box 42-1 grossly represents the functional unit of the pectoralis major muscle.²⁴

Box 42-1 Functional unit of the pectoralis major muscle

Action	Synergists	Antagonist
Shoulder internal rotation	Latissimus dorsi Teres major Subscapularis	Infraspinatus Teres minor
Shoulder flexion	Anterior deltoid Biceps brachii long head Coracobrachialis	Latissimus dorsi Posterior deltoid Triceps brachii long head
Shoulder adduction	Teres major Latissimus dorsi Subscapularis Coracobrachialis	Deltoid Supraspinatus
Shoulder protraction (sternal head)	Serratus anterior Pectoralis minor Subclavius	Rhomboid major Rhomboid minor Middle trapezius

Agonist muscles in parallel and in series, which may assist the clavicular section of the pectoralis major muscle, include the anterior deltoid, coracobrachialis, subclavius, scalenus anterior, and sternocleidomastoid muscles on the same side. The clavicular head and the anterior deltoid muscle work very closely together because they lie side by side, with adjacent attachments, and are separated only by the groove of the cephalic vein.

The more vertically oriented, lower fibers of the sternal sections of the pectoralis major muscle depress the shoulder with the help of corresponding fibers of the latissimus dorsi, lower trapezius, and lower serratus anterior muscles. The subclavius and the pectoralis minor muscles also assist these lower pectoralis major fibers.

3. CLINICAL PRESENTATION

3.1. Referred Pain Pattern

Pectoralis Major

Although the pectoralis major muscle may develop TrPs in any portion of the muscle, with pain and tenderness referred unilaterally without crossing midline, five areas are classically described, each with a distinctive pain reference pattern.²⁴

The TrPs located in the clavicular section (Figure 42-3A) often refer pain over the anterior deltoid muscle and locally to the clavicular section of the pectoralis major muscle itself.

A

B

C

D

Figure 42-3. Referred pain patterns (red) and TrP areas in the left pectoralis major muscle. Solid red shows essential areas of referred pain, and stippled red shows the spillover pain areas. A, The clavicular section. B, Intermediate sternal section. C, The lateral free margin of the pectoralis major muscle, which includes fibers of the costal and abdominal sections that form the anterior axillary fold. D, Parasternal pectoralis major TrPs.

Trigger points within the sternal section of the pectoralis major muscle (Figure 42-3B) are likely to refer pain to the anterior chest,²⁵⁻²⁷ down the medial aspect of the arm toward the medial epicondyle. Pain may also be referred to the volar aspect of the forearm and ulnar side of the hand to include the last two or two-and-a-half digits.²⁸ The uppermost of these sternal TrP areas (Figure 42-3B) lies at the three-way overlap of the clavicular and manubrial sections of the pectoralis major and the underlying pectoralis minor muscles.

In the costal and abdominal portions of the pectoralis major muscle, TrPs develop in two pectoral regions. One of these regions lies along the lateral border of the muscle; however, the full length of the fibers should be examined for the presence of TrPs. Trigger points closest to the border (Figure 42-3C) can cause breast tenderness with hypersensitivity of the nipple, intolerance to clothing, and often breast pain.²⁹

More medially, a TrP associated with somatovisceral cardiac arrhythmias³⁰ may be located on the right side between the fifth and sixth ribs, just below the point where the lower border of the fifth rib crosses a vertical line that lies midway between the margin of the sternum and the nipple (Figure 42-4). This TrP area has been observed only on the right side, except in situs inversus. The spot tenderness of this TrP is associated with ectopic cardiac rhythms but not with any pain complaint. There may be nearby tender points over or between adjacent ribs that are not pertinent to cardiac arrhythmia.

Figure 42-4. Right pectoralis major muscle TrP phenomena. Location of the “cardiac arrhythmia” TrP below the lower border of the fifth rib in the vertical line that lies midway between the sternal margin and the nipple line. On this line, the sixth rib is found at the level of the tip of the xiphoid process (arrow).

It is important for the clinician to note that TrPs within the left pectoralis major muscle may mimic pain symptoms of cardiac ischemia. In addition, patients may develop TrPs within this muscle after a myocardial infarction (viscerosomatic activation).

Subclavius

The subclavius muscle can develop TrPs that refer pain ipsilaterally into the upper extremity (Figure 42-5B). The pain may travel across the front of the shoulder, down the front of the arm, and along the radial side of the forearm bypassing the elbow and wrist to reappear on the radial half of the hand. In addition, the patient may experience pain in the dorsal and volar aspects of the thumb, the index finger, and the middle finger.

Figure 42-5. Subclavius muscle. A, Attachments of the muscle (medium red). B, Referred pain pattern (dark red) of a subclavius TrP. Stippled red is possible spillover in the lateral aspect of the hand.

3.2. Symptoms

When patients report pain in the chest, anterior shoulder, medial aspect of the arm, medial elbow, medial aspect of the hand, and the fourth and fifth digits, TrPs in the pectoralis major muscle should be considered as a possible source of symptoms. Patients may report pain and symptoms that appear to be cardiac in nature and, in fact, can be caused by TrPs in the pectoralis major muscle. Conversely, TrPs in the pectoralis major muscle can be activated by cardiac disease or events resulting in complaints of persistent chest pain even though the heart may have recovered (viscerosomatic reflex).

When the patient reports primary pain in the anterior aspect of the shoulder, the pectoralis major and minor, subclavius, infraspinatus, supraspinatus, deltoid (anterior, middle), biceps brachii, coracobrachialis, and scalene muscles are the most likely muscular sources of symptoms.³¹ Other investigators found a high prevalence (66%) of TrPs in the pectoralis major muscle in patients with unilateral shoulder impingement syndrome as compared to a matched control group,³² and still others found expansive pain referral patterns in both blue collar and white collar workers.³³ In addition, Alonso-Blanco et al³⁴ observed that active TrPs in the pectoralis major muscle were also highly prevalent in women with fibromyalgia syndrome.

When patients present with autonomic symptoms and pain in the subclavicular region (Figure 42-3A), it is important to consider TrPs within the clavicular head of the pectoralis major muscle. This phenomenon occurs when shortening of the clavicular portion produces a downward and forward pull on the medial part of the clavicle, placing tension on the clavicular portion of the sternocleidomastoid muscle, thus perpetuating or activating TrPs in this muscle.

Patients with pectoralis major TrPs are likely to be as aware of their interscapular back pain as they are of the pain referred by their pectoralis major TrPs. In fact, the pectoral muscle TrPs may be painlessly latent but potent as the cause of pain-producing overload of scapular adductors including the middle trapezius and rhomboid muscles. Trigger points in the pectoralis major muscle should be considered as a potential source of symptoms when the patient experiences pain in the interscapular region when performing scapular adduction or when attempting to lie supine. Patients may also experience difficulty or pain when performing glenohumeral abduction (particularly horizontal abduction).

A patient with significant TrP-associated shortening of the pectoralis major muscle will present with a stooped, rounded shoulder, and forward head posture. When observing the patient from the rear, the clinician may note faulty scapular position and asymmetries. Scapular and humeral head positions should be assessed at rest and during upper extremity elevation because malalignment can be a significant contributing factor to pectoralis major muscle overload during upper extremity functional activities requiring combined internal rotation and adduction especially from an overhead position. Trigger points in the pectoral muscles may restrict scapular adduction, which can be tested by having the patient place the back of the ipsilateral hand on the hip and move the elbow posteriorly for range of backward movement. Bilateral comparison is the most sensitive indicator of restriction if

muscle involvement is unilateral. Reproduction of interscapular pain is another indicator of restriction. With these postural imbalances, manual muscle testing will reveal weak or inhibited interscapular muscles.

To identify TrPs in the pectoralis major muscle that may or may not be limiting range of motion and thus influencing dysfunction, the clinician should identify limited range of motion by performing specific range of motion testing for all parts of the muscle. Because the patient with pectoralis major TrPs in isolation often presents with minimal to no range of motion limitations, a thorough examination of all factors contributing to the patient's pain report should be completed. The clinician can expect external rotation to be restricted because of pectoralis major TrPs, but must also consider that full shoulder elevation may be limited due to the prerequisite external rotation required to achieve full elevation (abduction or flexion).²⁴ One helpful sign in differentiating pectoralis major muscle restriction from subscapularis muscle restriction is greater loss of external rotation at 90° versus 45° of abduction.³⁸

TrPs in the pectoralis major muscle, when it is involved alone, cause minimal restriction of motion at the shoulder. The Apley's Scratch Test (shoulder extension, internal rotation, and adduction, Figure 21-3A) may be helpful in identifying muscle length deficits due to TrPs especially in the clavicular portion of the muscle. During this test, the shoulder girdle should not anteriorly tip forward while the patient attempts to reach the hand of the affected side behind the back and reaching as far up toward the opposite scapula as possible. Additional pectoralis major muscle length tests can be carried out in the supine position (Figure 42-6A to C).

Figure 42-6. Pectoralis major muscle length test. A, Quick bilateral screen. B, Clavicular portion. C, Sternal and abdominal portion. The humerus should be able to fall below the horizontal for normal pectoralis major muscle length.

Accessory joint motion should be tested in the glenohumeral joint, acromioclavicular joint, sternoclavicular joint, scapulothoracic joints, and thoracic rib cage. Oftentimes, joint hypomobility in the sternoclavicular joint or rib cage can cause impairment in shoulder elevation, contributing to alterations in the normal muscle activation patterns. Articular dysfunctions in the glenohumeral joint may also impair muscle activation patterns that can contribute to overload of the pectoralis major and rotator cuff muscles.

A cervical screen, neurologic examination including mobility testing of the neural tissues of the shoulder girdle should be done to eliminate radicular symptoms as causative. If referred hand and/or finger pain is present, a clinical examination of local tissues at the wrist and hand should be also conducted.

Patients may report breast tenderness or pain with hypersensitivity of the nipple and intolerance to clothing (allodynia). Trigger points in the sternal head of the pectoralis major muscle are likely to be the source of these symptoms.²⁹ This pain referral is most

common in women, but may also be seen in men. Trigger points in the central part of the pectoralis major muscle refer pain widely over the precordium (if on the left side) and may cause a sense of chest constriction that is readily confused with angina pectoris. A patient with TrPs in the intermediate fibers of the left sternal section is likely to complain of intermittent, intense chest pain (Figure 42-5A) that appears in the precordial region with upper limb activity and also at rest if the TrPs are severe.

Different studies reported that examination of TrPs reproduced pain symptoms in the neck, shoulder, and axillary regions in women following breast cancer surgery.^{35,36} In fact, development of active TrPs in the pectoralis major muscle was similar in woman who underwent mastectomy or lumpectomy.³⁷ Therefore, examination and treatment of TrPs should be part of the postoperative care for women experiencing pain in the neck, shoulder, arm, or axilla after mastectomy or lumpectomy surgery.

When patients report symptoms consistent with TOS (see Chapter 33), the subclavius muscle should be considered as a possible source of symptoms because the pain referral pattern from the subclavius muscle is in the same distribution of symptoms from TOS.

3.3. Patient Examination

After a thorough subjective examination, the clinician should make a detailed drawing representing the pain pattern described by the patient. This activity will assist in planning the physical examination and can be useful in monitoring the progression of the patient as symptoms improve or change. Any patient with primary reports of chest pain should alert the clinician to perform a thorough review of the cardiovascular and pulmonary systems. Any concerns regarding the involvement of the cardiovascular or respiratory systems as a source of symptoms should result in an immediate referral to the emergency room or a physician. For proper examination of the pectoralis major muscle, the clinician should observe shoulder girdle posture and scapula position, examine active and passive range of motion of the shoulder girdle, and observe muscle activation patterns and the scapulohumeral rhythm. The clinician should note when and where pain occurs. Pectoralis major TrPs can produce pain at rest or during movement, particularly during arm elevation in the coronal plane especially when combined with external rotation. The pain may or may not be present throughout abduction range of motion. Clinicians find that this muscle may be involved by itself, or be associated with other TrPs in the subclavius, scalene, anterior deltoid, pectoralis minor, and rotator cuff muscles.

Symptoms from TrPs within the pectoralis major muscle should be differentiated from symptoms being driven by the subclavius and scalene muscles. The subclavius muscle is more closely associated with lateral forearm and lateral hand pain, whereas the pectoralis major muscle is associated with medial elbow, forearm, and hand pain. The scalene muscle referred pain is similar to the subclavius muscle referred pain pattern. The Finger-flexion Test (see Figure 20-6) may be utilized to differentiate scalene from subclavius or pectoralis major muscle involvement. If this test is positive, the scalene muscles may be implicated because TrPs or restrictions in the pectoralis major or subclavius muscles will not

presumably affect this test.

The patient with chest pain due to pectoralis major TrPs is likely to report additional referred pain and restriction of movement at the shoulder because of associated TrPs in functionally related shoulder girdle muscles, which also need to be considered.

3.4. Trigger Point Examination

Pectoralis Major

Most of the TrPs found in the clavicular section, and TrPs in the parasternal section of the muscle, are identified by cross-fiber flat palpation (Figure 42-7A and B). Trigger points in the intermediate and lateral parts of the sternal and costal sections are best located by cross-fiber flat palpation (Figure 42-7B). The muscle may be placed on minimal to moderate tension by abducting the shoulder between 60° and 90° to maximize the spot tenderness found in a taut band. Local twitch responses may or may not be elicited, although they are easily obtained because this is a superficial muscle. The lateral part of the pectoralis major muscle is one of the easier muscles in which to identify taut bands by cross-fiber pincer palpation (Figure 42-7C). In women who have large breasts, the side-lying position can be utilized because gravity will aid in moving the breast tissue medially to allow better access to the pectoralis major muscle fibers (Figure 42-7D).

Figure 42-7. Palpation for TrPs in the pectoralis major muscle. A, Clavicular head cross-fiber flat palpation. B, Sternal head cross-fiber flat palpation. C, Lateral portion with cross-fiber pincer palpation. D, Side-lying cross-fiber flat palpation for a female patient.

To find the “cardiac arrhythmia” TrP (Figure 42-5B), the tip of the xiphoid process is located. Then, at this level on the right side, in a vertical line midway between the sternal border and the nipple line, the region of the hollow between the fifth and sixth ribs is examined for a tender spot. This TrP is found by pressing upward against the inferior edge of the fifth rib and exploring for spot tenderness. Tenderness here may be also be caused by a TrP in an intercostal muscle rather than the sought pectoralis major muscle TrP.

Subclavius

The subclavius muscle must be palpated through the clavicular division of the pectoralis major muscle, and localization of its TrPs is best achieved with the pectoralis major muscle placed on slack. To do this, the relaxed patient’s shoulder is placed in adduction and internal rotation. The clinician can palpate subclavius TrPs at the lateral portion of the medial third of the clavicle by rolling the palpating finger underneath the clavicle, deep into the recess and across the tense fibers (Figure 42-8). Palpation of the taut band of a TrP is not reliable through the pectoralis major muscle. Trigger points may also be found at the attachment of the muscle, just lateral to and below the costoclavicular joint from the central subclavius TrPs that are found closer to the mid-clavicle.

Figure 42-8. Palpation of the subclavius muscle.

4. DIFFERENTIAL DIAGNOSIS

4.1. Activation and Perpetuation of Trigger Points

In any part of the pectoralis major muscle, TrPs may be activated by unaccustomed

eccentric loading, eccentric exercise in unconditioned pectoralis major muscle, or maximal or submaximal concentric loading.³⁹ TrPs may also be activated or aggravated when the muscle is placed in a shortened or lengthened position for an extended period of time.

Pectoralis major TrPs are activated and perpetuated by a rounded shoulder posture because it produces sustained shortening of the pectoral muscles. This activation is likely to occur during prolonged sitting and when standing with a slouched, flat-chested posture.

Pectoralis major TrPs may be activated or reactivated in many ways including heavy lifting or weight training (especially when reaching out in front), carrying a heavy backpack, overuse of arm adduction (as with use of manual hedge clippers), sustained lifting in a fixed position (as with use of a power saw), immobilization of the arm in the adducted position (arm in a sling or cast), or sustained high levels of anxiety.

Sporting activities such as tennis, volleyball, swimming, baseball, and golf may place repetitive or excessive forces through the pectoralis major muscle. These activities, which require the pectoralis major muscle to produce a propulsive or excessive force (butterfly stroke, spiking a ball, bench press), place the muscle at risk for development of TrPs.

In acute myocardial infarction, pain is commonly referred from the heart to the mid-region of the pectoralis major and minor muscles. The injury to heart muscle initiates a viscerosomatic reflex process that activates TrPs in the pectoral major and minor muscles. Following recovery from the acute infarction, these self-perpetuating TrPs tend to persist in the chest wall unless wiped away like dust collected on a shelf.

4.2. Associated Trigger Points

Associated TrPs can develop in the referred pain areas caused by a TrP in another muscle.⁵⁸ Therefore, musculature in the referred pain areas for each muscle should also be considered. The sternalis (see Chapter 43) and pectoralis minor muscles (see Chapter 44) have a similar pain referral pattern and a close anatomic relationship to the pectoralis major muscle. Trigger points in the scalene muscles (see Chapter 20) also refer pain to the pectoral region and should be considered when pectoralis major TrPs are suspected.²⁸

Many muscles of the shoulder and upper extremity should be examined for associated TrPs when treating dysfunction of the pectoralis major muscle. Trigger points in the iliocostalis thoracis muscle between the second and the sixth thoracic vertebrae on the left⁵⁹ and the region of the left upper rectus abdominis muscle induce chest pain that strongly mimics pain of cardiac origin and can coexist with pectoralis major TrPs.⁶⁰ The anterior deltoid, coracobrachialis, biceps brachii, brachialis, flexor carpi ulnaris, flexor digitorum superficialis, and profundus and abductor digiti minimi muscles are all within the pain referral pattern of the pectoralis major muscle and could harbor associated TrPs. The subclavius muscle shares the proximal pain referral pattern in the chest, anterior shoulder, and upper arm; however, its pain referral pattern spreads to the radial aspect of the forearm and hand instead of the ulnar aspect. The pronator teres, supinator, extensor digitorum, brachioradialis, and extensor carpi radialis longus muscles should be also examined for the presence of associated TrPs.

In addition, muscles that comprise the functional unit may also have associated TrPs. The anterior deltoid and coracobrachialis muscles are synergists that substitute for impaired function of the pectoralis major muscle. The subscapularis, teres major, and latissimus dorsi muscles, which are also part of the synergistic functional unit, may develop associated TrPs. Involvement of the serratus anterior, rhomboids, and middle trapezius muscles, which are antagonists, often follows, especially in a patient with a rounded shoulder posture. The antagonistic infraspinatus, teres minor, and posterior deltoid muscles may also develop TrPs, resulting in significant shoulder stiffness. In addition, tense pectoral muscles can overload posterior muscles, causing painful stretch weakness. In either case, the interscapular muscles should be addressed.

4.3. Associated Pathology

Pectoralis Major

Differential diagnosis of symptoms caused by TrPs in the pectoralis major muscle should include angina pectoris; tear of the muscle belly⁴⁰; bicipital tendinitis; supraspinatus tendinitis; subacromial bursitis; medial epicondylalgia; lateral epicondylalgia; C5-C6 radicular pain; C7-C8 radicular pain; TOS; intercostal neuritis; irritation of the bronchi, pleura, and/or esophagus; mediastinal emphysema⁴¹; breast cancer; and lung cancer. Some of the less common noncardiac skeletal syndromes that cause pain and tenderness in the chest include the chest wall syndrome,⁴² Tietze's syndrome,^{43,44} costochondritis, hypersensitive xiphoid syndrome, precordial catch syndrome,^{45,46} slipping rib syndrome,⁴⁷ and rib-tip syndrome.⁴⁸ Each patient should be carefully examined to determine whether the symptoms are partially or entirely due to myofascial referred pain and tenderness, especially from TrPs in the pectoralis major muscle. Of these conditions, each has been reported as sometimes being relieved by injection of the tender area with a local anesthetic without reference to examination for TrPs. Because relief by injection is characteristic of TrPs, the resolution of pain may have been achieved by unknowingly treating the muscle dysfunction.

The pectoralis major muscle is one of four muscles that can produce myofascial symptoms consistent with TOS (see Chapter 33 for more on this condition). This muscle and the latissimus dorsi, teres major, and subscapularis muscles individually, and especially in combination, produce referred pain that mimics a TOS. The patient may, however, have a true entrapment or compressive TOS with similar symptoms and referred pain from scalene TrPs may also be present.

When a patient reports having breast soreness (referred tenderness), she or he also may describe a feeling of congestion in that breast. When compared with the other side, the breast may be slightly enlarged and feel doughy. These signs of impaired lymph drainage, possibly due to entrapment or reflex inhibition of peristalsis, soon disappear after inactivation of the responsible TrPs in the lateral border of the tense pectoralis major muscle (Figure 42-3C). The patient who presents with a painful or tender breast, often

with hypersensitivity of the nipple to light contact, may have TrPs in the lateral margin of the pectoralis major muscle^{28,29} (Figure 42-3C). The thought of having cancer may be a serious, but unexpressed fear in patients, who later express enormous relief when they realize that the pain has a benign treatable myofascial cause.

Other authors have noted that pectoralis major TrPs can simulate the symptoms of angina pectoris⁴⁹ and have illustrated similar referred pain patterns for pectoralis major TrPs in the clavicular and costal divisions⁵⁰ and in the sternal division and medial and lateral margins.⁵¹ The intensity, quality, and distribution of true cardiac pain can be reproduced by the pain referred from active TrPs in the anterior chest muscles.⁵²⁻⁵⁴ Although these patterns can mimic cardiac pain, TrP pain shows a much wider variability in its response to day-to-day activity than does the more consistent exercise response of angina pectoris.

A definitive diagnosis of active TrPs based on their characteristic signs and symptoms and a dramatic response to local treatment does NOT exclude cardiac disease. Adding to this diagnostic challenge is the fact that noncardiac pain may induce transient T-wave changes in the electrocardiogram.⁵⁵ A disorder of the heart may coexist and must be ruled out by appropriate tests of cardiac function.⁵⁶

TrPs within the pectoralis major muscle have been shown to have somatovisceral effects on the heart. A common example of this somatovisceral response is found in patients who experience episodes of supraventricular tachycardia, supraventricular premature contractions, or ventricular premature contractions without other evidence of heart disease. The patient with such an ectopic rhythm should be checked for TrP in the right pectoral region between the fifth and sixth ribs at the specific site described earlier³⁰ (Figure 42-5B). Although this TrP is tender to palpation, it is not usually a source of referred pain. Inactivation of the TrP promptly restores normal sinus rhythm when the TrP is contributing to an ectopic supraventricular rhythm and also can eliminate recurrences of the paroxysmal arrhythmia or frequent premature contractions for a long period of time.

In addition to somatovisceral effects, studies have demonstrated that there is a viscerosomatic effect between the visceral structures within the chest cavity and the musculature on the anterior chest wall. An example of this myofascial viscerosomatic interaction begins with coronary artery insufficiency, or other intrathoracic disease, that refers pain to the anterior chest. As a result of this pain referral, TrPs develop in the somatic pectoral muscles. Kennard and Haugen⁵⁷ related the presence of palpable TrPs in the chest muscles to chest and arm pain and to the disease process responsible for the pain. They found that 61% of 72 patients with cardiac disease, 48% of 35 patients with other visceral chest disease, and 20% of 46 patients with pelvic and lower extremity disease had tender TrPs in the chest muscles. In the patients with chest and arm pain due to cardiac and other unilateral intrathoracic disease, tender TrPs were strongly lateralized to the affected side.⁵⁷

Subclavius

Subclavius muscle shortening by TrPs can contribute to symptoms of a vascular TOS.

Shortening of the subclavius muscle because of TrPs will draw the clavicle down toward the subclavian artery and vein as they pass over the first rib. In some patients, this pressure can contribute to, if not cause, entrapment and the symptoms of a vascular TOS. See Chapter 33 for further information on TOS and myofascial considerations.

5. CORRECTIVE ACTIONS

The patient with pectoralis major TrPs should modify activities that repeatedly stress this muscle such as carrying a heavy backpack and weight training (especially bench press). Correction of rounded shoulder posture and maintenance of good dynamic posture are essential for lasting relief of pectoral TrPs. In standing, patients should not be encouraged to actively hold their shoulders back or stand in a “military posture” because this stance will aggravate pectoral muscle and interscapular TrPs. Focusing on the head position and standing tall will allow the shoulders to find their proper resting position.

Supportive sleeping posture is key to a lasting resolution of pectoralis major TrPs. When sleeping, the patient must avoid shortening of the pectoralis major muscle, as occurs when the arms are folded across the chest. A pillow can be used to support the arms to avoid this arm position. When lying on the pain-free side, the patient should support the uppermost forearm on a pillow to prevent the arm from dropping forward to the bed and thus shortening the affected pectoralis major muscle (see Figure 22-4A). When the patient lies on the affected side, the pillow fits in the axilla between the arm and the chest to prevent undue shortening of the pectoralis major muscle (see Figure 7-5B). In addition, the corner of the pillow should be tucked between the head and shoulder to drop the shoulder backward, not tucked under the shoulder (see Figure 7-5A).

When sitting for a prolonged period or when working at a computer, the chair should be adjusted so as to support the natural lumbar lordosis and the keyboard and monitor should be adjusted appropriately to prevent a slouched rounded shoulder and forward head posture. Patients should be discouraged from forcing their shoulders back with muscle action because this will aggravate symptoms. For further information on posture, refer to Chapter 76.

Pectoralis major TrPs can be self-treated with pressure release utilizing a tennis ball or other TrP release tools. In men, the entire pectoralis major muscle can be easily accessed through the skin; in women, the upper portion of the pectoralis major muscle can be treated through the skin, and the sternal portion must be accessed by moving the breast tissue aside as much as possible. A tennis ball, TrP release tool, or self-pressure release may be utilized in a seated position using the unaffected side to perform the technique (Figure 42-9A and B). For the lateral aspect of the pectoralis major muscle, a pincer grasp can be used for self-pressure release treatment (Figure 42-9C and D). Pressure should be applied to the TrPs, held for 15 to 30 seconds, and repeated 6 to 10 times. This technique can be used several times a day as long as favorable results are being obtained. In women who have large breasts, the supine or side-lying position can be utilized because gravity will aid in moving the breast tissue out of the way. For example, if the right pectoralis major muscle has TrPs

that need treatment, the patient would lie on their left side giving access to the right axillary border for self-treatment with the opposite hand (Figure 42-9E).

Figure 42-9. Self-pressure release of TrPs in the pectoralis major muscle. A, TrP pressure release tool. B, Self-pressure release. C, Self-pressure release using pincer grasp sitting. D, Supine. E, Side-lying position for a female patient.

Stretching techniques for the pectoralis major muscle should be gentle because stretching this muscle will also stretch the other internal rotators of the shoulder joint and neural tissues. The doorway stretch is useful to stretch all of the adductors and internal rotators of the shoulders. The patient stands in a narrow doorway with the forearms flat against the door facings to anchor the forearms and steps forward through the doorway to stretch the muscles (Figure 42-10). The patient should not grasp the doorjamb and hang on because that action interferes with the muscular relaxation needed for the stretch to be effective. One foot is placed in front of the other, and the forward knee is bent to accept the forward shift of bodyweight. The patient holds the head erect, looking straight ahead, neither craning the neck forward nor looking down at the floor. As the forward knee bends and the patient shifts the body through the doorway, a slow, gentle, passive stretch is exerted bilaterally on the pectoralis major muscle and on its synergistic muscles. The gentle

stretch is held for 30 seconds and can be repeated up to five or six times. The patient pauses, relaxes, and takes a few slow abdominal breaths between each cycle to enhance relaxation.

Figure 42-10. Self-stretch of pectoralis major muscle. A, Lower arm position. B, Mid position. C, High position.

The hand position against the doorjamb is adjusted to apply the stretch to different taut bands in the muscle. Fibers of the clavicular section are stretched best in the lower hand position (Figure 42-10A). By raising the hands to the middle hand position with the upper arms horizontal (Figure 42-10B), the sternal section is stretched. Moving the hands as high as possible, keeping the forearms against the doorjamb (Figure 42-10C), stretches the costal and more vertical abdominal fibers that form the lateral margin of the muscle. When doing this stretching exercise, the patient should be encouraged to distinguish the different feelings of stretch for each section of muscle. Because other structures are also placed on stretch with this technique, a gentle, comfortable stretch should be the goal. This exercise can be combined with the principles of contract-relax and reciprocal inhibition to good advantage.

In patients who require a less aggressive stretch, a towel roll or bolster support may be used in the supine hook-lying position. The towel roll or bolster is positioned vertically in the center of the spine, supporting both the head and thoracic spine. All portions of the pectoralis major muscle can be gently stretched in this position. Each stretch may be held for 30 seconds and repeated up to five times (Figure 42-11A to D).

Figure 42-11. Supine bolster stretch. A, Examples of bolsters: 1, Towel rolled in sheet; 2, half foam roll; 3, full B, Low position. C, Mid position. D, High position.

Full effectiveness of both of these stretch techniques requires the patient to be mindful of the intensity of stretch. The patient should be instructed to stretch the muscle to the point of comfortable tension (without pain) paying attention to any unfamiliar shoulder symptoms or arm/hand numbness and tingling. If pain, numbness, and/or tingling is felt in the arm, forearm, or hands, this exercise should be stopped immediately, and the patient should seek guidance from an appropriate health care practitioner.

Sternalis Muscle

“Alarming Agonizer”

Joseph M. Donnelly and Brian Yee

1. INTRODUCTION

The sternalis muscle is often forgotten, not only in human function, but just as notably as a contributor to myofascial pain. The sternalis muscle is highly variable and its fibers are superficial to the pectoralis major muscle, generally running parallel to the sternum. The muscle may be present on one or both sides. When trigger points (TrPs) exist in this muscle, the referred pain pattern is a deep substernal ache that is independent of movement. Patients will complain of a deep ache or soreness over the sternum, which cannot be reproduced with movements or posture alterations. Differential diagnosis should include costochondritis, Tietze’s syndrome, gastroesophageal reflux, esophagitis, and an anginal presentation of C7 radicular symptoms. Corrective actions include addressing pectoral and sternocleidomastoid TrPs, postural imbalances, sleeping position alteration, and most importantly TrP self-pressure release.

2. ANATOMIC CONSIDERATIONS

The anomalous sternalis muscle is highly variable in presence, symmetry, length, bulk, attachments, and innervation. It may occur bilaterally (Figure 43-1) or more often unilaterally, on either side of the sternum, or rarely, the two muscles may fuse across the sternum. Its reported origins or superior attachments include a combination of the sternum, the inferior border of the clavicle, the sternocleidomastoid fascia, the pectoralis major muscle, and the upper ribs and their costal cartilages. The insertion or inferior attachments include structures such as the lower ribs and their costal cartilages, the pectoralis major muscle, rectus abdominis sheath, and the external oblique aponeurosis.^{1,2} The muscle may be as thick as 2 cm (3/4 in) over the sternum, a depth through which it is difficult to palpate pectoralis major TrPs (Figure 43-1). Its maximum reported length ranges from a relatively short muscle of only 2.4 cm to very long specimens of 26.0 cm; the

maximum width ranges from 0.48 to 7.0 cm.¹

Figure 43-1. Commonly seen attachments of the anatomically variable sternalis muscle (*red*).

The sternalis muscle presents as a parasternal mass deep to the superficial fascia of the anterior thoracic wall and superficial to the pectoral fascia overlying the pectoralis major muscle.¹ It has been reported to be a cord-like structure, a flat band³ or an irregular and flame-like shape.⁴ A unilateral sternalis muscle is more common (67%) than bilateral (33%) with preferential occurrence on the right side (64% right, 36% left).

The sternalis muscle was found in 1.7% to 14.3% (median 4.4%) of cases in 13 studies of at least 10 200 cadaver specimens⁵; at most, in 48% of anencephalic specimens⁵; in

4.3% of 2 062 cadavers as summarized by Christian⁶; and in 6% of 535 cadavers according to Barlow.⁷ Eisler,⁵ Hollinshead,⁸ Grant,⁹ and Toldt¹⁰ have each illustrated the sternalis muscle. Cadaveric investigations reveal that the sternalis muscle has an overall prevalence of around 7.8% in the general population.¹ Christian⁶ illustrated two bilateral muscles while Shen et al reported one pair.¹¹ Barlow⁷ reported no significant difference in the incidence of the sternalis muscle in white and black Americans. Some of the highest rates have been reported in Asian populations (11.5%) compared with 8.4% in populations of African descent, and 4.4% in those of European descent. Women may have a slightly higher rate of occurrence than men (8.6% and 7.5% respectively), although some studies report no gender difference.^{7,-12,13} Results from operating rooms seem to support the notion that the sternalis muscle is clinically underreported.¹ Harish and Gopinath¹⁴ report 0.7% cases of a present sternalis muscle in their study.

Jelev et al¹⁵ outlined four basic morphologic characteristics that must be satisfied for a muscle to be accepted as the sternalis muscle: (1) location between the superficial fascia of the anterior thoracic region and the pectoral fascia; (2) origin from the sternum or infraclavicular region; (3) insertion onto the lower ribs, costal cartilages, aponeurosis of the external abdominal oblique muscle, or the sheath of the rectus abdominis muscle; (4) innervation by the anterior thoracic (pectoral) and/or intercostal nerves.

2.1. Innervation and Vascularization

Based on the innervation patterns of 26 sternalis muscles in 20 cadavers,⁶ the sternalis muscle was considered a variant of either the pectoralis major or rectus abdominis muscles. Sixteen of 26 sternalis muscles (62%) received their innervation from intercostal nerves (anterior primary divisions of thoracic spinal nerves) and were considered homologous to the rectus abdominis muscle. The remaining 38% received their innervation from the cervical plexus, usually via the medial pectoral nerve, which is derived from spinal nerves C8 and T1, so that these muscles were considered homologous with the sternal portion of the pectoralis major muscle. Two muscles received a dual innervation.⁶ Whether the sternalis muscle has an exact analogue in other species has been the subject of unresolved controversy. Its diverse innervation suggests that it may represent variable remnants of several muscles.

The blood supply is primarily derived from the perforating branches of the internal thoracic artery^{1,15-20} with additional supply from intermuscular connections from the pectoral branch of the thoracoacromial artery.¹⁹

2.2. Function

No skeletal movement is attributed to this muscle. No electromyographic data or clinical reports of muscular contraction of the sternalis muscle were located; thus, if, when, or why it contracts is unresolved. The sternalis muscle has no apparent physiologic function.³ Owing to its parasternal location, the sternalis muscle has been reported to confuse

radiologists by presenting as an irregular mass in the medial breast on routine mammograms, leading to the misdiagnosis of breast tumors^{4, 21, 22} or hematomas.²³

2.3. Functional Unit

The functional unit to which a muscle belongs includes the muscles that reinforce and counter its actions as well as the joints that the muscle crosses. The interdependence of these structures functionally is reflected in the organization and neural connections of the sensory motor cortex. The functional unit is emphasized because the presence of a TrP in one muscle of the unit increases the likelihood that the other muscles of the unit will also develop TrPs. When inactivating TrPs in a muscle, one must be concerned about TrPs that may develop in muscles that are functionally interdependent.²⁴ The functional relation of the sternalis muscle to other muscles must await determination of its specific function.

3. CLINICAL PRESENTATION

3.1. Referred Pain Pattern

The referred pain pattern of the sternalis muscle usually includes the entire sternal and substernal region and may extend on the ipsilateral side across the upper pectoral area and front of the shoulder to the underarm and to the ulnar aspect of the elbow (Figure 43-2).²⁵⁻²⁷ This pattern closely mimics the substernal ache of myocardial infarction or angina pectoris. The chest pain referred from this muscle has a terrifying quality that is remarkably independent of body movement. The left-sided pattern of the sternalis muscle differs from the referred pain of the left pectoralis major muscle in that the latter is more likely to extend beyond the elbow into the ulnar aspect of the left forearm and hand. Both muscles may contribute simultaneously to the pain reported by the patient.^{26, 28, 29}

Figure 43-2. A TrP in the left sternalis muscle gives rise to the referred pain pattern shown in red.

Trigger points may be located anywhere within the sternalis muscle: as high as the manubrium, as low as the xiphoid process, and on either or both sides, including the midline of the sternum when the muscle fuses across the sternum. Sternalis TrPs usually occur over the upper two-thirds of the sternum and are most likely to be found in the central part of the muscle, slightly to the left of the midline at the midsternal level. Anatomically, a unilateral muscle is more common on the right than on the left, but active TrPs appear to be more common on the left side, probably because of their activation from the heart from a viscerosomatic reflex.

Though the sternalis muscle may be only a small remnant of muscle, the intensity of pain arising from TrPs in it (or any other muscle) is not related to the size of the muscle, but to the degree of irritability and size of the TrPs.

At times, a TrP located at the confluence of the sternalis, pectoralis major, and sternal division of the sternocleidomastoid muscles can be the source of a dry, hacking cough. Palpation and treatment for the TrP may temporarily produce the cough but it slowly dissipates.

3.2. Symptoms

The symptoms associated with TrPs in this muscle are intense deep substernal pain and occasionally, soreness over the sternum. Since the pain arising from this muscle is not aggravated by movement, its musculoskeletal origin is easily overlooked.

3.3. Patient Examination

After a thorough subjective examination the clinician should make a detailed drawing representing the pain pattern that the patient has described. This depiction will assist in planning the physical examination and can be useful in monitoring the progression of the patient as symptoms improve or change. Any patient with primary reports of chest pain should alert the clinician to perform a thorough review of the cardiovascular and pulmonary systems. Any concerns regarding the involvement of the cardiovascular or respiratory systems as a source of symptoms should result in an immediate referral to the emergency room or a physician. Range-of-motion tests are typically negative in a patient with sternalis TrPs, since the pain is neither relieved nor aggravated by any musculoskeletal activity, such as movement of the shoulder girdle, deep breathing, or stooping. Trigger point palpation is the only confirming sign that TrPs in the sternalis muscle are the source of the patient's symptoms.

3.4. Trigger Point Examination

Sternalis TrPs are found by systematic cross-fiber flat palpation against the underlying sternum and costal cartilages (Figure 43-3). Firm pressure elicits focal deep tenderness at the TrP and projection of referred pain but rarely elicits a local twitch response. On examination, the patient has difficulty in distinguishing between the local and the referred pain that is elicited from this muscle, unless the pain radiates not only to the sternum but also to the shoulder or arm. Referred pain responses due to needle penetration of the TrP are more clearly distinguishable. Trigger points in the central part of the muscle are most commonly found to the left or right of the midline at the midsternal level.^{26,30}

Figure 43-3. Palpation of left sternalis muscle.

4. DIFFERENTIAL DIAGNOSIS

4.1. Activation and Perpetuation of Trigger Points

Since the sternalis muscle has no confirmed movement function, TrPs are thought to be activated, not by muscle loading or exercise, as is typical, but instead by its location within or proximity to the referral pain areas of other tissues. It is important to realize that patients with either acute myocardial infarction or angina pectoris are likely to develop active TrPs in both the sternalis and left pectoralis major and minor muscles. A sternalis TrP activated by an episode of myocardial ischemia, as in acute infarction, is likely to persist long after this initiating event.

4.2. Associated Trigger Points

Associated TrPs can develop in the referred pain areas caused by a TrP.³¹ Therefore, musculature in the referred pain areas for each muscle should also be considered. One rarely observes sternalis TrPs alone without the presence of TrPs in the pectoralis major and/or minor muscles. The possibility that a sternalis TrP is associated with other TrPs makes it important to examine the lower portion of the sternal division of the sternocleidomastoid muscle, which may refer pain downward over the sternum. Activation of TrPs also may result from direct trauma to the costosternal area.

4.3. Associated Pathology

The sternalis muscle has major implications in breast and thoracic surgery. When undetected before surgery it can interfere with procedures, leading to longer operative times. Yet when detected preoperatively it can be used as a muscular flap in reconstructive surgery and improve aesthetic results in breast augmentation by providing extra cover for the prosthesis.¹

When multiple areas of spot tenderness are found over the costochondral junctions without the referred pain feature of sternalis TrPs, the clinician should consider costochondritis or Tietze's syndrome.³² This syndrome is identified by upper anterior chest pain with tender, nonsuppurative swelling in the area of the costal cartilages or the sternoclavicular junctions. Multiple lesions are more frequent than single lesions and usually involve adjacent articulations. Also, in Tietze's syndrome, systemic manifestations are absent and radiographic and laboratory studies are normal, except for occasional reports of increased calcification at affected sites.³² The importance of distinguishing between chest pain of cardiac origin and that of chest wall origin has been emphasized.³³

In addition to costochondritis and cardiac disease, the clinician should consider gastroesophageal reflux, esophagitis, and an anginal presentation of C7 radicular symptoms. Conversely, a mistaken diagnosis of one of these conditions can be made when the symptoms arise from sternalis TrPs.

5. CORRECTIVE ACTIONS

For acute pain situations, due to sternalis TrP pain, the patient should be instructed to lie on their back with a quarter turn toward the side of discomfort (in slight flexion and rotation/side bending to the side of pain, if unilateral) with slight neck flexion due to its connection to sternocleidomastoid muscle and its interaction with the pectoralis major muscle.

As pain becomes less severe, it is important to educate patients in appropriate postures that promote neutral spine positions and rib positioning. Instruction in proper breathing patterns, emphasizing diaphragmatic breathing patterns more than upper chest respiratory patterns, as well as core and scapular stability is also important.

The patient should learn to perform self-pressure release on his or her own sternalis TrPs, followed by application of moist heat. The patient selects a tender spot and presses on it steadily against the underlying bone with one finger to the point of discomfort and holds it until it fully releases (Figure 43-4). This release is assisted by slow relaxed exhalation. It may remain quiescent indefinitely, unless the TrP is reactivated, as by recurring angina pectoris.³⁴

Figure 43-4. Trigger point self-pressure release.

Stretch of the sternalis muscle is not practical except for clinician applied myofascial release techniques, TrP injection, or dry needling techniques. Deep friction massage applied to the muscle fibers in the region of the TrP may also be beneficial.

Local treatment of sternalis TrPs is not complete until TrPs in the pectoralis major and/or minor muscles and the inferior end of the sternal division of the sternocleidomastoid muscle have been treated. The patient is less likely to experience recurrence of pain due to TrPs in the sternalis muscle if these other two muscles are also

released.

Pectoralis Minor Muscle

“Thoracic Outlet Imposter”

Joseph M. Donnelly and Deanna Hortman Camilo

1. INTRODUCTION

The pectoralis minor muscle is a thin, flat muscle that lies under the pectoralis major muscle along the anterior portion of the third, fourth, and fifth ribs. It moves the scapula forward (anterior tilt), downward, and inward (internal rotation) to depress the glenohumeral joint and stabilize the scapula when the upper extremity is moving downward against resistance. Pectoralis minor muscle length deficit is thought to be an important contributing factor to subacromial pain syndrome. Trigger points (TrPs) in the pectoralis minor muscle refer pain over the anterior deltoid region, often extending along the ulnar side of the arm, elbow, forearm, and palmar aspect of the hand to include the last three fingers. Symptoms may be exacerbated by slumped or rounded shoulder posture as well as with repetitive activities including throwing, gardening, crutch walking, and paradoxical breathing. Differential diagnosis should include thoracic outlet syndrome, C7 and C8 radicular pain or radiculopathy, supraspinatus or bicipital tendinopathy, and medial epicondylalgia. Corrective actions involve techniques to improve posture, effective workplace ergonomics, neutral sleeping positions, TrP self-pressure release, and self-stretching techniques.

2. ANATOMIC CONSIDERATIONS

The pectoralis minor muscle is a thin triangular shaped muscle that is seated immediately posteriorly to the pectoralis major muscle and lies over the rib cage. Notably, the anatomic relationship between the costal origin of the pectoralis major and minor muscles is highly variable in relation to the intermuscular space.¹ It originates from the outer surface of ribs three, four, and five and occasionally as high as the first rib and as low as the sixth rib near their costal cartilage and from the fascia of the external intercostal muscles.² The fibers ascend laterally and insert onto the medial border and superior surface of the coracoid

process of the scapula (Figure 44-1).^{2,3} A slip of the pectoralis minor muscle may extend beyond the coracoid process in about 15% of bodies to attach to tendons of adjacent muscles or to the greater tuberosity of the humerus.⁴ In fact, Lee et al⁵ reported a prevalence of 13.4% of ectopic insertion of the pectoralis minor muscle. Weinstabl et al⁶ also found that the pectoralis minor muscle had a continuous connection with the coracohumeral ligament in their study of 126 shoulder specimens, which is consistent with more recent sources.^{2,6,7}

Figure 44-1. Attachments of the pectoralis minor muscle (*red*) to the coracoid process of the scapula and to the third, fourth, and fifth ribs.

The tip of the coracoid process of the scapula also provides a site of attachment for the tendons of the coracobrachialis and short head of the biceps brachii muscles. These tendinous insertions are encased by the clavipectoral fascia.²

Although rare, other anatomic variations of the pectoralis minor muscle include the pectoralis minimus and pectoralis intermedius muscles. The pectoralis minimus muscle connects the first rib cartilage to the coracoid process, whereas the pectoralis intermedius muscle may attach more medially than the pectoralis minor muscle onto the third, fourth, and fifth rib cartilages and above the clavipectoral fascia covering the coracobrachialis and biceps brachii muscles. This arrangement sandwiches the pectoralis intermedius muscle between the pectoralis major and minor muscles.

Approximately 40% of pectoralis minor muscle fibers are type II, decreasing slightly after age 60. The volume of type II fibers is significantly decreased after that age.⁸

2.1. Innervation and Vascularization

The pectoralis minor muscle is innervated by branches of the medial and lateral pectoral nerves.² The lateral pectoral nerve is derived from spinal nerves C5, C6, and C7 and lies anterior to the muscle along with branches of the thoracoacromial artery. The medial pectoral nerve is a branch from the medial cord and is comprised of fibers from roots C8 and T1. It innervates and pierces the pectoralis minor muscle en route to innervate the sternal head of the pectoralis major muscle.^{2,9,10} Mehta et al¹¹ described a case report of an unusual innervation presentation of the pectoralis minor muscle in which the pectoralis minor muscle was pierced extensively by multiple branches from the medial pectoral nerve, but none from the lateral pectoral nerve.

Porzionato et al¹² demonstrated that the medial pectoral nerve originates from the medial cord in 49.3% of specimens, the anterior division of the lower trunk in 43.8% of specimens, and the lower trunk in 4.7% of specimens. The distal portion of the brachial plexus passes deep to the pectoralis minor muscle where the muscle attaches to the coracoid process,² which may explain the potential role of this muscle in thoracic outlet syndrome symptoms.

The primary vascular supply of the pectoralis minor muscle is through the deltoid and pectoral branches of the thoracoacromial artery and by branches of the lateral and superior thoracic arteries.² Although the lateral thoracic artery shows morphologic variability, it usually descends on the lateral border of the pectoralis minor muscle.¹³

The pectoralis minor muscle is the landmark for anatomically dividing the axillary artery into three parts: the first part superior to its medial border, the second part of the artery deep to the muscle, and the third part inferior to its lateral border. The upper border of the pectoralis minor muscle is separated from the clavicle by a triangular gap created by the clavipectoral fascia and the axillary vessels, nerves, and lymphatics lie posterior to this structure, just before they pass under the pectoralis minor muscle into the brachium.² When the arm is abducted and externally rotated at the shoulder (Figure 44-2A), the artery, vein, and nerves are bent and stretched around the pectoralis minor muscle near its attachment (Figure 44-2B). The neurovascular structures are likely to be compressed if the pectoralis minor muscle is tightened by TrPs or from increased pectoralis minor muscle tension, which also increases the entrapment potential of the C7 and C8 roots that pass

over the first rib, contributing to thoracic outlet syndrome symptoms.¹⁴

A

B

Figure 44-2. Entrapment of the lower brachial plexus and axillary artery by the right pectoralis minor muscle during the Wright full-abduction test. A, Abduction test position. B, Stretch and torsion of the brachial plexus and axillary artery can occur as they hook beneath the pectoralis minor muscle where it attaches to the coracoid process. The clavicle may also compress these neurovascular structures directly against the first rib as the scapula is forcefully pulled into adduction.

2.2. Function

The pectoralis minor muscle is one of five muscles that can both initiate and control scapular movement. The pectoralis minor muscle acts synergistically with the serratus anterior muscle to perform scapular protraction. If contracted independently, it performs a combination of movements including anterior tilting, protraction, and downward rotation of the scapula.¹⁵ Since the inward force component is blocked by the clavicle when the pectoralis minor muscle contracts, there is an associated elevation of the scapula and a resultant force that draws the glenoid fossa of the scapula obliquely down and forward (anterior tilt). At the same time, this force tends to lift the scapula's medial border and inferior angle away from the rib cage (winging of the scapula).¹⁶

The shoulder depression function of the pectoralis major and latissimus dorsi muscles is assisted by the pectoralis minor muscle that directly depresses the scapula through its attachment on the coracoid process. Depression of the shoulder by the pectoralis minor muscle stabilizes the scapula when the arm exerts a downward pressure against resistance.¹⁷ This coracoid depression is used to elevate and pull the shoulder forward. The pectoralis minor muscle stabilizes the scapula against any elevation force, as needed during activities such as crutch walking, driving a stake into the ground, and digging holes.¹⁶

Wickham et al¹⁸ investigated muscle activity using electromyography (EMG) on 15 shoulder muscles during shoulder elevation. These authors found that the supraspinatus, middle deltoid, and middle trapezius muscles activated prior to limb movement and the pectoralis minor muscle was the second to last muscle to activate (at 16° of shoulder elevation) with a peak maximum volitional isometric contraction (MVIC) of 30% between 135° and 165° of shoulder elevation.¹⁸ Castelein et al,¹⁵ in an attempt to identify MVIC of the deep scapulothoracic muscles utilizing fine wire EMG, found six positions that maximally activated the pectoralis minor muscle. The test position that activated the pectoralis minor muscle to the highest MVIC was the combination of internal rotation and glenohumeral elevation to 90° in the coronal plane. The investigators surmised that this position requires the pectoralis minor muscle to pull the scapula anteriorly and inferiorly toward the ribs to stabilize the scapula during resisted glenohumeral internal rotation.¹⁵ They also found that pure protraction from the supine position, as described by Kendall et al¹⁹ for a manual muscle test of this muscle, produced 11% less MVIC than the other test positions. They conclude that clinical tests utilized to look at pectoralis minor muscle strength may not automatically lead to highest EMG activation, especially when utilizing fine wire EMG.¹⁵

Castelein et al²⁰ also investigated the role of the pectoralis minor muscle as a synergist to the serratus anterior muscle during three common exercises (modified push up plus on the wall, modified knee push up on the floor, and serratus punch standing) utilizing surface and fine wire EMG. The wall pushup plus and the modified knee push up on the floor activated the pectoralis minor and serratus anterior muscles very similarly; however, the serratus anterior punch standing maximally activated the serratus anterior muscle with minimal synergistic activation of the pectoralis minor muscle.²⁰

The main function of the pectoralis minor muscle is to provide scapular stabilization, especially during functional activities. Therefore, it has a propensity to lose its extensibility, which places the scapula in an abnormal position and leads to rounded shoulder posture, subacromial pain syndrome, and scapular dyskinesia.^{3,–21,22} The role of the pectoralis minor muscle in subacromial impingement syndrome during elevation activities was investigated using surface and fine wire EMG on the superficial and deep scapulothoracic muscle respectively.²³ This study compared scapulothoracic muscle activation during shoulder elevation between individuals with subacromial impingement syndrome and asymptomatic controls. They found that the pectoralis minor muscle was significantly more active in the patient group during all elevation activities as compared to the control group, a result that supports the theory that the pectoralis minor muscle has a role in subacromial impingement syndrome.

2.3. Functional Unit

The functional unit to which a muscle belongs includes the muscles that reinforce and counter its actions as well as the joints that the muscle crosses. The interdependence of these structures functionally is reflected in the organization and neural connections of the sensory motor cortex. The functional unit is emphasized because the presence of a TrP in one muscle of the unit increases the likelihood that the other muscles of the unit will also develop TrPs. When inactivating TrPs in a muscle, one must be concerned about TrPs that may develop in muscles that are functionally interdependent. Box 44-1 grossly represents the functional unit of the pectoralis minor muscle.²⁴

Box 44-1 Functional unit of the pectoralis minor muscle

Action	Synergists	Antagonist
Shoulder depression	Pectoralis major Subclavius Latissimus dorsi Teres major Trapezius (lower) Serratus anterior	Trapezius (upper) Levator scapulae Rhomboids

Shoulder protraction	Serratus anterior Pectoralis major Subclavius	Rhomboideus major Rhomboideus minor Trapezius (middle, lower)
----------------------	---	--

The pectoralis minor muscle forms a synergistic functional unit that creates additional support for vigorous inhalation with the levator scapulae, upper trapezius, and sternocleidomastoid muscles in addition to the parasternal internal intercostals, lateral external intercostals, diaphragm, and scalene muscles. Additionally, electromyographically, the pectoralis minor muscle is active in forced inspiration but not in quiet breathing.¹⁶

3. CLINICAL PRESENTATION

3.1. Referred Pain Pattern

Trigger points in the pectoralis minor muscle refer pain most strongly over the anterior deltoid area. The pain may extend upward over the subclavicular area and sometimes covers the entire pectoral region on the ipsilateral side. Pain can also be referred along the ulnar side of the arm, elbow, forearm, and palmar aspect of the hand to include the medial three fingers (Figure 44-3). A similar referral pattern can be found with TrPs in the clavicular division of the pectoralis major muscle (see Figure 42-3B).²⁵ Pain from either pectoral muscle, and specifically the pectoralis minor muscle, can closely mimic the pain of cardiac ischemia.^{26,27} In fact, Lawson et al²⁸ described a case report when the pectoralis minor muscle was the pain source in a patient with anterior chest pain. Proper treatment of the pectoralis muscle was effective for reducing symptoms.

Figure 44-3. Referred pain pattern (*solid red* is the essential portion, *stippled red* shows the spillover portion) in the right pectoralis minor muscle.

3.2. Symptoms

Trigger points in the pectoralis minor muscle should be considered as a potential source of symptoms when a patient reports pain or difficulty with reaching forward and up or reaching backward with the arm at shoulder level. When the patient's primary report of pain is in the anterior aspect of the shoulder, the pectoralis major and minor, subclavius, infraspinatus, supraspinatus, deltoid (anterior, middle), biceps brachii, coracobrachialis, and scalene muscles are the most likely muscular sources of symptoms.²⁹ The intensity and quality, as well as the distribution, of cardiac pain may be reproduced by this pectoral muscle's referred pain pattern.^{27, 28}

The shortened pectoralis minor muscle may cause distinctive neurovascular symptoms through entrapment of the axillary neurovascular bundle below the clavicle.^{30, 31} This condition is known as pectoralis minor syndrome and may result in "pain, weakness, paresthesias, and arterial/venous insufficiency" of the affected upper extremity.³⁰ Pectoralis minor muscle shortening or tightness must also be considered in cases of brachial plexus compression.³¹ The outcomes of patients with thoracic outlet syndrome and pectoralis minor syndrome vary and depend on duration of symptoms before initiation of physical therapy or surgical intervention.^{30, 31} In fact, in some patients with neurogenic thoracic outlet syndrome, the isolated treatment of pectoralis minor muscle can be very effective, thus supporting the role of this muscle in this symptomatology.³²

When the patient reports swelling in the hand and fingers these symptoms are more closely associated with TrPs in the scalene muscles as the axillary vein is located under the scalene muscle but not under the pectoralis minor muscle. Thoracic outlet syndrome and TrP considerations are presented in Chapter 33.

3.3. Patient Examination

After a thorough subjective examination the clinician should make a detailed drawing representing the pain pattern that the patient has described. This depiction will assist in planning the physical examination and can be useful in monitoring the progression of the patient as symptoms improve or change. Any patient with primary reports of chest pain should alert the clinician to perform a thorough review of the cardiovascular and pulmonary systems. Any concerns regarding the involvement of the cardiovascular or pulmonary systems as a source of symptoms should result in an immediate referral to the emergency room or a physician. For proper examination of the pectoralis minor muscle, the clinician should observe shoulder girdle posture, scapular position, active and passive range of motion of the shoulder girdle, muscle activation patterns, and the scapulohumeral rhythm. The clinician should note when and where pain occurs. A patient with significant TrPs and shortening of the pectoralis minor muscle will usually demonstrate rounded shoulders because of the forward and downward tilt of the coracoid process caused by the pectoralis minor muscle. Lee et al³³ recently observed a negative correlation between the degree of forward scapular posture and pectoralis minor muscle shortening. In fact, the adaptive shortening or tightness of the pectoralis minor muscle is one of the potential biomechanical mechanisms associated with altered scapular alignment at rest and scapular motion during arm elevation (scapular dyskinesis) in patients with shoulder complaints.³⁴ Stretching of the pectoralis minor muscle has been found to be effective for reducing rounded shoulder posture²¹ and for increasing pectoralis minor muscle length.³⁵ When observing the patient from the rear, the clinician may note scapular position and asymmetries. The medial and inferior border of the scapula may be off the rib cage giving the appearance of a “winged scapula.” This abnormal resting position will cause scapular dyskinesia during functional upper extremity movements.

The increased tension due to TrPs in the pectoralis minor muscle prevents the patient from reaching fully behind the back at shoulder level and overhead efficiently due to scapular dyskinesia. The anterior depression of the coracoid process and downward rotation of the glenoid fossa that are caused by pectoralis minor muscle tension limits full elevation of the arm at the shoulder girdle. Examination of pectoralis minor muscle length is essential when the patient presents with subacromial impingement syndrome. Borstad³ established excellent interrater reliability for examining pectoralis minor muscle length using the Pectoralis Minor Index (PMI) which accounts for the patient’s anthropometrics. Other investigators have found excellent interrater reliability to determine pectoralis muscle length in patients with subacromial impingement syndrome and healthy controls.^{36,37}

When the pectoralis minor and subscapularis muscles are shortened by TrPs, they

restrict the combined movement of abduction and external rotation at the shoulder. However, subscapularis TrPs primarily restrict glenohumeral motion, whereas pectoralis minor TrPs restrict scapular mobility on the chest wall. With the arm abducted to 90°, external rotation is restricted markedly by both muscles; however, with the shoulder at 45° elevation,³⁸ the subscapularis muscle primarily restricts external rotation. Also, when elevation of the shoulder is restricted by pectoralis minor muscle tautness, the patient may be aware of pulling on the ribs or tightness in the anterior chest wall at the limit of elevation.

Accessory joint motion should be tested in the glenohumeral joint, acromioclavicular joint, sternoclavicular joint, scapulothoracic joints, and thoracic rib cage. Oftentimes, joint hypomobility in the sternoclavicular joint or rib cage can cause impairment in shoulder elevation contributing to alterations in the normal muscle activation patterns. Articular dysfunctions in the glenohumeral joint may also impair muscle activation patterns contributing to overload of the pectoralis minor and rotator cuff muscles.

A cervical screen, neurologic signs, and mobility of the neural tissues of the shoulder girdle and upper extremity should be investigated to eliminate neural symptoms as source of the patient's symptoms. If referred hand and/or finger pain is present, a clinical examination of local tissues at the wrist and hand should be also conducted. The Wright's test for hyper-abduction syndrome should also be performed to rule out vascular compromise from a shortened pectoralis minor muscle.³⁹

Symptoms from TrPs in the pectoralis minor muscle must be differentiated from scalene TrPs as the pain referral pattern in the anterior chest and upper extremity is very similar. The Finger-flexion test (see Figure 20-6) may be utilized to differentiate scalene from pectoralis minor muscle involvement. If this test is positive, the scalene muscles may be implicated, as TrPs or restrictions in the pectoralis minor muscle will not affect this test.

The patient with chest pain due to pectoralis minor TrPs is likely to suffer additional referred pain and restriction of movement at the shoulder due to associated TrPs in functionally related shoulder girdle muscles which also need to be considered.

3.4. Trigger Point Examination

The pectoralis major muscle should be examined first for active TrPs that might obscure and confuse the localization of TrPs in the underlying pectoralis minor muscle. If the clinician is unsure of the position of the pectoralis minor muscle under the pectoralis major muscle, it can be located by palpation when the patient tenses the pectoralis minor muscle by performing shoulder protraction. To do this, the patient is positioned supine and is instructed to raise the shoulder away from the examining table, while relaxing the arm and carefully avoiding downward pressure against the table with the hand. In the seated position, the patient holds the arm close to the side and a little to the rear to inhibit the pectoralis major muscle, then strongly protracts the shoulder and inhales deeply with the chest. Both maneuvers activate the pectoralis minor muscle so that it can be identified.

In both the supine and seated positions, pectoralis minor TrPs can be localized either

by cross-fiber flat palpation through the pectoralis major muscle against the chest wall (Figure 44-4A) or by cross-fiber pincer palpation (Figure 44-4B). With either approach, the pectoralis major muscle is slackened by keeping the patient's arm toward the front of the body and the forearm on the abdomen, and the pectoralis minor muscle may be placed on the desired degree of stretch by adducting the scapula toward the military-brace position. The two pectoral muscles may be distinguished by noting the muscle fiber direction of palpable bands and of local twitch responses.

Figure 44-4. Palpation of TrPs in the pectoralis minor muscle. The overlying pectoralis major muscle is slackened by supporting the arm as shown, or by placing the forearm on the abdomen. A, Cross-fiber flat palpation of the pectoralis minor muscle through the pectoralis major muscle. B, Cross-fiber pincer palpation around the pectoralis major muscle. The thumb contacts the pectoralis minor muscle anteriorly and the fingers grasp it through the pectoralis major muscle. Together they can partially separate it from the chest wall. The pectoralis minor muscle may be tautened for better identification of its TrPs by elevating the shoulder.

In the supine position, the pectoralis minor muscle can usually be palpated directly by cross-fiber pincer palpation (Figure 44-4B). The pectoralis major muscle may be further slackened by placing the arm in the position described above, and if additional relief is necessary, the shoulder is protracted by placing a towel roll under it. The clinician places the thumb in the apex of the axilla and slides it against the chest wall beneath the pectoralis major muscle toward the midline, until it encounters the muscle mass of the pectoralis minor muscle. That muscle (and the pectoralis major muscle above it) are then encompassed by a pincer grasp between the thumb and fingers (Figure 44-4B) partially separating it from the chest wall. The fibers of the pectoralis minor muscle can then be

palpated directly through the skin for a taut band and hyperirritable spot tenderness. Identification of TrPs in the pectoralis minor muscle may be enhanced by elevating the shoulder cephalad to tauten the pectoralis minor muscle, which increases the sensitivity of its TrPs without tightening the pectoralis major muscle.

4. DIFFERENTIAL DIAGNOSIS

4.1. Activation and Perpetuation of Trigger Points

In any part of the pectoralis minor muscle, TrPs may be activated by unaccustomed eccentric loading, eccentric exercise in unconditioned pectoralis minor muscle, or maximal or submaximal concentric loading.⁴⁰ Trigger points may also be activated or aggravated when the muscle is placed in a shortened or lengthened position for an extended period of time.

Pectoralis minor TrPs may be activated due to their presence within the zone of pain induced by myocardial ischemia, by trauma (a gunshot wound through the upper chest, or fracture of upper ribs), by a whiplash type motor vehicle accident,⁴¹ by strain through overuse as a shoulder depressor, by overload as an accessory muscle of inspiration (severe coughing or to assist paradoxical breathing), by poor seated posture, or by prolonged compression of the muscle with a backpack with a tight strap over the front of the shoulder. Habitually slumped posture, rounded shoulder posture, and forward head posture can also activate and perpetuate TrP formation in the pectoralis minor muscle. Repetitive forceful downward motions of the arms (crutch walking), working with arms out in front for a long period of time, heavy lifting, overhead throwing, volleyball, or tennis can overload the pectoralis minor muscle due to its association with scapular stabilization during shoulder internal rotation with the upper extremity in an elevated position. Weakness of the lower trapezius muscle can allow the scapula to anteriorly tilt and lead to adaptive shortening of the pectoralis minor muscle, activating or perpetuating TrPs in the muscle.

4.2. Associated Trigger Points

Associated TrPs can develop in the referred pain areas of TrPs in another muscle.⁴² Therefore, musculature in the referred pain areas for each muscle should also be considered.

Trigger points within the pectoralis minor muscle rarely occur without TrPs in the pectoralis major muscle. Therefore, the same muscles that are commonly associated with pectoralis major muscle involvement are likely to have associated TrPs when the pectoralis minor muscle is involved. The anterior deltoid, scalene, and sternocleidomastoid muscles should be examined for the presence of TrPs. The coracobrachialis, biceps brachii, flexor carpi ulnaris, flexor digitorum superficialis and profundus, and abductor digiti minimi muscles are all within the pain referral pattern of the pectoralis minor muscle and should be considered.

In addition, muscles that comprise the functional unit may also have associated TrPs. The teres major and latissimus dorsi muscles, which are also part of the synergistic

functional unit, may develop TrPs. Involvement of antagonists such as the levator scapulae, rhomboids, middle and lower trapezius muscles often follows, especially in a patient with a rounded shoulder posture.

4.3. Associated Pathology

Differential diagnosis of symptoms caused by TrPs in the pectoralis minor muscle includes thoracic outlet syndrome, pectoralis minor syndrome, C7 and C8 radicular pain or radiculopathy, supraspinatus tendinopathy, bicipital tendinopathy, and medial epicondylalgia.

Pectoralis minor syndrome is differentiated from thoracic outlet syndrome by the area in which the neurovascular bundle is compressed.³¹ Thoracic outlet syndrome often involves compression of the neurovascular bundle above the clavicle in the scalene triangle.³¹ Pectoralis minor syndrome involves compression of the subclavian artery, subclavian vein, and brachial plexus below the clavicle within the sub-pectoralis minor muscle space.^{30,31} Typical clinical presentation of pectoralis minor syndrome includes tenderness over the pectoralis minor tendon in addition to weakness, pain, paresthesias, and/or temperature changes in the affected upper extremity.³⁰ Special tests used to diagnose pectoralis minor syndrome and thoracic outlet syndrome include Roos, Adson's, Halsted's, and Wright's hyper-abduction tests (see Chapter 33). These tests should be used in combination with neurodynamic testing, myotomal testing, and dermatomal testing in order to differentiate pectoralis minor syndrome from pectoralis minor TrPs.

Articular dysfunctions likely to be associated with pectoralis minor TrPs includes elevation of the third, fourth, and fifth ribs.

5. CORRECTIVE ACTIONS

The patient with pectoralis minor TrPs should modify activities that repeatedly stress this muscle such as carrying a heavy backpack, weight training (especially bench press), and any other activity that overwork the pectoral muscles. Correction of rounded shoulder posture²¹ and maintenance of good dynamic posture are essential for lasting relief of pectoralis minor TrPs. In standing, patients should not be encouraged to actively hold their shoulders back or stand in a "military type posture" as this will aggravate the pectoral and interscapular TrPs. Focusing on the head position and standing tall will allow the shoulders to find their proper resting position. When sleeping, the patient must avoid shortening of the pectoralis minor muscle, as occurs when the arms are folded across the chest. When lying on the back, the corner of the pillow should be tucked between the head and shoulder to drop the shoulder backward, not tucked under the shoulder (see Figure 7-5A). A pillow should also be placed between the axilla and chest wall supporting the upper arm so that the arm is in a neutral position. Allowing the arm to fall behind the body will place the pectoralis minor muscle in a prolonged shortened position (see Figure 22-4B).

When sitting for a prolonged period or working at a computer, the chair should be adjusted so as to support the natural lumbar lordosis and the keyboard and monitor

adjusted appropriately to prevent a slouched or rounded shoulder posture. Patients should be discouraged from forcing their shoulders back with muscle action as this will aggravate symptoms. For further information on posture retraining refer to Chapter 76.

Pectoralis minor TrPs can be self-treated with self-pressure release techniques utilizing a tennis ball or other TrP pressure release tools. A TrP release tool or tennis ball may be used in standing, seated, or supine position using the unaffected side to perform the technique (Figure 44-5A). The patient may also perform self-pressure release with the opposite hand as shown in Figure 44-5B. Pressure should be applied to the TrPs, held for 15 to 30 seconds, and repeated six times. This technique can be used several times a day as long as favorable results are being obtained. In women who have large breasts, the supine or side-lying position may be utilized as gravity will aid in moving the breast tissue out of the way. For example, if the right pectoralis minor muscle has TrPs that need treatment, the patient would lie on their left side giving access to the right axillary border for self-treatment with the opposite hand.

Figure 44-5. Pectoralis minor muscle self-pressure release techniques. A, Using a trigger point release tool in supine. B, Patient self-release using opposite hand.

Stretching techniques for this muscle should be gentle and started with the upper extremity in the mid or lower position as stretching this muscle will also stretch the other internal rotators of the shoulder joint and neural tissues. Additionally, the in-doorway stretch is useful to stretch all of the adductors and internal rotators at the shoulders. The patient should learn to maintain full pectoral muscle length by using a corner/doorway stretch (see Figure 42-10) or lying on the back on a foam roller with the arms at the side (Figure 44-6A and B). A gentle stretch is held for 30 seconds and can be repeated up to five or six times. Post isometric relaxation can also be used by asking the patient to take a deep abdominal breath, hold for 6 seconds, and slowly breathe out to their toes and relax. In the relaxation phase, the patient is instructed to reach their hands toward their toes gently stretching the pectoralis minor muscle.

Figure 44-6. Pectoralis minor muscle stretch on bolster. A, Bird's-eye view. B, View from the side.

For full effectiveness with both of these stretch techniques, the patient needs to learn the concept of barrier release. The clinician should instruct the patient to properly stretch the muscle to the point of comfortable tension (without pain), paying attention to any unfamiliar shoulder, chest or interscapular pain, or arm/hand numbness and tingling. If numbness and tingling are felt in the upper arm, forearm, or hands, this exercise should be stopped immediately and the patient should seek guidance from an appropriate health care practitioner.

It is imperative that the clinician and/or patient identifies and limits activities that are leading to overuse of the pectoralis minor muscle. These offending activities may include gardening, working at a desk, ambulation with crutches, and apical breathing patterns.

Intercostal and Diaphragm Muscles

“Stich in the Side”

Joseph M. Donnelly

1. INTRODUCTION

The external and internal intercostal muscles are located between the ribs in a crisscross pattern. The dome-shaped diaphragm muscle has a unique central tendon and separates the thoracic and abdominal cavities. Its central tendon is surrounded by muscle fibers that attach to the inferior thoracic outlet peripherally. The intercostal muscles function in both postural and respiratory roles. The intercostal muscles are mechanically suited for active rotation and side-bending of the thoracic spine and rib cage. The function of the diaphragm muscle is inhalation. During quiet inhalation, the diaphragm, scalene, and parasternal intercostal muscles are active. Exhalation mainly occurs passively by the recoil of the lungs. The abdominal muscles are active during forced expiration. Pain from trigger points (TrPs) in the intercostal muscles primarily refers locally in the region of the TrP. Pain from TrPs in the diaphragm muscle refers to the upper border of the ipsilateral shoulder at the angle of the neck and to the anterolateral costal margin. Symptoms associated with TrPs in the intercostal muscles are pain and limited range of motion (ROM) when rotating to look behind and chest pain that increases with deep respiration, especially when coughing or sneezing. Shortness of breath may be associated with diaphragm TrPs. Patient examination should include a thorough assessment of posture, cervical, and thoracic spine ROM, and respiratory mechanics. Accessory motion testing of the cervical spine, especially C3-C5, thoracic spine and rib cage, and shoulder girdle joints, should be carried out. Trigger point examination for intercostal muscles should start with the painful segment looking for narrowed rib space and continue along the full segment looking for spot tenderness. Diaphragm TrPs are not palpable and can be difficult to differentiate from transverse abdominis muscle tenderness along the costal margin. Differential diagnosis should include rib articular dysfunctions, costochondritis, myocardial infarction, and pleural effusion. Corrective actions to prevent perpetuation and/or recurrence of intercostal or diaphragm TrPs should include postural education, instruction

in diaphragmatic breathing, self-pressure release, and self-stretching.

2. ANATOMIC CONSIDERATIONS

Intercostals

The external and internal intercostal muscles have a crisscross arrangement, crossing each other at nearly a right angle, similar to the external and internal abdominal oblique muscles (see Chapter 49), and in the same directions. Each muscle spans the distance between two ribs (or costal cartilages). The external intercostal muscles are considerably thicker than the internal intercostal muscles. The vessels and nerves supplying these muscles run deep to the internal intercostal muscles and are protected by a slight overhang of the inferior margin of the more cephalad rib. The innermost intercostal muscles, which used to be considered variant subcostal muscles, are located deep to the vessels and nerve and have a fiber direction nearly the same as the corresponding internal intercostal muscles.¹

External Intercostals

The 11 external intercostal muscles on each side do not extend quite the full length of each intercostal space, reaching only to the costal cartilage anteriorly, except between the lowest ribs (Figure 45-1). They do reach the end of the rib posteriorly at the tubercle (Figure 45-2) where they blend with the fibers of the superior costotransverse ligament. Anteriorly, the external intercostal muscles have only a fascial extension, the external intercostal membrane, that reaches to the sternum.² The external fibers are angled obliquely inferomedially as seen from in front (Figure 45-1) and obliquely inferolaterally as seen from behind (Figure 45-2). Each muscle attaches from the lower border of the rib above and to the upper border of the rib below.² Fibers from the lower ribs may blend with the external abdominal oblique muscle.³ Figure 49-2 provides a convenient way of remembering the direction of each muscle.

Figure 45-1. Exterior of anterior thoracic wall, showing the anatomic relations and attachments of intercostal and related respiratory muscles. The external intercostal muscles are darkest red, the internal intercostal muscles are intermediate red. The external intercostal muscles do not extend beyond the costochondral junctions medially, except between the lowest ribs. Other muscles are light red. All but the omohyoid muscle attach to the thoracic cage and could directly influence respiration.

Figure 45-2. Exterior of posterior thoracic wall, showing anatomic relations and attachments of intercostal and related respiratory muscles. The external intercostal muscles are dark red, the internal intercostal muscles are intermediate red. Other muscles are light red. The posterior scalene (cut), external intercostal, and the levatores costarum muscles (levator costae longus and brevis) are primary muscles for inhalation that appear in this figure. The serratus posterior superior muscles help to elevate the ribs during forced inhalation. The serratus posterior inferior (cut), quadratus lumborum (cut), and internal abdominal oblique (cut) muscles shown here may assist exhalation. The detailed drawing between ribs 7 and 8 on the right side shows that the internal intercostal muscles are absent medial to the region of the angle of the ribs but are represented medially as the internal intercostal membrane. The neurovascular bundle runs between the internal intercostal muscle or membrane, which lies superficial to it, and the innermost intercostal muscle or membrane which lies deep to it. The internal intercostal and innermost intercostal muscles have an almost identical fiber direction and are usually referred to collectively as the internal intercostal

muscles. The intercostal neurovascular bundle actually lies deep to the lower border of the cephalad rib and might not be visible from this view.

Levatores Costarum

The 12 posterior, extrathoracic levatores costarum muscles can be considered an extrathoracic nonintercostal version of the external intercostal muscles (Figure 45-2 left side). They attach above to the tips of the transverse processes from C7 through T11 and attach below and more laterally to the adjacent rib (levator costae brevis muscle) between the rib's tubercle and its angle, or in the lower four ribs the muscle has two slips that span to the adjacent lower rib or to the second rib below its origin (levator costae longus muscle).²

Each muscle attaches above from the costal groove of the cephalad rib and inserts to the superior border of the rib below.² The internal intercostal fiber direction is the reverse of the direction of the external intercostal fibers; the internal intercostal fibers are angled obliquely inferolaterally in the front of the chest (Figures 45-1, 45-3 and 45-8). Since the muscle has the same fiber direction as it continues around the chest, the fibers appear to be angled obliquely inferomedially when viewed in the back of the chest (Figure 45-3).

Figure 45-3. Interior of the posterior chest wall showing anatomic relations and attachments of the intercostal muscles and also major blood vessels. The internal intercostal muscles are intermediate red. The diaphragm and external intercostal muscles are dark red, and the arteries are darkest red. Other muscles are light red. Reproduced and adapted with permission from Ferner H, Staubesand J. *Sobotta Atlas of Human Anatomy*. Vol. 2. Munich: Urban & Schwarzenberg; 1983.

Innermost Intercostals

The innermost intercostal muscles lie between the intercostal nerves and vessels and the endothoracic fascia and parietal pleura. When present, they run tandem with the inner intercostal muscles. They are often unsubstantiated in the highest levels of the thoracic spine and generally thicken into existence inferiorly. They may interdigitate with the neighboring subcostales muscles posteriorly.¹

Subcostales

The subcostales muscle can be considered a variation of the internal intercostal muscles. The subcostales muscle spans from the upper ribs internal surface near the rib angle and descends to attach to the second or third rib below. It has the same fiber direction as the internal intercostals and is most fully developed in the lower part of the thorax.² The subcostales muscle very likely functions in concert with the internal intercostal muscles of the lower thorax.

Transverse Thoracis

The transversus thoracis muscle is an interior, anterior chest muscle that covers the internal surface of the anterior thoracic wall and is not intercostal (Figure 45-4).² It lies deep to the sternum and the parasternal intercostal muscles and is composed of tendinous and muscular fibers that attach in a fan-like arrangement. The upper digitations of the muscle reach from the inner surface of the lower sternum and xiphoid process upward (craniad) to the costal cartilages of the second to sixth ribs in a vertical arrangement. The intermediate fibers have an oblique arrangement, and the lowest fibers are essentially horizontal and blend with the fibers of the transversus abdominis muscle. The transverse thoracis muscle varies in its attachments side to side in the same individual and is variable between individuals.²

Figure 45-4. Interior of the anterior thoracic wall. The subclavian and internal thoracic arteries are darkest red, the diaphragm muscle (shown in part and only on the left side) is dark red, the internal intercostal muscles are intermediate red, and the remaining muscles are light red. Note that, generally, only the internal intercostal muscles continue anteriorly and as far medially as the sternum (completing coverage of the anterior costal interspaces). The external intercostal muscles (not seen in this view) stop short at the costochondral junctions. The diaphragm muscle is a primary muscle for inhalation. Note how it extends downward to lie against the lowest rib. Reproduced and adapted with permission from Agur AM. *Grant's Atlas of Anatomy*. 9th ed. Baltimore, MD: Williams & Wilkins; 1991.

Diaphragm

The diaphragm muscle is a dome-shaped musculofibrous structure that separates the thoracic and abdominal cavities (Figures 45-4 and 45-5).⁴ The dome of the diaphragm muscle has a central tendon which is a strong aponeurosis situated near the center of the muscle. Centrally, it lies immediately inferior to and is blended with fibers of the pericardium.² It is surrounded by muscle fibers that form an extended “skirt” that attaches peripherally to the circumference of the inferior thoracic outlet. The muscle is divided into

a sternal portion that attaches anteriorly to the sternum, a costal portion that attaches laterally to the costal margin, and a lumbar portion that attaches posteriorly by the paired medial and lateral arcuate ligaments. The sternal portion arises from the posterior aspect of the xiphoid process. The costal portion arises from the internal surfaces of the costal cartilages and internal surfaces of the lower six ribs which also interdigitates with the transverse abdominis muscle. The lumbar portion arises from two aponeurotic arches, the medial and lateral arcuate ligaments.² The medial arcuate ligament extends over the upper portion of the psoas major muscles as fibrous attachments between the L1 or L2 vertebral body and the transverse process of L1. The lateral arcuate ligaments are thickened fascial bands covering the quadratus lumborum muscle and extend from the transverse processes of the first lumbar vertebrae laterally to the midportion of the 12th ribs and by two muscular crura to the bodies of the upper lumbar vertebrae. The lumbar portion also attaches to two bilateral arcuate ligaments which span from the vertebrae to the transverse processes and from those processes to the 12th rib (Figure 45-5).²

Figure 45-5. Caudal (abdominal) surface of diaphragm muscle (red), which is the most important muscle for inhalation. A, Internal aspect of left hemidiaphragm as seen from the right side of body. B, Diaphragm muscle viewed from below, showing its attachment to the caudal margins of the thoracic cage. Reproduced with permission from Kendall FP, McCreary EK, Provance PG. *Muscles: Testing and Function*. 4th ed. Baltimore, MD: Williams & Wilkins; 1993.

The diaphragm muscle is penetrated by the aorta, vena cava, and esophagus. The arcuate ligaments provide passage posteriorly for the psoas major and quadratus lumborum muscles (Figures 45-3 and 45-5).

2.1. Innervation and Vascularization

Intercostals

Each intercostal muscle is supplied by adjacent branches of the corresponding intercostal nerve.²

The muscles of the thoracic wall receive their vascularization from the internal thoracic artery via the musculophrenic artery, the superior intercostal artery, posterior intercostal artery, subcostal and superior thoracic arteries, and the descending aorta. Additional vascular supply is provided by the vessels that supply the upper limb.²

Diaphragm

The diaphragm muscle receives motor innervation from the right and left phrenic nerves, which originate from cervical nerves C3-C5 and facilitate both sensory and motor function. The paired phrenic nerves are located posteriorly in the lateral compartment of the neck and travel anteriorly as they course through the thorax. The phrenic nerves run along the anterior surface of the pericardium before they reach the diaphragm muscle, where they arborize on the superior and inferior surfaces. Sensory innervation to the peripheral part of the muscle is through the lower six to seven intercostal nerves.^{2, 4}

The diaphragm muscle receives its vascularization from the subcostal and lower five intercostal arteries, the superior and inferior phrenic arteries, the musculophrenic and pericardiophrenic arteries. The major vascular supply to the diaphragm muscle is provided by the right and left inferior phrenic arteries.²

2.2. Function

Recent studies have helped clarify much of the controversy associated with the activity and role of several respiratory muscles, including the intercostal and diaphragm muscles. To understand their function, it is helpful to understand basic respiratory mechanics. Inhalation is an active process requiring muscular effort. Exhalation during quiet breathing is largely a passive process performed by the elastic recoil of the lungs.⁵ In that sense, all expiratory muscles are to some degree accessory muscles of respiration recruited with increased respiratory demand.

Intercostals

The function of the intercostal muscles depends on their internal–external position, on their anteroposterior position, and on their transverse location on the rib cage. In addition, the muscle's superior–inferior position on the rib cage affects the relative order and magnitude of recruitment. The only portion of the intercostal muscles associated with primary inspiration are the parasternal portion of the internal intercostal muscles. It is believed that both the internal and external intercostal muscles are active during both

phases of ventilation.⁶

It is of fundamental importance that the lateral portion of intercostal muscles are tailor-made for rotating the thoracic spine and rib cage, a function that is frequently overlooked. During right trunk rotation, the left external intercostal muscles and the right internal intercostal muscles are activated to perform this motion.⁶

Diaphragm

The diaphragm muscle is the primary muscle of ventilation during quiet breathing and responsible for producing up to 80% of the inspirational force.⁷ It also aids in emesis, urination, and defecation by increasing intra-abdominal pressure and helps prevent gastroesophageal reflux by exerting external pressure at the esophageal hiatus.

Respiratory Mechanics

Movement of the chest wall during inhalation is a complex integrated process that requires sophisticated coordination of numerous muscles. Lung volume is controlled by three basic movements. Figure 45-6 illustrates two of the movements: (1) elevation of the sternum (Figure 45-6A) that increases the anteroposterior diameter by rotating the ribs around the spinal attachments, and (2) spreading of the lower ribs (Figure 45-6B) that increases the lateral diameter of the thorax by rotating the ribs around their sternal attachments.⁸ The downward piston-like motion of the diaphragm muscle provides the third movement (Figure 45-7). The sternal elevation movement is often compared to that of an old-fashioned pump handle, and the lateral rib movement to that of a bucket handle (one on each side).

Figure 45-6. Change of sternum and rib positions with inhalation. A, Lateral view of the chest showing the upward and outward (forward) movement of the anterior rib cage during

inhalation, which increases intrathoracic volume. This can be compared to a “pump-handle” movement. Position 1, ordinary exhalation; position 2 (dotted lines), quiet inhalation; position 3 (dashed lines) deep inhalation. B, View from above showing how, for ribs attaching to the costal cartilages below the sternum (vertebrochondral ribs), the movement is upward and lateral, which increases intrathoracic volume. The dashed lines represent the position of the rib during inhalation. The line labeled a-b represents the axis of movement. This upward and lateral rib movement can be compared on each side to the movement of a bucket handle. Reprinted with permission from Clemente CD. *Gray's Anatomy*. 30th ed. Philadelphia, PA: Lea & Febiger; 1985.

Figure 45-7. Schematic of respiration dynamics. A, Inhalation. The sagittal section (right figure of A) shows how the combination of depression (contraction) of the diaphragm muscle (long down arrow) that is displacing the abdominal contents downward and simultaneous expansion of the thoracic cage (diagonal up arrow) reduce intrathoracic pressure. This sucks air into the lungs (short down arrow), inflating them. The frontal section (left figure in A) shows the depressed diaphragm muscle and inflated lungs. B, Exhalation. The sagittal section (right figure in B) shows how depression of the thoracic cage (diagonal down arrow) and elevation (relaxation) of the diaphragm muscle (long up arrow) tend to increase intrathoracic pressure. During quiet respiration the elastic recoil of the lungs and chest forces air out of the lungs (short up arrow), deflating them. The frontal section (left figure) shows the elevated diaphragm muscle and deflated lungs. In forced exhalation, the abdominal muscles displace the abdominal contents inward and upward and pull the thoracic cage downward and inward, accelerating airflow out of the lungs.

The axis of rotation of a rib is defined by its articulations with the vertebral body and the transverse process. Since most ribs are inclined obliquely approximately 45° to the horizontal, when the rib rotates upward it increases the volume within the rib cage, which is associated with inhalation. The upper ribs that attach to the sternum with short costal

cartilages tend to move in unison, whereas the lower ribs that are attached with longer costal cartilages have more freedom to move independent of sternal motion.⁹

The pump-handle movement of inhalation that elevates the sternum (and produces predominantly anteroposterior expansion) depends primarily on the intercostal muscles located at the sides of the thorax for which these muscles are mechanically well-situated.⁸ The intercostal muscles suited to raising the bucket handles on each side of the chest (expanding the transverse diameter of the rib cage) are located nearly midline close to the sternum and the spine, especially the parasternally located internal intercostal muscles and the paraspinally located levatores costarum muscles. These relationships were identified by calculations using three dimensional finite element analysis of the human rib cage⁸ and were confirmed experimentally in dogs.¹⁰

The depression of the diaphragm muscle, by its activity during inhalation and its passive elevation during exhalation, is illustrated in the sagittal sections in Figure 45-7. The corresponding effect on lung volume is shown in the frontal sections in Figure 45-7. Contraction of the diaphragm muscle tends to elevate and spread the lower costal margin and lower ribs when support and resistance are supplied to the central tendon by the abdominal contents.¹¹ The muscles largely responsible for these movements are illustrated in Figure 45-8 in greatly simplified form with arrows that indicate the force vector produced by contraction of the muscle.

Figure 45-8. Schematic of respiratory mechanics illustrating some of the most important respiratory muscles and their actions (thick black arrows). Abd. m., abdominal muscles; Di,

diaphragm muscle; Pab, abdominal pressure; Ppl, pleural pressure. Reprinted with permission from Roussos C. Function and fatigue of the respiratory muscle. *Chest*. 1985;88(suppl):124s-132s.

Muscles of Inhalation

The muscles primarily responsible for inhalation are the diaphragm, parasternal internal intercostals, scaleni, upper and more lateral external intercostals, and levatores costarum muscles. The diaphragm muscle, which is the main respiratory muscle in humans, does not expand the entire chest wall but just the abdomen and lower rib cage. Expansion of the cranial half of the rib cage is accomplished by other inspiratory muscles, in particular the anterior scalenus and parasternal intercostal muscles.⁹ From their attachments to the ribs, the costal fibers of the diaphragm muscle run in the cranial direction next to the ribs for some distance.⁹ This relationship is important because contraction of these fibers elevates the lower ribs when depression of the dome of the diaphragm muscle is resisted by the abdominal contents.^{9,12}

During quiet inhalation, electrical activity of the diaphragm muscle precedes that of the external intercostal muscles¹³; the diaphragm muscle produces 70% to 80% of the inhalation force.⁵ This is why paradoxical breathing is such a serious dysfunction. Hyperinflation of the lungs due to obstructive lung disease puts the diaphragm muscle at a serious disadvantage, and under some circumstances the flattened diaphragm muscle can reverse its effect by pulling the costal margin in rather than lifting it up and out.¹⁰

During quiet breathing, the first external intercostal muscles (between the first and second ribs) are always active, the second pair of muscles are usually active, and the third, only occasionally. With increasingly more forced respiration, successively more caudal external intercostal muscles are recruited during inhalation.¹³

The anterior scalene muscles are always active in quiet inhalation (Figure 45-8) and are likely to activate shortly before the parasternal internal intercostal muscles.¹³ The activity of the scalene muscles is needed during inhalation to prevent the downward suction produced by the piston action of the diaphragm muscle from pulling the sternum down and in. A downward motion of the sternum tends to reduce intrathoracic volume rather than increase it. The scalene muscles respond increasingly vigorously to increasing respiratory effort.¹³

The posteriorly located levatores costarum muscles (Figure 45-2), which also show some activity in quiet respiration,¹³ become increasingly active with increasing ventilatory demand.¹⁰ They are anchored proximally to the vertebral column, not to another rib. They elevate the rib cage with effective leverage. A small upward movement of the ribs, so close to the vertebral column, is greatly magnified at the sternum.

The diaphragm muscle initiates quiet inhalation quickly followed by activity of other primary muscles of respiration including the scalene, the parasternal internal intercostals, the levatores costarum, and the upper and more lateral external intercostal muscles.

Harper et al,¹⁴ utilized B-mode ultrasound to look at costal diaphragm muscle function in 150 healthy subjects. They found that most of the subjects used their diaphragm muscle

during quiet breathing with no significant difference between sides or across age ranges. They did find that in older men the left side thickens more than the right. Additionally, they found a fair number of individuals who either did not utilize their diaphragm muscle at all or did so minimally during quiet breathing.

As the vigor of forced respiration increases, additional (accessory) muscles of inhalation are recruited. The total list of muscles that can contribute to labored inhalation is long. Which muscles are activated and how much they are activated depend strongly on the circumstances. Therefore, there is considerable diversity of opinion as to the relative roles of muscles that may serve as accessory muscles of respiration.¹⁵

The scalene muscles serve as primary muscles of inhalation. With increased ventilatory demand, the sternocleidomastoid muscles also become active bilaterally and rapidly increase their level of activity. The sternocleidomastoid appears to be the most important accessory muscle. Other muscles that may be recruited include the upper trapezius, serratus anterior superior and serratus posterior superior, pectoralis major and minor, latissimus dorsi, thoracic erector spinae, and subclavius muscles.⁷

With paradoxical respiration, accessory muscles of inhalation must carry a major part of the load because the respiratory effects of the intercostal muscles and the diaphragm muscle largely cancel each other's efforts.

Muscles of Exhalation

During quiet respiration, exhalation is largely a passive process dependent on the elasticity of the lungs. The muscles primarily responsible for exhalation during periods of increased demand are the abdominal, interosseous internal intercostal, transversus thoracis, and subcostal muscles. The lowest (11th) intercostal pair is most important for exhalation, and an electromyogram (EMG) study showed that as intercostal activity developed during forced exhalation, recruitment progressed upward from the 11th pair of muscles. Electrical activity of the transversus thoracis muscle appeared only during exhalation.¹³

When functioning as expiratory muscles, the abdominal muscles squeeze the abdominal contents upward and pull the chest cage downward, increasing intra-abdominal pressure that elevates the diaphragm muscle, accelerates expiratory airflow, and empties the lungs more than would occur with passive expiration. In this way, these muscles regulate end-expiratory lung volume and breathing efficiency.¹⁶

During forced exhalation, the abdominal muscles are the prime movers assisted by the internal intercostal muscles (with the exception of the parasternal internal intercostal muscles, which support inhalation). With increased ventilatory demand, the latissimus dorsi, quadratus lumborum, and erector spinae muscles may also be recruited.³

Postural Functions

Experimental evidence¹⁷ supports the view that intercostal muscles, particularly the laterally located external intercostal muscles in the more cephalic spaces, are mainly involved in postural functions. The opposite appears to be the case for the intercartilaginous muscles

(located anteriorly) and the levatores costarum muscles (located posteriorly), which in all circumstances, exhibit phasic inspiratory activity quite similar to the diaphragm muscle.¹⁷

A verified postural role of the intercostal muscles is rotation of the thorax.^{6,18} Respiration is executed with bilaterally synchronized intercostal muscle activity. The crisscross pattern of these muscles makes them admirably suited to a rotation function if the internal intercostal muscles on one side contract with the external intercostal muscles on the opposite side and vice versa. Whitelaw et al⁶ reported that the right external intercostal muscles were strongly activated by rotation of the trunk to the left and that the right internal intercostal muscles were strongly activated by rotation of the trunk to the right. Rimmer et al¹⁸ demonstrated that the tonic discharge of internal and external intercostal muscles induced by holding a rotated position is modulated by respiration. When the respiration and rotation functions are compatible, they reinforce the EMG activity. When they are incompatible, respiration takes precedence and inhibits the rotation function.¹⁸

The external intercostal muscles on the left side and the internal intercostal muscles on the right side both rotate the trunk to the right. Conversely, the internal intercostal muscles on the left side and external intercostal muscles on the right side rotate the trunk to the left. The corresponding internal and external abdominal oblique muscles would augment these rotations and the iliocostalis lumborum muscle augments rotation toward the side on which that muscle lies. The multifidi and rotatores muscles on the right can help to rotate the trunk to the left. The lateral interosseous intercostal, the lateral abdominal, and the quadratus lumborum muscles help to side bend the trunk toward the ipsilateral side.

The scalene muscles, which are primary players in respiration, also serve an important postural role. They stabilize the neck against lateral movement. Unilaterally, they laterally flex the neck; bilaterally, they forward flex the neck. Other accessory respiratory muscles (such as the sternocleidomastoid and the upper trapezius muscles) also flex the neck and rotate the head.

Special Functions

Many complex special functions including coughing, sneezing, vomiting, gasping, running, and speech depend on the muscles of the trunk.

Both coughing and sneezing are protective reflexes that defend the airways against inhaled particles and noxious substances and remove mucus by inducing high airflow velocities during forced exhalation. A cough has three phases: inhalation, compression, and expulsion. Following reflex inhalation, the brief compressive phase involves continued activity of the diaphragm muscle and activation of ribcage and abdominal expiratory muscles against a closed glottis. The expulsive phase begins with opening of the glottis as relaxation of the diaphragm muscle and vigorous reflex expiratory muscle activity produce high airflow velocities.¹⁹ Repeated coughing can induce enthesopathy in the attachments of, and activate and perpetuate TrPs in, the expiratory muscles (especially the abdominal muscles). A coughing spell can become excruciatingly painful for this reason.

The neurogenesis for sneezing is somewhat different than for coughing. During this

reflex, there are often intermittent pauses during the inspiratory effort, and expired air is diverted through the nose in addition to the mouth.¹⁹ Since a prolonged series of sneezes is much less likely to occur than a protracted period of coughing, sneezing is less likely to produce muscular distress.

The inhalations and exhalations of gasping, which are induced by severe hypoxia (or during panic attacks), are more sudden in beginning and ending compared to the rhythmic respirations of eupnea (normal breathing). This unique pattern of autonomic ventilatory activity differs fundamentally from eupnea because the neurogenesis of gasping depends on a specific region of the medulla.²⁰

Another reflex respiratory activity, vomiting, involves violent contraction of expiratory muscles. Vomiting can be induced by reverse peristalsis of the duodenum, by motion sickness, pregnancy, or other systemic causes. It is such a primitive reflex that it is preserved in decerebrate animal preparations and is produced by the thoracoabdominal respiratory muscles. Expulsion of the gastric bolus by vomiting is usually preceded by retching, which involves successive waves of reflex cocontraction of the diaphragm and abdominal muscles that override the respiratory cycle. Recurrent attacks of retching are feared by clinicians and patients because of the severe fatigue they can induce in respiratory muscles, and attacks have occasionally led to rib fractures.²¹ Again, this muscle overload can produce severely painful enthesopathy and can activate TrPs that persist after an attack.

Most conditioned runners show a tight locomotor-respiratory coupling which is established during the first four or five strides of the run. The ratio is usually two strides to one respiratory cycle. Inexperienced runners show little or no tendency for such coupling.²² During prolonged maximal exercise, the blood flow requirements of respiratory muscles are comparable to those of propulsive limb muscles.²³

Mantilla and Sieck 2013 found changes in diaphragm muscle structure and function in various disease and clinical conditions, which affected more fatigable, but less frequently activated, motor units that are not required for vital ventilator function. They suggest that improving muscle strength may be advantageous in diseases that affect diaphragm muscle fatigability. They conclude that future studies should investigate how atrophy and reduced fatigability of fast twitch motor units containing Type IIx and/or IIb fibers can be improved.²⁴

2.3. Functional Unit

The functional unit to which a muscle belongs includes the muscles that reinforce and counter its actions as well as the joints that the muscle crosses. The interdependence of these structures functionally is reflected in the organization and neural connections of the sensory motor cortex. The functional unit is emphasized because the presence of a TrP in one muscle of the unit increases the likelihood that the other muscles of the unit will also develop TrPs. When inactivating TrPs in a muscle, one must be concerned about TrPs that may develop in muscles that are functionally interdependent. Box 45-1 grossly represents the functional unit of the intercostal and diaphragm muscles.²⁵

Box 45-1 Functional unit of the intercostal and diaphragm muscles

Action	Synergists	Antagonist
Inspiration	Diaphragm Parasternal intercostals Scalenes Sternocleidomastoid Levatoris costarum Upper and lateral external intercostals	External oblique abdominis Internal oblique abdominis Rectus abdominis Transversus abdominis Quadratus lumborum Erector spinae
Expiration	External oblique abdominis Internal oblique abdominis Rectus abdominis Transversus abdominis Transversus thoracis Quadratus lumborum Erector spinae	Diaphragm Parasternal intercostals Scalenes Sternocleidomastoid Levatoris costarum Upper and lateral external intercostals
Trunk rotation	Ipsilateral internal intercostals Contralateral external intercostals Ipsilateral internal oblique abdominis Contralateral oblique external abdominis	Contralateral internal intercostals Ipsilateral external intercostals Contralateral internal oblique abdominis Ipsilateral external oblique abdominis

The role of the internal and external intercostal muscles during ventilation remains controversial with the exception of the parasternal internal intercostal muscles (active during inspiration); however, their role in trunk rotation is well established.^{6,18} Muscles that attached the thorax to the shoulder girdle, vertebral column, head, or pelvis may assist with ventilation depending on the ventilatory demand.

Muscles around the lumbo-pelvic region contribute to its stability by an internal positive pressure that creates functional strength and stability. This pressure is regulated mostly by an intra-abdominal pressure mechanism provided by such key muscles as transversus abdominis, pelvic floor, and diaphragm muscles. Other muscles such as lumbar multifidus, internal and external oblique abdominales, psoas major, quadratus lumborum, rectus abdominis, and gluteal muscles also all provide lumbo-pelvic stability. The concept of intra-abdominal pressure may be compared to a sealed can of soda as the coordination of the key muscles (ie, diaphragm, pelvic floor, transversus abdominis) provides a stable chamber for the pressurized abdominal contents. In the absence of muscle dysfunction,

which would be comparable to damage of the soda can, the contents are securely contained despite inevitable changes in pressure. The lumbo-pelvic girdle then allows larger, more superficial muscles around the trunk to provide further stability as well as gross movement and torque needed for daily and athletic activities.

3. CLINICAL PRESENTATION

3.1. Referred Pain Pattern

Intercostal Muscles

Trigger points in intercostal muscles refer pain locally in the region of the TrP and tend to refer pain anteriorly along that interspace toward the front of the thorax, rather than toward the back (Figure 45-9). The more posteriorly the TrP is located, the stronger is its tendency to refer pain toward the front. Active TrPs may refer pain to the intercostal spaces above and below the TrP. Bonica and Sola²⁶ illustrated a similar local intercostal muscle pain pattern around the TrP.

Figure 45-9. A, Examples of referred pain patterns (dark red) of TrPs in intercostal muscles (light red). A TrP can occur in any intercostal muscle. The more dorsally the TrP is located, the farther the pain pattern tends to extend toward the sternum. Patterns tend to follow the curvature of the ribs. B, TrPs in the central diaphragm muscle can refer pain to the upper border of the ipsilateral shoulder at the angle of the neck, and other TrPs refer to the anterolateral aspect of the lower border of the rib cage as in a “stitch in the side.”

Diaphragm

During vigorous exercise, diaphragm TrPs can produce the pain commonly described as a “stitch in the side” that is felt deep anterolaterally in the region of the lower border of the rib cage. The pain tends to be aggravated by continued exercise and relieved by rest (Figure

45-9B).

Pain arising from stimulation of the central dome portion of the diaphragm muscle can be referred to the upper border of the ipsilateral shoulder. Stimulation of the peripheral part is referred as an aching pain to the region of the adjacent costal margin. The difference in pain distribution depends on the innervation of the stimulated site.²⁷ Among a series of 17 patients complaining of chest pain and dyspnea attributed to spasm of the diaphragm muscle,²⁸ nine complained of pain in the substernal region and eight located their pain in or near the right hypochondrial region, which suggests that the location of the pain identified the nerve supply and identified from which part of the diaphragm muscle the pain originated. This principle may also apply to pain referred from diaphragm TrPs.

Fields²⁷ called attention to experiments of Capps²⁹ that involved direct stimulation of the peritoneal (caudal) surface of the diaphragm muscle with a smooth bead or the rough end of a wire. In three subjects, stimulation of the central portion of the diaphragm muscle with the bead caused a sharp, localized pain that was illustrated as referring to the middle region of the anterior border of the upper trapezius muscle about half way between the acromion and the base of the neck. Stimulation with the rough end of the wire produced pain of great intensity at the same location. One subject described the sensation as, “the wire sticking into my neck,” and could point to the precise spot with a fingertip. When pressed, that spot was abnormally tender. On the other hand, in one subject tested, stimulation of the peripheral margin of the diaphragm muscle produced a diffuse pain referred to the costal border. The patient indicated the area with his hand placed transversely over the lower ribs and over the right hypochondrium. The difference in the quality and location of the pain referred from the central compared to the peripheral parts of the diaphragm muscle may reflect the marked differences in their sources of innervation and a difference in spatial resolution of receptors in these tendon and muscle.

3.2. Symptoms

When the patient reports an aching pain along the rib interface and is unable to lie in the position that places body weight on the affected side, the intercostal muscles should be considered as a possible source of the patient's symptoms. Patients may also report increased pain and symptoms during cardiorespiratory exercises that increase the ventilatory demand, especially inspiration. The patient may also report significant exacerbation of painful symptoms with either coughing or sneezing.

Cardiac arrhythmia, including auricular fibrillation, can depend on the arrhythmia TrP considered in detail in Chapter 42. It may be located in intercostal muscles on the right side between the fifth and sixth ribs midway between the sternal border and nipple line. When a TrP of this nature occurs, cardiac arrhythmia may be one symptom of intercostal TrPs.

When a patient's primary report of pain is that of a “stitch in the side,” especially when performing cardiorespiratory exercise that requires rapid deep breaths, the diaphragm muscle should be considered as a source of symptoms. The pain is likely to be most intense

at the end of a full exhalation when the diaphragm fibers are stretched. Coughing can also be excruciatingly painful.

Seventeen patients diagnosed with episodic spasms of the diaphragm muscle²⁸ complained of chest pain, dyspnea, and inability to get a full breath. Sometimes attacks were precipitated by anxiety-producing situations. Patients sometimes had so much difficulty breathing that they feared they might die. This demonstrates the importance of the diaphragm muscle. The author²⁸ did not consider TrPs as a source of these patient's symptoms.

A hiccup represents a reflex contraction of the diaphragm muscle. The anatomy, physiology, and clinical aspects of hiccups were thoroughly reviewed by Travell.³⁰ Often hiccups can be relieved by mechanical (and cold) stimulation of the uvula, suggesting that an area in the mucosa or musculature of the uvula can be a major factor in causing hiccups.³⁰ Also, TrPs of the diaphragm muscle are suggested by the observation that exhalation tends to relieve the hiccups, and deep inhalation (shortening the muscle fibers) tends to aggravate them. However, this respiratory effect may also be an example of respiratory synkinesis.³¹

3.3. Patient Examination

After a thorough subjective examination the clinician should make a detailed drawing representing the pain pattern that the patient has described. This depiction will assist in planning the physical examination and can be useful in monitoring the progression of the patient as symptoms improve or change. Any patient with primary reports of chest pain should alert the clinician to perform a thorough review of the cardiovascular and pulmonary systems. Any concerns regarding the involvement of the cardiovascular or respiratory systems as a source of symptoms should result in an immediate referral to the emergency room or a physician.

In myofascial pain disorders, patients will very commonly (if not exclusively) present with an asynchrony between respiratory mechanics and posture that not only affects the function of the lumbo-pelvic area but also affects the function of the upper and lower quarter regions and extremities as a whole. Especially in patients with chronic myofascial pain, physical observation of the patient's static posture can indicate much about their respiratory state as well as trunk stability that ultimately provides information about the patient's pain state.

For proper examination of the intercostal and diaphragm muscles, the clinician should observe standing posture, especially shoulder girdle posture, scapula position, and spinal curves. The clinician should also monitor the ventilation cycle and breathing patterns. The clinician should examine diaphragmatic breathing, and if the patient presents with a paradoxical breathing pattern, high priority should be given to effectively correct this ineffective breathing pattern, both during initial therapy and at follow-up visits. This treatment is discussed further in Section 5 of this chapter.

Respiratory mechanics should be assessed during resting respiration and with forced

inhalation and exhalation from an anterior, lateral, and posterior perspective. The clinician should note upward and outward motion (pump handle) in the anterior rib cage, upward and lateral motion (bucket handle) in the vertebrochondral rib cage, and caliper motion in ribs 11 and 12.

The vital capacity of the patients with intercostal and/or diaphragm TrPs is likely to be reduced because the TrPs often painfully restrict deep inhalation or full exhalation even with normal coordinated diaphragmatic breathing pattern. In normal respiratory mechanics, the diaphragm muscle would expand primarily with a secondary upper chest rib expansion. However, when the diaphragm muscle no longer provides the volumetric exchange of oxygen that it is intended to provide, excessive upper chest respiration develops to compensate for the lack of diaphragmatic contributions. As time goes on, a feed forward loop develops and the patient develops a learned pattern of a predominate upper chest breathing pattern (paradoxical breathing). This respiratory pattern results in static resting postures with an elevated lower rib cage, increased thoracolumbar extension and increased myofascial tension of the upper rib and neck muscles such as the scalenes, sternocleidomastoid, and upper trapezius muscles—as if the patient were holding an inspired breath. The paradoxical respiratory pattern results in an ‘inspired rib cage position’ such that the patient not only presents with flared out lower ribs and increased upper chest muscle tone, but also reduced abdominal expansion. This posture indicates that the diaphragm muscle may not be contracting appropriately and a lack of lateral rib cage expansion may result in an overall loss of pulmonary function.

This alteration in breathing mechanics and resting postures adds more stress to the thoracolumbar spine and can be a major contributing factor not only to low back pain (LBP), but as well as upper and lower quarter injuries since these regions rely heavily on the foundation of the thoracolumbar and pelvic region stability. As in any other muscle that develops TrPs due to excessive use and poor mechanics, the diaphragm and intercostal muscles can also easily develop myofascial dysfunction.

Active and passive movement testing of the trunk may reveal a loss of rotation in one or both directions, and/or limited lateral flexion due to TrPs in the intercostal muscles. The clinician should also examine for TrPs in the abdominal oblique, serratus posterior inferior, and iliocostalis lumborum muscles, which may also restrict trunk rotation and lateral flexion.

The patient may present with limited shoulder elevation on the affected side because of painfully restricted rib mobility due to TrPs in the intercostal muscles. Intercostal TrPs are usually aggravated by contralateral trunk lateral flexion, and may be somewhat relieved by ipsilateral trunk lateral flexion.

Patients with TrPs in the diaphragm muscle are likely to experience pain at the end of a maximal exhalation due to stretching of the muscle. To increase the sensitivity of testing, the patient can increase stretch tension on the diaphragm muscle near the end of full exhalation by a vigorous contraction of the abdominal muscles. If the abdominal musculature is weak, the patient can apply external pressure to the abdomen to increase intra-abdominal pressure forcing the diaphragm muscle upward and stretching it.

Performing this abdominal maneuver during continued exhalation ensures an open glottis. The effectiveness of this effort is blocked if the patient closes the glottis, which is what patients normally do when contracting the abdominal muscles to increase intra-abdominal pressure. Vigorous coughing at nearly complete exhalation can also elicit pain from TrPs in the diaphragm muscle. If the TrPs have caused appreciable enthesopathy, any vigorous cough is likely to be painful.

Among 17 patients with episodes that were diagnosed as diaphragmatic spasm, the author²⁸ was able to induce an attack in 12 of them during fluoroscopic examination. As the patient had increasing difficulty taking in a full breath, the diaphragm muscle became progressively contracted until it was essentially flat across the abdomen and the patient was in serious respiratory distress because of inability to inhale adequately. Episodes were usually precipitated by engaging the patients in discussion of topics known to be very emotionally stressful to them. The diaphragmatic spasm (or contracture) eliminated diaphragmatic function and was blocking both the pump-handle and bucket-handle movements of the thorax.²⁸ Increased diaphragmatic muscle tension caused by TrPs would produce a similar effect to a significantly lesser degree and would also be aggravated by emotional distress.

Accessory joint motion should be tested in the cervical spine (especially C3-C5 due to the relationship of the phrenic nerve roots), thoracic intervertebral and facet joints, costovertebral joints, rib cage, sternoclavicular joint, manubriosternal joint, xiphisternal joint, and scapulo-thoracic joints. Oftentimes, joint hypomobility in the thoracic spine or rib cage can cause impairment in respiratory mechanics leading to overload and TrP formation in the intercostal and diaphragm muscles.

Additional testing of all muscles which attach from the shoulder girdle, head and neck, and pelvis to the thorax should be carried out as all these muscles can act as accessory respiratory muscles depending on the position of the trunk and upper extremities.

3.4. Trigger Point Examination

Intercostal Muscles

Intercostal TrPs are usually located anterolaterally or posterolaterally and less commonly in the extreme anterior and posterior portions of the muscle (Figure 45-10A). The parasternal internal intercostal muscles are an exception to this finding and should be carefully investigated utilizing cross-fiber flat palpation in the supine position (Figure 45-10B). Careful examination of the parasternal internal intercostal muscles should be performed in cases of suspected costochondritis and Tietze syndrome. These syndromes may be caused by, or associated with, TrPs in these workhorse respiratory muscles.

Figure 45-10. Cross-fiber flat palpation for identification of intercostal TrPs. A, Posterolateral trunk. B, Cross-fiber flat palpation of parasternal internal intercostal TrPs. For female patients modesty may be maintained by the patient using their own hand to move and cover their breast tissue. C, Cross-fiber flat palpation near the costal fibers of diaphragm muscle. D, Palpation of the diaphragm muscle side-lying.

To locate intercostal TrPs, the clinician should examine the rib cage for abnormally narrow rib interspaces that could indicate tense intercostal muscles or a rib dysfunction. This can be performed in supine, side-lying, and prone positions depending on the patient's report of pain. The patient usually describes pain along a narrowed interspace if active intercostal TrPs are the source of the patient's symptoms. The region of increased muscle tension and of TrP tenderness can be found by running the palpating finger between the ribs for the full length of the suspected segment and can be identified with cross-fiber flat palpation (Figure 45-10A and B).

Dr Travell observed that a TrP in the intercostal muscle located posteriorly between ribs 4 and 5, close to the rhomboid minor muscle, initiated a hiccup when pressed before TrP injection but not following the TrP injection.²⁵

Diaphragm

Palpation for TrPs in the diaphragm muscle can be performed in side-lying, supine, or seated position. The midfiber central TrPs of the diaphragm muscle are not accessible to palpation. However, TrPs in the costal portion of the diaphragm muscle are detectable just inside the anterior lower border of the thoracic rib cage (Figure 45-10C and D).

Tenderness detected in this region could originate in the diaphragm, the external oblique abdominis, internal oblique abdominis, or transversus abdominis muscles. The external and internal oblique abdominis muscles attach to the ribs externally above the costal margin (Figure 49-4), whereas the transversus abdominis muscle attaches to the costal margin and interdigitates with angulated diaphragm fibers (see Figures 45-4 and 49-3). Palpation of the abdominal muscle during an active contraction will assist in the identification of the specific muscle based on fiber direction and can help the clinician to differentiate taut bands and TrP tenderness in the more superficial abdominal muscles from tenderness in the deeper muscles.

The ambiguity of distinguishing between the attachment tenderness of the transversus abdominis and diaphragm muscles at the costal margin can be resolved by testing sensitivity to stretch. To differentiate between the transversus abdominis and the diaphragm muscles the clinician can assess whether pain and tenderness are increased by stretching the abdominal muscles (protruding the abdomen) or by stretching the diaphragm muscle (compressing the abdomen near the end of exhalation).

4. DIFFERENTIAL DIAGNOSIS

4.1. Activation and Perpetuation of Trigger Points

In any part of the intercostal or diaphragm muscles, TrPs may be activated by unaccustomed eccentric loading, eccentric exercise in unconditioned muscle, or maximal or sub-maximal concentric loading.³² Trigger points may also be activated or aggravated when the muscle is placed in a shortened or lengthened position for an extended period of time. A slumped or forward head posture may activate TrPs in the intercostal or diaphragm muscles. Chronic coughing as many individuals with chronic obstructive pulmonary disease (COPD) or individuals who smoke experience will activate and perpetuate TrPs in the respiratory muscles.

Intercostal Muscles

A posture or activity that activates a TrP, if not corrected, can also perpetuate it. For the intercostal muscles, postural considerations are very important.

Intercostal TrPs may be activated by gross or local impact trauma, excessive coughing, and chest surgery.^{26,33} Chest retractors used during surgery were found likely to leave painful clusters of intercostal TrPs.³⁴ Open heart surgery that employed incision of the sternum rather than ribs was more likely to result in TrPs in the pectoralis major and minor muscles than in the anterior intercostal muscles.³⁴ Other causes for activation include an attack of herpes zoster,³⁵ fracture of a rib to which the muscle attaches, and possibly a breast implant.

Intercostal TrPs also may become active in association with intrathoracic lesions, such as pneumothorax, pyothorax, and pleural effusion (secondary to a tumor). These associated TrPs are likely to involve the last three intercostal muscles and a complaint of posterolateral

low chest pain.

Significant perpetuating factors can be anxiety, repetitive trunk rotation, overexertion in sports, or a chronic cough. Trigger points in the overlying pectoralis major muscle, and paradoxical breathing may also activate and perpetuate intercostal TrPs. It is not always clear which comes first as the abnormal respiratory pattern and the TrPs seem to reinforce each other.

Diaphragm

Anxiety, chest breathing, and overexertion in exercise, such as rapid walking or running or a persistent cough, can activate and perpetuate TrPs in the diaphragm muscle. Any condition that causes labor intensive respiration can also cause TrPs to develop in the diaphragm muscle. Keeping the stomach flat at all times to demonstrate a slim physique will alter normal respiratory mechanics and cause the diaphragm muscle to develop TrPs. A slumped posture with forward head position can also activate TrPs in the diaphragm muscle. It is likely they could appear following gastrectomy or any chest surgery.

4.2. Associated Trigger Points

Associated TrPs can develop in the referred pain areas caused by TrPs.³⁶ Therefore, musculature in the referred pain areas for each muscle should also be considered.

Spot tenderness of the chest wall in locations where the serratus anterior muscle attaches to ribs may appear to be intercostal TrPs. A palpable taut band in the serratus anterior muscle over the rib rather than in the intercostal space helps to identify the TrP in the serratus anterior muscle versus intercostal muscles. The pectoralis major and minor, scalenii, sternocleidomastoid, upper trapezius and latissimus dorsi muscles should also be assessed for the presence of TrPs. In addition, muscles that comprise the functional unit may also have or produce associated TrPs.

Full elevation of an upper limb opens up the intercostal spaces on the same side and stretches fascial tissues over the chest wall. This movement is painful to patients who have intercostal TrPs, who are recovering from thoracotomy, or who have herpes zoster with or without intercostal TrPs. Patients with these conditions are vulnerable to developing a painful myofascial “frozen” shoulder because of the pain-induced restricted ROM at the shoulder that encourages the development and perpetuation of subscapularis TrPs as described in Chapter 26.

At times, the cardiac arrhythmia TrP associated with the pectoralis major muscle (see Chapter 42) appears just as likely to be located in an intercostal muscle between rib 5 and 6 on the right.

Diaphragmatic TrPs may form as a result of referred pain in the upper portion of the rectus abdominis muscle on the same side. On examination, the tenderness of rectus abdominis TrPs is increased by stretching that muscle or by asking the supine patient to raise the feet off of the examining table. If these movements do not increase the TrP sensitivity, then tenderness to pressure applied inside the lower border of this region of the

rib cage most likely indicates diaphragm TrP involvement.

Articular dysfunction associated with intercostal TrPs is usually isolated to one or two rib levels and presents as an exhalation restriction or a depressed rib. This dysfunction is best treated by inactivating the TrPs, by using respiration to augment relaxation, or by functional (indirect) techniques. Diaphragm TrPs have no recognized articular dysfunctions related to them other than generalized loss of accessory motion in the thoracic spine and rib cage.

4.3. Associated Pathology

Intercostal Muscles

Differential diagnoses of symptoms caused by intercostal TrPs should include herpes zoster, rib articular dysfunctions, fibromyalgia, cardiac diseases (in cases of left unilateral intercostal TrPs), painful rib syndrome,³⁷ Tietze syndrome or costochondritis (which was clearly differentiated by Calabro et al³⁸), thoracic radiculopathy, and intercostal muscle spasm (considered one of the most common and generally unrecognized, benign causes of chest pain).³⁹

Serious intrathoracic disease that can mimic the symptoms of intercostal TrPs include myocardial infarction, tumor, pleural effusion, and pyothorax. These conditions must be ruled out and when present, they also can induce and perpetuate TrP activity in the respiratory muscles. Thus, if intercostal TrPs respond poorly to treatment, imaging of the chest and a search for other conditions is indicated.

Intercostal TrPs commonly develop in conjunction with an attack of herpes zoster.³⁵ In a study by Chen, the neurogenic pain of herpes was often described as a shooting pain that was generally responsive to Tegretol therapy. Pain from TrPs was described as a localized ache that, in these cases, persisted despite Tegretol therapy but responded to TrP treatment.³⁵ The TrP pain is most likely to be prominent in the chronic stage of a herpes attack and may be the only remaining source of chest pain. The intercostal TrP pain tends to be well localized, most commonly in the posterolateral part of the chest.

Diaphragm

With regard to diaphragm TrPs, differential diagnoses include diaphragmatic spasm,²⁸ peptic ulcer, gastroesophageal reflux, and gallbladder diseases (in cases of right-side unilateral diaphragmatic TrPs).

Atypical chest pain (which, when in the lower sternal area, has also been called “slipping rib syndrome,” xiphoidalgia, or precordial catch syndrome) was shown in one characteristic example to be due to a TrP in the diaphragm muscle.⁴⁰ Clinical research studies are still needed to clarify the relation between these syndromes and TrPs.

When chest pain is closely associated with increased tension of the diaphragm muscle it must not be assumed that the tension is caused by spasm. Increased muscle tension and

pain in the absence of spasm are cardinal features of TrPs.

Kolar et al⁴¹ investigated the function of the diaphragm muscle during postural limb isometric activities in patients with chronic LBP and healthy controls. Both groups had normal pulmonary function test results prior to the study. Dynamic resonance imaging and specialized spirometer readings were used in all subjects to measure diaphragm muscle function. They found patients with chronic LBP had a higher diaphragm muscle resting position with smaller diaphragm muscle excursions during tidal breathing measurements. They conclude that the abnormal postural function of the diaphragm muscle may serve as one underlying factor in patients with chronic LBP.

Janssens et al⁴² investigated diaphragm muscle fatigability in 10 individuals with LBP as compared to 10 healthy normal controls. They utilized transdiaphragmatic twitch pressure measurements prior to, 20, and 45 minutes after inspiratory muscle loading. They found a failure in the diaphragm muscle to potentiate is much more common in individuals with LBP as compared to the healthy normal controls. They conclude that individuals with LBP exhibit significant diaphragm muscle fatigue at 20 and 45 minutes following inspiratory muscle loading. They suggest that fatigability of the diaphragm muscle may be an underlying mechanism of persistent LBP, and this may contribute to impaired spinal motor control anteriorly. Inspiratory muscle training may be indicated to decrease diaphragm muscle fatigability however further studies are warranted.

Vostatek et al⁴³ investigated changes in the diaphragm muscle in regards to shape and motion when postural demands on the body were increased utilizing magnetic resonance imaging (MRI). They included 17 subjects with chronic LBP and 16 healthy normal controls. The ROM of the diaphragm muscle was two to three times greater in the control group with a diaphragm muscle excursion of 40 mm in the control group as compared to 22 mm in the LBP group. The control group also demonstrated a lower breathing frequency during postural demands. They conclude that the postural and breathing components are better balanced and more harmonious within its movement in the control group, and their findings confirmed worse diaphragm muscle cooperation in the subjects with LBP.

Although there is no specific evidence that hiccups are directly related to diaphragm TrPs, it is interesting that breathing while in the position of as full exhalation as possible (which stretches the diaphragm muscle) tends to reduce hiccup activity and discourage its return, while taking a deep inhalation (which shortens diaphragm muscle fibers) can reactivate hiccups.³⁰ The fact that severance of both phrenic nerves may not terminate hiccups suggests that hiccups can be produced by reflex activity of the inspiratory chest muscles without diaphragmatic contraction. Dr Travell spent many years exploring ways to end persistent hiccups in challenging cases, and in 1977³⁰ summarized some of the techniques she had found to be most effective.

5. CORRECTIVE ACTIONS

Forward head, slumped posture needs to be corrected to facilitate erect posture which

improves respiratory efficiency. Proper posture and respiratory mechanics are interdependent of each other, and both must be addressed when patient's present with TrPs in the intercostal or diaphragm muscles. When posture and respiratory mechanics are not optimized, evidence suggests that not only is there a decrease in oxygen exchange, but also a decrease in lumbo-pelvic stability as well as an overall loss in movement efficiency.^{41, 43} The initial resting posture of the thorax and rib cage are crucial for the ideal synergy of the structure of the rib cage, spine, and pelvis and the muscles surrounding these areas that allow for proper respiration and lumbo-pelvic stability.

Therefore, it is vital that education and correction of the patient's posture and respiratory mechanics are provided by the clinician. Good posture is also essential for maintenance of muscle length and effective respiratory patterns. The clinician should educate the patient about what the inspired rib cage position indicates and how it relates to their pain and dysfunction. The patient should be trained in how to self-correct their posture to attain a more optimal position and should employ proper breathing technique with an emphasis on a diaphragmatic breathing pattern (Figure 45-11).

Figure 45-11. Diaphragmatic breathing. A, The patient places one hand on the stomach and the other on the chest. B, The patient takes a deep breath through their nose. The patient should feel their stomach rise and minimal to no motion in the chest. C, At the end of the inspiration the patient should hold for 3 to 5 seconds and slowly exhale through their mouth with pursed lips.

When lower thoracic intercostal and/or diaphragm TrPs are identified on one side, the

release technique illustrated and described in Figure 45-12 can be used as a self-pressure release technique. This procedure is done in the supine position with the hips and knees flexed to relax the abdominal musculature. The patient hooks his or her fingers under the lower ribs of the affected side and then inhales deeply in a slow, relaxed manner. During slow exhalation, the patient's fingers follow the diaphragm muscle in and under the ribs and then apply upward traction on the ribs for the actual release. This procedure also helps to release lower intercostal TrPs as well.

Figure 45-12. Self-release of the diaphragm muscle. This self-stretch procedure is done in the supine position with the hips and knees flexed to relax the abdominal musculature. A, The patient hooks his or her fingers under the lower ribs of the affected side and then inhales deeply in a slow, relaxed manner. B, During slow exhalation, the patient's fingers follow the diaphragm muscle in and under the ribs and then apply upward traction on the ribs for the actual release. This self-stretch procedure also helps to release lower intercostal TrPs. C, This technique may also be performed in side-lying.

Maximum elevation of the diaphragm muscle is achieved in the supine position by letting the breath out completely and then contracting the abdominal muscles. This places the diaphragm muscle on maximum passive stretch with some additional help from reciprocal inhibition supplied by the voluntary contraction of the abdominal muscles.⁴⁴ Pressure should be applied to the area of sensitive TrPs and held for 15 to 30 seconds and repeated 6 to 10 times. This technique can be used several times a day as long as favorable results are being obtained. In some cases the clinician may need to perform a manual

technique to assist in release of TrPs in the diaphragm and intercostal muscles (Figure 45-13).

Figure 45-13. Diaphragm muscle release with the patient supine. The clinician stands at the patient's side opposite to the side to be released and places both hands anteriorly at the lower border of the patient's rib cage. The patient is instructed to breathe in normally in a relaxed manner and then breathe out slowly. During exhalation, the clinician's thumbs follow the diaphragm muscle inward under the rib cage and then lift the rib cage anteriorly. This procedure is also helpful for releasing lower intercostal TrPs. Female patients may use their hands to block the breast tissue.

Inactivation of TrPs in the intercostal muscles can be achieved by application of self-pressure release technique using a finger (Figure 45-14). Pressure should be applied to the sensitive TrPs between two ribs and held for 15 to 30 seconds and repeated 6 to 10 times. This technique can be used several times a day as long as favorable results are being obtained.

Figure 45-14. Self-pressure release of trigger points in the intercostal muscles. A, Anterior release technique. B, Lateral release technique.

In addition to releasing the specific pain-producing TrPs, it is helpful to release all tense myofascial tissues in that region. In the lower thorax, an effective approach to release TrPs in these lower intercostal muscles is illustrated and described in Figure 45-15.^{45, 46}

Figure 45-15. Release of lower intercostal muscle tension caused by TrPs. This technique is sometimes called “lower rib release” and can also be used to release TrP tension of the latissimus dorsi muscle. Patient is A, supine or B, side-lying with the arm on the affected side positioned upward and reaching over the head. One hand of the clinician (the right hand in this figure) is placed so as to span the lateral aspect of the patient’s lower ribs; the other hand is placed in the patient’s axillary region for stabilization. The patient is then instructed to take a deep breath. During the exhalation phase, the clinician’s right hand applies gentle downward pressure (caudally directed) on the patient’s lower ribs. As the patient inhales, the clinician resists elevation of the lower ribs, and as the patient exhales, the clinician’s downward pressure facilitates depression and release of the lower ribs. The

patient is instructed to reach overhead toward the opposite shoulder during exhalation, which accentuates the stretch of the intercostal and latissimus dorsi muscles. The stretch cycle is repeated until release is satisfactory.

The muscle fibers of the diaphragm muscle are placed on stretch by maximum exhalation, which moves the dome of the diaphragm muscle up into the chest cavity. The fibers are also stretched by any compression of the abdomen at full exhalation. The diaphragm muscle is inaccessible to direct manual therapy techniques, such as TrP release. However, it and the lower intercostal TrPs can be released by the technique illustrated and described in Figure 45-15.

An increase in intra-abdominal pressure for added stretch to the diaphragm muscle on full exhalation can be accomplished in various ways, such as voluntary contraction of the abdominal muscles, application of hand or arm pressure to the abdomen, and bending the body forward on exhalation.

When the patient has a chronic cough, it must be controlled before one can obtain lasting relief from TrPs in these respiratory muscles. If the source of the cough cannot be eliminated, the patient can learn how to suppress a cough and raise the sputum by clearing the throat, assisted by a cough suppressant, if necessary.

Serratus Anterior Muscle

“Flank Foe”

Deanna Hortman Camilo and César Fernández de Las Peñas

1. INTRODUCTION

The serratus anterior muscle is a broad, flat muscle that is structurally divided into three groups of muscle fibers. These three groups of muscle fibers work together as scapular stabilizers to keep the scapula seated against the thoracic wall. Trigger points (TrPs) in the serratus anterior muscle can refer pain in the anterolateral chest, the inferior angle of the scapula, the medial aspect of the arm, and into the palm and ring finger. Rarely, serratus anterior TrPs may cause chest pain and pain with deep inhalation. Activation and perpetuation of TrPs can result from prolonged running, heavy overhead lifting, push-ups, and strenuous coughing. Damage during surgical procedures, such as a mastectomy for the treatment of breast cancer, can also activate TrPs in the serratus anterior muscle. Differential diagnosis should include assessment of the diaphragm and pectoralis major muscles, thoracic spine, rib cage, and long thoracic nerve. Corrective actions should include proper training of diaphragmatic breathing, correction of sleeping position, improving mechanics with sporting activities, and self-pressure release and/or self-stretching.

2. ANATOMIC CONSIDERATIONS

The serratus anterior muscle is composed of three groups of fibers. The most superior group of fibers lies parallel with the underlying ribs. These fibers originate from the first and second ribs and insert onto the superior angle of the scapula.¹ The middle portion runs at a 45° angle to the underlying ribs. This group of fibers originates from the second, third, and fourth ribs and inserts onto the anterior aspect of the medial scapular border.¹ The most inferior portion of the muscle is the strongest part of the muscle and originates from ribs five through nine and inserts onto the inferior angle of the scapula (Figure 46-1).¹ This anatomic division has been recently confirmed by Webb et al.² The lower fibers of the serratus anterior muscle attaches to the lower ribs and interdigitates anteriorly with the

external oblique muscle that becomes continuous with the contralateral internal oblique and femoral adductor muscles.¹ This anatomic connection among the serratus anterior, external oblique, internal oblique, and the femoral adductor muscles has been termed the “serape effect,” and it demonstrates the impact that upper extremity function has on the trunk and lower extremity since simultaneous recruitment of the lower extremity and trunk muscles increases the activation of the serratus anterior muscle during the forward punch plus exercise.³

Figure 46-1. Attachments of the right serratus anterior muscle (*red*). The clavicle has been removed and the scapula rotated backward. The fibers of the muscle are divided into three groups and are identified by their fiber direction and the rib to which each digitation or segment attaches.

2.1. Innervation and Vascularization

The serratus anterior muscle is innervated by the long thoracic nerve which is derived from the anterior rami of spinal nerves C5-C7 and sometimes C8 nerve root.⁴ The fibers of the upper portion of the muscle receive innervation mainly from C5; the middle portion is innervated by C5 and C6, and the lower portion from C6 and C7.¹ The long thoracic nerve lies superficial to the serratus anterior muscle in the line of the anterior axillary fold. Smith et al⁵ demonstrated that a separate superior branch of the long thoracic nerve innervates the upper fibers of the serratus anterior muscle. The remaining parts of the muscle are innervated by the descending portion of the long thoracic nerve following its passage over the upper portion of the serratus anterior muscle. The long thoracic nerve is not vulnerable to entrapment within the serratus anterior muscle; however, branches from C5 and C6 (two of the nerve roots that form the long thoracic nerve) pass between the anterior and middle scalene muscle,⁶ and the branches are therefore vulnerable to entrapment by TrP activity in the middle scalene muscle. Trauma to the long thoracic nerve may cause paralysis of the serratus anterior muscle that results in winging of the scapula (ie, the scapula does not remain stabilized snugly against the thoracic wall).

The serratus anterior muscle receives its vascular supply from the superior thoracic artery, lateral thoracic artery, and thoracodorsal artery.¹

2.2. Function

The serratus anterior muscle is active during all upper extremity motions; however, it is most active during shoulder flexion and abduction due to its stabilizing effect on the scapula, and its contribution to upward rotation. This is particularly relevant for the upper part of the muscle since the middle part provides the scapular abduction, and the lower part contributes to upward rotation, abduction, and posterior tilting of the scapula.⁷ When elevating the upper extremity, as with flexion and abduction, the scapula undergoes upward rotation, external rotation, and posterior tilting. As the serratus anterior muscle contracts to move the scapula laterally around the chest wall, the displacement is resisted by the lower fibers of the trapezius muscle. In order to achieve 180° of humeral elevation, the scapula must depress, adduct, and tilt posteriorly at end-range upward rotation.⁸ These motions are coordinated by the serratus anterior muscle.

The superior portion of the serratus anterior muscle forms the main axis of rotation for the scapula, and the middle fibers draw the scapula forward.⁴ The inferior fibers of the muscle upwardly rotate the scapula while maintaining scapular position against the thorax during upper extremity elevation.^{4,9}

By abducting the scapula, the serratus anterior muscle protracts the shoulder girdle, as when the individual exerts effort to push an object forward. Thus, this muscle helps to stabilize the scapula against the posterior thorax during forward-pushing efforts.⁹ With the upper extremity fixed against a surface, it displaces the thorax posteriorly during a push-up from the floor or during a push back from the wall.

Because of its contribution to scapular mechanics and stabilization, the serratus anterior muscle plays a large role in overhead sporting activities. The serratus anterior muscle, in combination with the upper trapezius and anterior deltoid muscles, is active during the wind-up phase of the baseball pitch.¹⁰ These muscles work together to upwardly rotate and elevate the scapula when the arm is brought overhead. As the pitching arm is lowered to the chest level, the serratus anterior muscle eccentrically contracts to control downward rotation of the scapula.¹⁰ Additionally, electromyography (EMG) evidence demonstrates that maximum serratus anterior muscle contraction occurs during the cocking phase of the baseball pitch. Baseball pitchers with decreased activity from the serratus anterior muscle may be at an increased risk of subacromial pain syndrome and rotator cuff pathology due to a lack of scapular upward rotation, which may lead to misalignment of the scapula while the humerus is externally rotating and horizontally adducting.¹⁰ Electrocardiogram analysis of the golf swing has also demonstrated moderate activity of the serratus anterior muscle in the lead arm during the take-away phase of the swing and of the trail arm in the acceleration and deceleration phases.¹⁰

The serratus anterior muscle illustrates a paradoxical situation that sometimes arises with regard to the effect of TrPs and their functional implications. Because of the increased tension caused by the taut bands, one would not expect winging of the scapula to be a symptom of TrPs in the serratus anterior muscle. However, TrPs can have some effects that are largely uninvestigated and poorly understood. Clinically, scapular winging can sometimes be relieved by inactivating serratus anterior TrPs. Weakness in this case could reflect a combination of reflex facilitation of antagonist muscles and inhibition of the serratus anterior muscle. Janda¹¹ identified this muscle as one prone to weakness and inhibition leading to biomechanical imbalance in the shoulder girdle. This muscle inhibition, if left untreated, may lead to poor scapular positioning with upper extremity movements and secondary impingement as well as rotator cuff tears.³ In fact, athletes with shoulder and scapular dyskinesia exhibit weakness within the serratus anterior muscle that is associated with decreased upward rotation of the scapula.¹² Decreased muscle activation of the serratus anterior muscle is also found in non-athlete subjects with shoulder and scapular dyskinesia.¹³

2.3. Functional Unit

The functional unit to which a muscle belongs includes the muscles that reinforce and counter its actions as well as the joints that the muscle crosses. The interdependence of these structures is functionally reflected in the organization and neural connections of the sensory motor cortex. The functional unit is emphasized because the presence of a TrP in

one muscle of the unit increases the likelihood that the other muscles of the unit will also develop TrPs. When inactivating TrPs in a muscle, one must be concerned about TrPs that may develop in muscles that are functionally interdependent. Box 46-1 grossly represents the functional unit of the serratus anterior muscle.¹⁴

Box 46-1 Functional unit of the serratus anterior muscle

Action	Synergists	Antagonist
Shoulder protraction	Pectoralis major Subclavius Pectoralis minor	Rhomboid major Rhomboid minor Middle trapezius
Scapular upwardrotation	Trapezius (upper, lower fibers)	Rhomboid major Rhomboid minor Levator scapulae Latissimus dorsi

3. CLINICAL PRESENTATION

3.1. Referred Pain Pattern

Trigger points in the serratus anterior muscle can refer pain to the anterolateral part of the chest, the inferior angle of the scapula, medial aspect of the arm, and into the palm and ring finger (Figure 46-2). Kelly¹⁵ suggested that TrPs in the serratus anterior muscle should be considered as a source of symptoms when a patient reports pain anterolaterally at mid-chest level. Others suggested that serratus anterior TrPs are a common source of pain referral to the medial aspect of the arm, extending to the palm and ring finger.^{16,17}

Figure 46-2. Referred pain pattern (essential areas *solid dark red*, spillover areas *stippled dark red*) from TrPs in the right serratus anterior muscle (*medium red*), as seen from the back, front, and side view. Trigger points in fibers covering the first two ribs can be difficult or nearly impossible to reach for examination.

In some patients, TrPs in the serratus anterior muscle contribute to abnormal breast sensitivity, in combination with TrPs in the pectoralis major muscle,¹⁸ which are usually responsible for this patient reported symptom. Trigger points in the serratus anterior muscle can be found in any fiber of the muscle; however, the posterior attachment of the muscle located along the underside of the medial border of the scapula is difficult, if not impossible to localize and treat.

3.2. Symptoms

Chest pain from serratus anterior TrPs may be present at rest, during respiration, or during functional activities. When the TrPs are latent, pain may be precipitated by deep breathing (ie, a “stitch in the side”) while running. Similar pain may also arise from TrPs in the external abdominal oblique muscle, which interdigitates with the lowest group of serratus anterior fibers; or if the “stitch” is a little lower, it may result from diaphragm TrPs. A runner may press against, or squeeze, the painful area for relief in order to keep going; taking a few slow full breaths may also help. Patients report having difficulty finding a comfortable position at night and often are unable to lie on the affected side. In fact, chronic chest pain is a challenge for clinicians, and serratus anterior muscle pain is often overlooked. Vargas-Schaffer et al¹⁹ described a case series where patients experienced a significant reduction in pain after injection of serratus anterior TrPs.

Patients with TrPs in the serratus anterior muscle may report that they are “short of breath” or that they “can’t take a deep breath because it hurts.” Although patients are likely to receive a cardiopulmonary work-up for dyspnea, at least part of the cause is reduced tidal volume due to restriction of chest expansion by pain or by increased tension caused by TrPs in the serratus anterior muscle. Serratus anterior TrPs can enhance the pain associated with myocardial infarction when the left serratus anterior muscle is affected. The enhanced referred pain from these TrPs has been relieved by inactivating the pectoral and serratus anterior TrPs on the left side.²⁰ Pain is rarely aggravated by the usual tests for range of motion at the shoulder but may result from a strong effort to protract the shoulder girdle, for example during a serratus anterior punch. Trigger points may alter muscle activation patterns altering scapulo-humeral rhythm in the shoulder girdle.

Additionally, following breast cancer surgery, women may experience symptoms that mimic neuropathic post-mastectomy pain, which can also be caused or exacerbated by TrPs in the serratus anterior muscle. Torres-Lacomba et al²¹ found that 24% of 106 women who had undergone breast cancer surgery exhibited active TrPs in the serratus anterior muscle 1-year after surgery.

3.3. Patient Examination

After a thorough subjective examination, the clinician should make a detailed drawing representing the pain pattern that the patient has described. This depiction will assist in planning the physical examination and can be useful in monitoring the progression of the patient as symptoms improve or change. A patient's reports of chest pain should alert the clinician to perform a thorough review of the cardiovascular and pulmonary systems. Any concerns regarding the involvement of the cardiovascular or pulmonary systems as a source of symptoms should result in an immediate referral to the emergency room or a physician. For proper examination of the serratus anterior muscle, the clinician should observe shoulder girdle posture and scapula position, examine active and passive range of motion of the shoulder girdle, and observe muscle activation patterns and the scapulo-humeral rhythm. The clinician should note when and where pain occurs during testing motions.

Rounded shoulder posture and prominence of the superior border and spine of the scapula on the affected side can result from abduction and rotation of the scapula by restrictions in serratus anterior muscle fibers. Lee et al²² observed that slouched sitting posture affects scapular movement, inducing a scapular dyskinesia during arm elevation leading to overactive scapular stabilizers, including the serratus anterior muscle. The patient with a unilateral rounded shoulder posture is similar to that seen when the pectoralis major or minor muscles develop unilateral TrPs, but the pectoralis major muscle is often nearly equally affected on both sides of the body. Some patients may show winging of the scapula due to TrP inhibition of the serratus anterior muscle and facilitation of its antagonists.

The clinician should observe the patient's rib cage movement during respiration. Active TrPs in the serratus anterior muscle inhibit expansion of the lower chest due to pain. Upon inspiration, the patient can expand the upper thoracic rib cage, but measurement of chest expansion around the lower margin of the rib cage is likely to show marked restriction. After inactivation of TrPs in the serratus anterior muscle, a smaller minimum and a larger maximum lower chest circumference should be observed. The resultant marked increase in volume of tidal air is associated with relief of respiratory pain and dyspnea. Also, in the patients who experience a feeling of "air hunger" associated with rapid shallow respirations, the respiratory cycles usually revert to normal depth when all active serratus anterior TrPs have been inactivated.

Before treatment for serratus anterior TrPs, the patient is likely to underuse the diaphragm muscle and overuse the muscles of respiration in the neck, eg, scalene muscles. The diaphragmatic dysfunction and the reduced lower chest expansion appear to represent reflex inhibitory influences on respiration since the serratus anterior muscle is normally an accessory respiratory muscle for increased demand rather than a primary muscle of respiration along with the diaphragm and scalene muscles.

The clinician should stand behind the patient and observe scapular motion and scapulo-humeral rhythm while the patient performs shoulder flexion and elevation movements. Although the range of arm elevation may be within normal limits, scapulo-humeral rhythm and muscle activation can be disrupted by serratus anterior TrPs.

Differences in scapular position, specifically tilt, between affected and unaffected shoulders in patients with shoulder pain are significantly associated with pain and disability and changes in serratus anterior muscle activity.²³ The presence of either active or latent TrPs in the shoulder girdle musculature, including the serratus anterior muscle, may provoke an inconsistent pattern of motor activation and control during shoulder motion.²⁴ Therefore, the presence of TrPs in upward scapular rotators can alter the muscle activation pattern during scapular plane elevation, potentially predisposing the patient to overuse conditions including impingement syndrome, rotator cuff pathology, and myofascial pain.²⁴

The serratus anterior muscle should be tested directly for weakness or inhibition. Trigger points in the serratus anterior muscle may limit scapular range of adduction and the patient is likely to experience pain at the end of available movement, in contrast to the greater and pain-free range of motion on the uninvolved side. Subacromial pain syndrome can involve over-activation of the upper fibers of the trapezius muscle and a decrease in maximal activation of the serratus anterior muscle.²⁵

The serratus anterior muscle can also exhibit over-activity, which is dysfunctional in patients who have undergone neck dissection surgery for cancer and whose surgical side demonstrated clinical signs of accessory nerve injury.²⁶ Therefore, it is important that clinicians conduct a complete clinical examination of the shoulder girdle in patients with suspicion of serratus anterior TrPs.

3.4. Trigger Point Examination

Due to its superficial position, parts of the serratus anterior muscle are easy to palpate. Trigger points can be located in any of the muscle fibers of the muscle. Cross-fiber flat palpation is used to identify a taut band and TrPs. Since the serratus anterior muscle lies over the ribs, clinicians should differentiate between rib jumps and taut bands. Snapping palpation of the serratus anterior muscle can induce a local twitch response in the palpable taut band. For examination, the patient is side-lying, with the ipsilateral arm partly extended and the elbow bent (Figure 46-3). With the arm extended, the clinician locates the mid-axillary line, which is the optimal anatomic reference for palpation of TrPs in the serratus anterior muscle.

Figure 46-3. Cross-fiber flat palpation for TrPs in serratus anterior muscle.

4. DIFFERENTIAL DIAGNOSIS

4.1. Activation and Perpetuation of Trigger Points

In any part of the serratus anterior muscle, TrPs may be activated by unaccustomed eccentric loading, eccentric exercise in an unconditioned serratus anterior muscle, or maximal or sub-maximal concentric loading.²⁷ Trigger points may be also activated or aggravated when the muscle is placed in a shortened or lengthened position for an extended period of time.

Serratus anterior TrPs may be activated by muscle overload during excessively fast or prolonged running, push-ups, lifting heavy weights overhead, or strenuous coughing due to respiratory disease. Serratus anterior TrPs appear to be particularly vulnerable to torsional stresses, for example, when an automobile driver makes an abrupt forceful turn of a steering wheel in an attempt to avoid an accident or when the thorax rotates vigorously while the upper limb is in a fixed position.

Another cause of TrP activation in the serratus anterior muscle is surgery, particularly mastectomy for breast cancer²¹ or any surgery involving the nine uppermost ribs.

4.2. Associated Trigger Points

Associated TrPs can develop in the referred pain areas of TrPs in another muscle.²⁸ Therefore, muscles in the referred pain areas for each involved muscle should also be considered for examination. The latissimus dorsi, rhomboid major and minor, infraspinatus, coracobrachialis, biceps brachii, and flexor carpi ulnaris muscles should be examined for the presence of associated TrPs when the serratus anterior muscle is

implicated.

Patients with TrPs in the serratus anterior muscle rarely have involvement of only this muscle. Pain from serratus anterior TrPs is most likely only responsible for producing one layer of the patient's symptoms. Muscles of the serratus anterior muscle's functional unit must be considered as possible contributors to the overall pain presentation since they may harbor associated TrPs. Inter-scapular pain that is predominantly unilateral usually involves some combination of TrPs in the ipsilateral upper and mid-thoracic paraspinal muscles, the rhomboid muscles, the middle fibers of the trapezius muscle, and possibly the serratus posterior superior and scalene muscles.

Other muscles that may experience overload due to shortening and reduced function of the serratus anterior muscle include the latissimus dorsi muscle, pectoralis minor muscle, and other accessory muscles of inspiration. These muscles may develop TrPs that remain latent for a long period of time. Muscles that can produce a "stitch in the side" (in addition to the serratus anterior muscle) are the diaphragm and the external abdominal oblique muscles.

4.3. Associated Pathology

Differential diagnosis of symptoms caused by TrPs in the serratus anterior muscle should include costochondritis, intercostal nerve entrapment, C7-C8 radicular pain or radiculopathy, and herpes zoster.

Referred pain to the chest from the serratus anterior muscle must be distinguished from a rib fracture or intercostal TrP. In one patient, the stress fracture of a rib was attributed to serratus anterior muscle tension.²⁹ Referred pain to the chest on the left side must be differentiated from symptoms of cardiac disease. The referred pain to the back from the serratus anterior muscle requires consideration of TrPs in the middle portion of the trapezius, rhomboid, and paraspinal muscles as well as visceral organs such as the pancreas.

Mid-thoracic articular dysfunctions can produce similar symptoms to those of the serratus anterior muscle. Scapular winging may arise due to damage to the long thoracic nerve, most commonly caused by a traction or compression injury.³⁰ Thus, if scapular winging is observed, the clinician must consider long thoracic nerve damage as well as a C7 radiculopathy as a potential cause of serratus anterior muscle weakness.

In the presence of serratus anterior TrPs, examination of the rib cage can sometimes reveal what appears to be elevation of ribs two through ribs eight or nine. Abnormal tension of the serratus anterior muscle alone can mimic an articular dysfunction of the ribs when, in fact, the apparent articular dysfunction is simply the result of the increased muscle tension caused by the serratus anterior TrPs. In that case, inactivation of the TrPs alleviates whatever apparent articular dysfunction is noted.

5. CORRECTIVE ACTIONS

Patients benefit from avoiding or modifying activities that are likely to activate TrPs in the serratus anterior muscle when possible. If activation of TrPs is due to respiratory disorders

or upper respiratory infection, the patients can learn to gently clear the throat and to utilize protective bracing when deep coughing is necessary. Patients should be instructed in and encouraged to utilize diaphragmatic breathing. Sporting activities such as throwing, swimming, rock climbing, and golfing, as well as workout activities such as push-ups, heavy overhead lifting, and chinning should be avoided or modified as they all overload the serratus anterior muscle.

Patients with very irritable TrPs in the serratus anterior muscle are often unable to attain a comfortable position for sleeping. Lying on the affected side is painful because of pressure on the TrPs, and lying on the other side can be painful as well if the arm of the affected side falls forward onto the bed, placing the muscle in a shortened position. The latter problem is remedied by use of a pillow to support the arm in front of the chest, and to keep it and the scapula from falling forward as illustrated in Figure 22-4A.

Serratus anterior TrPs can be self-treated with pressure release utilizing a tennis ball or other TrP release tools. Trigger point pressure release can be performed in a seated, side-lying, or standing position (Figure 46-4). A seated self-stretch of the muscle can also be used after self-release and to restore healthy function of the muscle. The patient stabilizes the scapula of the involved side by placing the ipsilateral arm behind the chair back. After taking in a deep breath, the patient exhales slowly and turns the thorax toward the contralateral side. In Figure 46-5 the patient rotates the thorax toward the left (turns the front of the chest toward the left) to stretch the right serratus anterior muscle.

Figure 46-4. Self-pressure release. A and B, Using trigger point pressure release tool. C, Manual self-pressure release.

Joseph M. Donnelly and Jennifer L. Freeman

1. INTRODUCTION

The serratus posterior superior muscle is a thin muscle that lies beneath the rhomboid muscles and superficial to the splenii and erector spinae muscles and can be the cause of scapulocostal syndrome and upper extremity symptoms similar to thoracic outlet syndrome. It originates from the lower nuchal ligament, supraspinous ligament, and the spinous processes of C7-T3. It travels inferolaterally to attach to ribs two through five. It has been thought to function during respiration; however, there are no studies that support this notion. Its pain referral pattern is a deep ache below the scapula, proximal up to the cervical spine, and distal to the posterior arm, down to the forearm and hand in a C8-T1 distribution. Patients with serratus posterior superior trigger points (TrPs) may report interference with activities of daily living (ADLs), difficulty holding arms outstretched in front, and trouble sleeping on the affected side. The shoulder girdle and cervical spine should be examined when serratus posterior superior TrPs are suspected. Special attention should be given to the scalene muscles, pectoralis muscle length, scapular position, and any evidence of scapular dyskinesia. Real time ultrasound affords the clinician an opportunity to visualize this muscle and is recommended for TrP injection or dry needling treatment. Differential diagnosis should include scalene TrPs, thoracic outlet syndrome, C7-C8 radicular symptoms, olecranon bursitis, and ulnar neuropathy. Corrective actions should include instruction in proper posture and self-pressure release.

The serratus posterior inferior muscle can be a source of persistent flank pain when all other dysfunctions have been eliminated. It originates from the spinous processes of T11, T12 to L1-L2, and the thoracolumbar fascia. It travels superolaterally to attach to ribs 9 to 12. The function of this muscle has not yet been determined; however, recent research disputes its historically accepted role in respiration. The functional unit is more closely aligned with that of the iliocostalis and longissimus thoracis muscles, as well as the quadratus lumborum muscle. Pain from serratus posterior inferior TrPs is referred to the

flank area of the trunk over the ribs and occasionally to the anterior aspect of the trunk. Patients typically report a pain that persists in the flank area following resolution of thoracolumbar musculoskeletal dysfunction. Examination should include postural assessment of the thoracolumbar spine and lower extremity. Somatic dysfunction of the sacroiliac joint should be ruled out. Trigger points may form in this muscle from activities that require prolonged extension and rotation of the trunk or from leg length discrepancy. Erector spinae TrPs and associated articular dysfunctions should be treated prior to addressing TrPs in the serratus posterior inferior muscle. Differential diagnosis should include ruling out renal diseases and lower thoracic radicular pain. Corrective actions include effective sleeping, standing, and sitting postures, along with self-pressure release techniques.

2. ANATOMIC CONSIDERATIONS

Serratus Posterior Superior

The serratus posterior superior muscle originates from the dorsal midline fascia, lower aspect of the nuchal ligament, the spinous processes of C7 through T2 or T3 and their respective supraspinous ligaments.¹ It slopes downward and laterally to the cranial borders of the second through the fifth ribs (Figure 47-1). The number of digitations is variable and the muscle is sometimes absent.¹

Figure 47-1. Attachments of the serratus posterior superior muscle (*red*) to numbered vertebrae and ribs.

The fibers of the serratus posterior superior muscle are inclined at approximately 45° to the horizontal and lie immediately beneath the fibers of the rhomboid muscles, nearly parallel to them (Figure 47-2). Paraspinally, the vertically aligned fibers of the longissimus thoracis and iliocostalis muscles lie deep to the serratus posterior superior muscle.²

Figure 47-2. Anatomic relations of the serratus posterior superior muscle (*dark red*). The cut trapezius and rhomboid muscles (*light red*) lie over all of the serratus posterior superior muscle, and the iliocostalis and longissimus thoracis muscles (not shown) lie beneath part of this muscle.

2. SERRATUS POSTERIOR INFERIOR

The serratus posterior inferior muscle originates from the thin aponeurosis of the spinous processes of T11,12 and L1-L3 and their respective supraspinous ligaments, and it blends with the lumbar portion of the thoracolumbar fascia.¹ Its fibers travel superolaterally and insert through four digitations to attach to ribs 9-12, just lateral to their angles¹ (Figure 47-3). The digitations to one or more ribs, especially to the ninth and 12th ribs, are sometimes missing. Occasionally, the entire muscle is absent.^{1,3}

Figure 47-3. Attachments of the serratus posterior inferior muscle laterally to the lowest four ribs and medially to the aponeurosis extending from the spinous processes of the T11 to L2 vertebrae.

2.1. Innervation and Vascularization

Serratus Posterior Superior

The serratus posterior superior muscle is innervated by the second through fifth intercostal nerves, which are branches of the anterior primary rami of T2-T5.¹

Serratus Posterior Inferior

The serratus posterior inferior muscle is innervated by the anterior primary divisions of spinal nerves¹ T9 through T12, unlike the erector spinae muscles which are innervated by the posterior divisions.

2.2. Function

Serratus Posterior Superior

The serratus posterior superior muscle, due to its anatomic alignment of fibers, is thought to raise the ribs to which it is attached, thereby expanding the chest and aiding inhalation; however, there are no electromyographic studies that have validated this assumption.^{1, 4}

Serratus Posterior Inferior

The serratus posterior inferior muscle attaches to the lower ribs, and due to its anatomic alignment, it has been described as an exhalation muscle or as functioning to pull the lower ribs downwards and backwards.¹ However, one older electromyographic study found no respiratory activity attributable to the muscle.⁵

The functions of the serratus posterior superior or inferior muscles have not been definitively determined in humans, and there is a paucity in the literature regarding their purpose. Vilensky et al⁶ suggest that there is no evidence to support the role of the serratus posterior superior or inferior muscles in respiration. They conclude that the clinical importance of these muscles is their ability to generate pain, especially in the shoulder (scapulocostal syndrome) and flank. These muscles may have proprioceptive and postural functions, though to date, no research has been conducted to explore these theories.

In a study by Loukas et al⁷ that compared cadavers with a history of chronic obstructive pulmonary disease (COPD) to those without, no difference in the morphology, topography, or morphometry of these muscles was found. Based on these results, the authors concur with Vilensky's⁶ suggestion that the serratus posterior superior and inferior muscles do not have a respiratory function.⁷

2.3. Functional Unit

The functional unit to which a muscle belongs includes the muscles that reinforce and counter its actions as well as the joints that the muscle crosses. The interdependence of these structures is functionally reflected in the organization and neural connections of the sensory motor cortex. The functional unit is emphasized because the presence of a TrP in one muscle of the unit increases the likelihood that the other muscles of the unit will also develop TrPs. When inactivating TrPs in a muscle, one must be concerned about TrPs that may develop in muscles that are functionally interdependent.²

Serratus Posterior Superior

If one considers the function of the serratus posterior superior muscle to be a muscle of inspiration then the diaphragm, intercostal, levator costae, and scalene muscles would act synergistically. Muscles of expiration would be considered as its antagonists in this scenario.

Serratus Posterior Inferior

The serratus posterior inferior muscle appears to act synergistically with the ipsilateral iliocostalis and longissimus thoracis muscles, unilaterally for rotation and bilaterally for extension of the spine. As an accessory muscle of exhalation, it would likely act synergistically with the quadratus lumborum muscle.

3. CLINICAL PRESENTATION

3.1. Referred Pain Pattern

Serratus Posterior Superior

The essential pain reference area of this muscle is a deep ache under the upper portion of the scapula (Figure 47-4A). This pain is perceived as deeper than the similar upper back pain that arises from the middle trapezius muscle. Pain is usually felt intensely over the posterior border of the deltoid and over the long head of the triceps brachii muscles.⁸⁻¹⁰ It often covers the entire triceps brachii region with an accent on the olecranon process of the ulna and occasionally includes the ulnar side of the forearm, hand, and the entire fifth digit. Anteriorly, the pectoral region may occasionally be painful (Figure 47-4B). Trigger points in the serratus posterior superior muscle often cause numbness into the C8-T1 distribution of the hand.¹¹

Figure 47-4. Referred pain pattern of a TrP in the right serratus posterior superior muscle. Essential pain is *solid red*, spillover pain is *stippled red*. A, Back view of pain pattern. B, Front view of pain pattern. C, Scapula abducted, making the muscle accessible to palpation and injection/dry needling. D, Scapula in resting position, partially covering the serratus posterior superior muscle.

The most troublesome TrPs in the serratus posterior superior muscle are the ones that lie beneath the scapula. The problem occurs when the scapula compresses the sensitive region of enthesopathy against the underlying rib to which the muscle fibers attach. Among 76 painful shoulders in 58 patients, this muscle was a cause of pain in 98% and the single source of pain in 10%.⁹

Serratus Posterior Inferior

Trigger points in the serratus posterior inferior muscle produces aching discomfort over and around the muscle in the area commonly referred to the flank of the trunk (Figure 47-5). The pain extends across the back and over the lower ribs. Patients may identify this annoying ache as muscular in origin at the thoracolumbar junction. Occasionally, the pain is perceived as extending through the body to the chest.

Figure 47-5. Referred pain pattern (essential zone is *solid dark red*, spillover zone is *stippled dark red*) of TrPs in the right serratus posterior inferior muscle (*light red*).

3.2. Symptoms

Serratus Posterior Superior

The patient may report a deep steady ache under the scapula at rest and with ADLs. Little or no change in the intensity of pain occurs with unloaded movements. However, pain may be increased by lifting objects with outstretched hands or by other activities that cause the scapula to press against TrPs in the muscle, such as lying on the painful side. When asked to point to the painful area, patients usually reach back with the opposite arm but are unable to touch the sore area because the shoulder blade covers it.

McCarthy et al¹² identified serratus posterior superior TrPs as a source of symptoms in a 43-year-old woman diagnosed with scapulocostal syndrome who presented with ongoing constant aching pain in the upper subscapular area, which radiated proximally to the cervical spine, and down the posterior aspect of the shoulder and ulnar aspect of the forearm into the fourth and fifth digits. Differential diagnostic tests were unremarkable and the patient failed to progress in physical therapy. The treatment included an ultrasound-guided TrP injection into the serratus posterior superior TrPs. At both 30 minutes and 2 weeks post injection, the patient reported relief of her resting symptoms, and was able to perform ADLs including lying on the affected side without pain. The authors therefore conclude that ultrasound-guided TrP injection can confirm a diagnosis of scapulocostal syndrome and be therapeutically beneficial.^{12,13}

Serratus Posterior Inferior

Patients may report pain in the flank area of the trunk especially when TrPs of associated major muscles of the back have been eliminated. A patient may be left with a nagging or “annoying” ache in the lower thoracolumbar region that is temporarily relieved with stretching. The onset of the symptoms may be related to activities such as working overhead on a ladder or activities that require combined trunk extension and ipsilateral rotation.

Maximal deep inhalation and coughing usually do not evoke pain from the serratus posterior inferior TrPs as they may from TrPs in the serratus anterior, quadratus lumborum, and deep abdominal wall muscles.

3.3. Patient Examination

After a thorough subjective examination the clinician should make a detailed drawing representing the pain pattern that the patient has described. This depiction will assist in planning the physical examination and can be useful in monitoring the progression of the patient as symptoms improve or change.

Serratus Posterior Superior

For proper examination of the serratus posterior superior muscle, the clinician should

observe shoulder girdle posture and scapula position, examine active and passive range of motion of the shoulder girdle, and observe muscle activation patterns, including the scapulo-humeral rhythm. Cervical and thoracic spine active and passive range of motion should also be assessed. The clinician should note when and where pain occurs. When observing the patient from the rear, the clinician may note scapular position and asymmetries. The medial and inferior border of the scapula may be off the rib cage giving the appearance of a “winged scapula.” This abnormal resting position will cause scapular dyskinesia during functional upper extremity movements and potentially, increased compression on the serratus posterior superior muscle. Pectoralis minor muscle length should be assessed especially when anterior tipping of the scapula is noted as this may also place abnormal compressive loading of the scapula on the serratus posterior superior muscle.

Accessory joint motion should be tested in the glenohumeral, acromioclavicular, sternoclavicular, and scapulo-thoracic joints, as well as the thoracic rib cage and cervicothoracic vertebrae. Oftentimes, joint hypomobility in the sternoclavicular joint or rib cage can cause impairment in shoulder elevation that contributes to alterations in the normal muscle activation patterns.

Symptoms from TrPs in the serratus posterior superior muscle must be differentiated from scalene TrPs as the pain referral pattern in the scapular region and upper extremity is very similar.

Patients with intrathoracic disease that compromises ventilation, such as emphysema, are in double trouble if they also develop TrPs in this serratus posterior superior muscle. These individuals generally do not exhibit rounded shoulder posture (as compared with those with rhomboid and pectoral muscle involvement), and they have little or no apparent restriction of movement. They often have scoliosis, especially the functional type that results from a leg length discrepancy or small hemipelvis.

Serratus Posterior Inferior

For proper examination of the serratus posterior inferior muscle, the clinician should observe spinal and lower extremity posture, examine active and passive range of motion of the thoracolumbar spine, and observe muscle activation patterns of the thoracolumbar region. The clinician should note when and where pain occurs. Patients may demonstrate slight restriction of thoracolumbar flexion and of spinal extension due to pain, and may be limited in rotating the torso away from the painful side. Manual examination and palpation of this muscle may be the most definitive examination procedure performed by the clinician.

Accessory joint motion should be assessed in the lower thoracic and upper lumbar inter-vertebral segments, and the lower thoracic rib cage. Iliac crest motion palpation should also be performed due to the related function of the quadratus lumborum.

3.4. Trigger Point Examination

Serratus Posterior Superior

The patient sits and leans forward slightly, with the arm hanging forward and down on the side to be examined (Figure 47-6), or with the ipsilateral hand placed in the opposite axilla, to fully abduct the scapula.⁹ The scapula must be abducted and pulled laterally to uncover the serratus posterior superior TrPs beneath the scapula (Figures 47-4C and 47-6). The serratus posterior superior muscle is palpated through the trapezius and rhomboid muscles (Figure 47-2). Cross-fiber flat palpation may elicit local twitch responses of TrPs in the overlying trapezius fibers, which can be identified because of the nearly horizontal orientation of those superficial fibers. However, local twitch responses in the deeper, obliquely oriented rhomboid and serratus posterior superior fibers are not so readily perceived, but may be palpable. Some authors do not believe this muscle can be palpated.⁴

Figure 47-6. Palpation for TrPs in serratus posterior superior muscle using cross-fiber flat palpation. Patient in prone lying with arm off the edge of the table and scapula maximally protracted to gain access to the muscle deep to the rhomboids.

A serratus posterior superior TrP is identified as a spot of deep tenderness when palpated against an underlying rib. It is unlikely that a taut band will be palpable through the two overlying muscles. When manual pressure on a TrP induces the characteristic serratus posterior superior referred pain pattern that the patient recognizes as familiar, it convinces them of the relationship between this TrP and the pain they experience.

Serratus Posterior Inferior

Trigger points in the serratus posterior inferior muscle may be difficult to palpate through, and distinguish from, the overlying latissimus dorsi muscle. However, the mid-fiber TrPs

are usually identifiable utilizing a cross-fiber flat palpation technique (Figure 47-7). The TrPs at the lateral attachments of the muscle, close to the muscle's rib attachments, are also readily palpated. Local twitch responses are difficult to elicit and detect by cross-fiber flat palpation in this muscle but may be felt during TrP dry needling or injection.

Figure 47-7. Palpation for TrPs in the serratus posterior inferior muscle using cross-fiber flat palpation.

4. DIFFERENTIAL DIAGNOSIS

4.1. Activation and Perpetuation of Trigger Points

In any part of the serratus posterior superior and inferior muscles, TrPs may be activated by compressive loading from the scapula, unaccustomed eccentric loading, eccentric exercise, or maximal or sub-maximal concentric loading.¹⁴ Trigger points may also be activated or aggravated when the muscle is placed in a shortened or lengthened position for an extended period of time.

Serratus Posterior Superior

Movements and postures that stretch and overload the serratus posterior superior muscle may activate TrPs. These situations include prolonged computer use, utilizing an ergonomically inefficient workstation, prolonged overhead activities, repeated forward reaching, and protrusion of the thorax against the scapula by a structural or functional scoliosis.

Serratus Posterior Inferior

The serratus posterior inferior muscle is one of many back muscles that are susceptible to overload during the combined movement of lifting, turning, and reaching. Trigger points in the serratus posterior inferior muscle may develop due to mechanical overload or concurrently with TrPs in associated muscles. Standing on a ladder with the back hyperextended to work overhead may activate TrPs in this muscle, and paradoxical breathing or a leg length discrepancy may perpetuate them.

4.2. Associated Trigger Points

Associated TrPs can develop in the referred pain areas caused by TrPs.¹⁵ Therefore, musculature in the referred pain areas for each muscle should also be considered.

Serratus Posterior Superior

Trigger points in the scalene muscles can induce associated TrPs in the serratus posterior superior muscle¹⁶ and occasionally the relationship occurs in the reverse direction; the serratus posterior superior muscle can be the source of TrPs in the scalene muscles.

Trigger points in the serratus posterior superior muscle lie within the pain reference zone of the scalene muscles. The scalene TrPs may, in part, mimic the pain pattern of the serratus posterior superior muscle. The neck should always be examined for scalene TrPs if a TrP is found in the serratus posterior superior muscle. Other muscles that should be examined for associated TrPs include the rhomboid major and minor, iliocostalis and longissimus thoracis, multifidus, infraspinatus, posterior deltoid, triceps brachii, pectoralis major and minor, and flexor carpi ulnaris muscles as they are in the region of referred pain from the serratus posterior superior muscle.

Serratus Posterior Inferior

Trigger points in the iliocostalis and longissimus thoracis muscles, and in the multifidus muscle have pain referral patterns that overlap that of the serratus posterior inferior muscle and should be addressed prior to attempts to address TrPs in the serratus posterior inferior muscle. The specific area of discomfort associated with TrPs in this muscle is likely to be noticed only after successful treatment of symptoms arising from TrPs in associated muscles.

4.3. Associated Pathology

Serratus Posterior Superior

Differential diagnoses of symptoms caused by TrPs in the serratus posterior superior muscle includes thoracic outlet syndrome, C7-C8 radicular pain, olecranon bursitis, and ulnar neuropathy. The referred pain pattern of this muscle mimics the distribution of pain caused by eighth cervical root compression¹⁷ and this diagnosis must be considered. Confusion is further aggravated by the referred numbness into the C8-T1 distribution of the hand,¹¹

which may cause a clinician to diagnosis the patient as having C8-T1 radiculopathy, when the symptoms are actually caused by TrPs in the serratus posterior superior muscle.

Fourie¹⁸ described a scapulocostal syndrome associated with myofascial dysfunction. The pain and tenderness was caused by an enthesopathy of the lateral attachments of the serratus posterior superior digitations to the ribs. This syndrome can be diagnosed and managed clinically by utilizing ultrasound-guided TrP injection.¹²

Articular dysfunction associated with this muscle usually occurs at the T1 level. Exquisite tenderness is commonly noted directly over the spinous process of this segment. On inspection, this configuration of articular dysfunctions presents as a regional extension of the upper thoracic spine with inability to flex forward across the involved segments.

Serratus Posterior Inferior

Differential diagnoses of the symptoms caused by TrPs in this muscle include renal diseases (caliectasis, pyelonephritis, or ureteral reflux), and a lower thoracic radicular pain. The most common articular dysfunction associated with serratus posterior inferior TrPs is a neutral dysfunction extending from T10 to L2. Occasionally, one finds a concurrent depression or “exhalation” dysfunction of the lower four ribs.¹⁹

5. CORRECTIVE ACTIONS

Serratus Posterior Superior

The patient should maintain normal lumbar lordosis during both standing and sitting. When seated, this posture is facilitated by placing an appropriately sized lumbar pillow in the small of the back, then relaxing and leaning against the back of the chair so that the pillow maintains both the normal lumbar and thoracic curves without muscle strain. When sleeping, the patient must avoid compressive loading of the muscle by the shoulder blade. When lying on the back, the corner of the pillow should be tucked between the head and shoulder, not tucked under the shoulder (see Figure 7-5A). A pillow should also be placed between the axilla and chest wall supporting the upper arm so that the arm is in a neutral position. Allowing the arm to fall behind the body will place the pectoral muscles in a prolonged shortened position resulting in a compressive load on the serratus posterior superior muscle and aggravating the TrPs under the scapula (see Figure 22-4B).

It is very important that the patient uses coordinated diaphragmatic breathing, (see Figures 20-12 and 20-13) not paradoxical breathing, to minimize overload of the upper-chest muscles of inspiration, especially the scalene muscles.

While supine, the patient may find it possible to apply pressure release by lying on a tennis ball placed under the interscapular region or using a TrP release tool in sitting (Figure 47-8A), if the shoulder blade can wrap around the side sufficiently. As an alternate strategy, a companion may be taught to apply pressure release.

Figure 47-8. Self-pressure release of TrPs using TrP release tool. A, Serratus posterior superior muscle. B, Serratus posterior inferior muscle.

Serratus Posterior Inferior

Many of the effective corrective actions for this muscle are covered in other chapters, including the use of lifts to correct the compensatory scoliosis caused by a small hemipelvis when sitting or by a leg length discrepancy when standing; normalization of paradoxical breathing (see Figures 20-12 and 20-13); sitting in well-fitted chairs with adequate lumbar support; standing with a normal lordotic lumbar curve; and sleeping on a firm mattress that supports the natural curves of the spine. Placing a pillow between the legs when sleeping on the side will also keep the spine in a neutral position, thus decreasing abnormal tension on these muscles.

A manual release technique with respiratory augmentation as described and illustrated in Figure 47-9 is recommended. Its effectiveness can often be augmented by post-isometric relaxation. The patient's ipsilateral arm is placed overhead to pull the rib cage upward and the torso toward the opposite side to take up slack in the muscle. Similar to the serratus posterior superior muscle, the serratus posterior inferior muscle can also be treated in sitting or standing with a TrP release tool (Figure 47.8B).

Figure 47-9. Manual stretch of the left serratus posterior inferior muscle. Patient lies on right side with left arm elevated.

Thoracolumbar Paraspinal Muscles

“Ropey Rivals”

Michelle Finnegan, Margaret M. Gebhardt, and Jennifer L. Freeman

1. INTRODUCTION

The paraspinal muscles are comprised of two layers, a superficial layer of long-fibered extensors (erector spinae), and a deep layer of shorter, more diagonal extensor rotators (spinotransverse muscles). The erector spinae group is comprised of the spinalis, longissimus, and iliocostalis muscles. Within the erector spinae, the longissimus and iliocostalis muscles can be an important source of trigger point (TrP) pain. The spinotransverse group includes the rotatores, multifidus, and semispinalis muscles. Collectively, these back muscles have attachments to C7, the ribs, the thoracic and lumbar spine, and thoracolumbar fascia. They insert to various trunk landmarks including the ribs, lumbar spine, iliac crest, sacrum, and thoracolumbar aponeurosis. Innervation of the erector spinae muscles is provided by the lateral branches of the dorsal rami of the thoracic and lumbar spinal nerves, while the spinotransverse group is innervated by the medial branch of the dorsal rami of the appropriate spinal nerve. The primary functions of the thoracolumbar paraspinals are extension of the thoracic and lumbar spine and lateral trunk flexion. They also function eccentrically to control the trunk as it flexes forward. The iliocostalis muscle refers pain toward the shoulder, chest wall, scapula, abdomen, and down toward the lumbar region. The longissimus muscle refers pain to the lumbar region and buttock. The multifidus muscle refers pain to the region around the spinous process of the adjacent vertebrae, to the abdomen, coccyx, posterior thigh and leg, as well as the anterior thigh. A patient with TrPs in this muscle group will commonly report back pain and have difficulty bending forward. Activation and perpetuation of TrPs in the thoracolumbar paraspinals can result from prolonged awkward postures, quick bending and twisting of the spine, and a leg length discrepancy. Differential diagnosis includes visceral pathology, segmental joint dysfunction, fibromyalgia, radiculopathy, myositis ossificans, fibrodysplasia ossificans progressiva, and acute paraspinal compartment syndrome. Corrective actions should include postural reeducation, a focus on effective ergonomics, proper sleep

positions, and elimination of positions and movements that cause recurrent overload on the muscle, self-pressure release of TrPs, and self-stretch exercises.

2. ANATOMIC CONSIDERATIONS

The anatomic complexity of the paraspinal muscles is simplified by classifying them into two layers, a superficial layer of long-fibered extensors (erector spinae) and a deep layer of shorter, more diagonal extensor rotators (spinotransverse muscles) (Figures 48-1 and 48-2). The erector spinae group consists of the spinalis, longissimus, and iliocostalis muscles. The spinotransverse group includes the rotatores, multifidus, and semispinalis muscles.¹ The validity of these traditional classifications is questionable, and recent morphologic evidence suggests that all the epaxial muscles may only be variations of just a few muscles.²

Superficial (Erector Spinae)

The erector spinae group is divided into the most medial spinalis muscles, the most lateral iliocostalis muscles, and the longissimus muscles in between. Each muscle may be further divided and discussed relative to the portion of the spine it spans. For example, the iliocostalis thoracis muscle spans a portion of the trunk generally inferior to the iliocostalis cervicis muscle and superior to the iliocostalis lumborum muscle, with some opportunities for overlap. Generally, the more superior components of each of these approximately vertically running muscles are also the most medially located when they overlap, eg, the longissimus capitis muscle is medial to the longissimus cervicis muscle, which is medial to the longissimus thoracis muscle. These classifications are helpful in understanding the anatomy of this complex set of muscles. However, because there is much convergence and interdigitation between them, as well as much morphologic similarity, considering actions and treatment of these muscles as larger functional groups is most effective.^{1,2} See anatomy texts for further detail regarding these denominations and relationships. For more information on the superior portions of the erector spinae muscles, see Chapter 16.

The most medial muscle of the erector spinae group is the spinalis muscle. Although it can be absent or hard to distinguish in the cervical and lumbar regions, it is typically evident in the thoracic spine. The fascicles that comprise the spinalis thoracis muscle run from spinous process to spinous process of vertebrae throughout the thoracic spine with a varying number of segments bridged. Fibers from the spinalis muscle often blend with the adjacent longissimus muscle.¹

The centrally located longissimus muscle is the largest of the erector spinae group (Figure 48-1). It typically has robust lumbar and thoracic components (these are named together as the “longissimus thoracis muscle”) that receive the most clinical attention. The thoracic portion consists of fascicles with small, fusiform muscle bellies that have short rostral tendons and longer caudal tendons. As with all the erector spinae muscles, the bellies of the muscle are tiered, with the highest one being the most medial and the lowest one lying most laterally. The upper four fascicles arise from the tips of the first four thoracic transverse processes, whereas subsequent fascicles have bifid tendons that arise from the

transverse process and the adjacent rib at each of the lower eight thoracic segments. The long caudal tendons are gathered in parallel to form a wide aponeurosis, allowing them a variety of caudal insertions. The tendons of the uppermost fascicles insert into the lumbar spinous processes and the supraspinous ligament. Those from the first thoracic segment reach the L1-L2 level, whereas fascicles from T6 reach the L5 level. Fascicles from T7-T9 reach the median crest of the sacrum, while whereas those from T10 and T11 attach to the posterior surface of the third segment of the sacrum. The fascicle from T12 attaches to the sacrum and dorsal segment of the iliac crest. The lumbar portion of the longissimus muscle has bundles that arise from the accessory process and medial half of the posterior surface of the transverse process of each of the five lumbar vertebrae. The bundles from the first four lumbar segments converge onto a common flat tendon that covers the lateral surface of the muscle, separating it from the lumbar fibers of the iliocostalis muscle. The fascicle from the L1 vertebra attaches rostrally and dorsally to the aponeurosis, whereas successive fascicles attach ventrally and caudally to the aponeurosis. The fascicle from the L5 vertebra inserts deep to the aponeurosis, into the anteromedial aspect of the ilium and upper fibers of the dorsal sacroiliac ligament.¹

Figure 48-1. Attachments of the superficial (erector spinae muscle) group of paraspinal muscles (red): *medially* the longissimus thoracis muscle, and *laterally* the iliocostalis thoracis and iliocostalis lumborum muscles.

Generally, the iliocostalis muscle is located lateral to the longissimus muscle (Figure 48-1). The thoracic portion is comprised of eight to nine fascicles that arise respectively from the lower eight or nine ribs at their angles, just lateral to the iliocostalis cervicis muscle. The muscle bellies of the fascicles each give rise to a caudal tendon that together form a dorsal aponeurosis that covers the lumbar portion of the iliocostalis muscle and inserts into the medial end of the iliac rest and its dorsal segment.¹ The lumbar portion has fascicles that arise from the tips of the L1-L4 transverse processes and the thoracolumbar fascia, lateral to the tips. They travel inferiorly toward the ilium and insert into the medial end and dorsal segment of the iliac crest. The fascicle from L4 is the most ventral and lateral attachment while the fascicle from L1 is the most dorsal and medial attachment.

Figure 48-2. Attachments of the deep group of paraspinal muscles. Right, The more superficial of this group is the semispinalis thoracis muscle at the thoracic level (light red), which overlies the multifidi muscles, and the multifidi muscles at the thoracic, lumbar, and sacral levels (dark red). Left, The rotatores muscles form the deepest layer at both the thoracic and lumbar levels. The rotatores muscles occur above the sacral level. Only the multifidi muscles extend across sacral segments.

Deep Paraspinal (Spinotransverse)

The spinotransverse muscles are a group of muscles comprised of interconnected fascicles that run between spinous and transverse processes of vertebrae throughout the spine. Classical delineations have used different names to subclassify this group into three main categories based on the length of fascicles and proximity to the spine: the smallest and deepest being named the rotatores muscles, the longest and most superficial labeled the semispinalis muscle, and the multifidus muscle having a length and depth between the two. However, recent morphologic studies dispute these classifications on the basis of shared similarity in attachments, fiber alignment, fiber type of these muscles' fascicles, and a lack of separate epimysiums for each fascicle. Discussions of the spinotransverse muscle system may be better informed by an understanding that the categorization of these fascicles into separate muscles is purely nominal and does not represent a functional difference.²

The deepest and shortest fascicles of the spinotransverse muscle system (the rotatores muscles) span only one to two segments. There are typically 11 pairs of this type, with the first pair starting between the first and second thoracic vertebrae and the last ending between the 11th and 12th thoracic vertebrae. They connect the lamina and base of the spinous process above to the posterior aspect of the transverse process one to two levels below, respectively.¹

The middle segments of the spinotransverse muscle system (the multifidus muscle) cover the lamina of the vertebrae in the thoracic and upper lumbar sections; however, at the lumbosacral levels, it expands to also cover the posterior surface of the sacrum. These fascicles typically span two to five segments. Several fascicles arise from the caudal edge of the lateral surface of the spinous process and from the caudal end of its tip, then travel inferiorly to insert into the transverse elements of vertebrae two, three, four, or five levels below. In the thoracic spine, this element is the posterior surface of the transverse processes and in the lumbar spine it is the mammillary processes.¹ This type of fascicle is generally thickest in the lumbar and sacral portions of the spine.

The longest and most superficial fascicles of the spinotransverse muscle group (the semispinalis muscle) are comprised of thin fibers with long tendons on each end. These fibers cover those of the shorter fascicles (the multifidus muscle). Traditionally, they are thought to have a capital, cervical, and thoracic portions, arising from as high as the occiput and the spinous processes of C2-T4 and insert into the transverse processes of T6-T10¹; however, this layer of long fascicles has been found throughout the lumbar spine as well.²

2.1. Innervation and Vascularization

The erector spinae muscle group is innervated by the lateral branches of the dorsal rami of the thoracic and lumbar spinal nerves. At the lumbar levels, the lateral branches innervate the iliocostalis muscle, while the intermediate branches innervate the longissimus. The spinotransverse muscle group is innervated by the medial branches of the dorsal rami of the appropriate spinal nerves.¹

The intrinsic muscles of the back receive vascular supply from several arteries including the superior intercostal artery via dorsal branches of the upper two posterior intercostal arteries, the posterior intercostal arteries of the lower nine spaces via dorsal branches of the subcostal arteries, dorsal branches of the lumbar arteries, dorsal branches of arteria lumbalis, and dorsal branches of the lateral sacral arteries.¹

2.2. Function

Superficial Paraspinal (Erector Spinae)

The erector spinae muscles are strong extensors of the spinal column that more commonly act eccentrically than concentrically. Bilaterally, the muscles extend the thoracic and lumbar spine when firing concentrically. Unilaterally, the muscles laterally flex the trunk when firing concentrically. The erector spinae muscles on the contralateral side will eccentrically control lateral trunk motion and, when acting bilaterally, eccentrically control the trunk when bending forward. When fully flexed, most parts of the erector spinae muscles become electromyographically silent.¹

In individuals with low back pain, the multifidus, paraspinals, external oblique, and rectus abdominis muscles have increased electromyogram (EMG) activity.³ However, the increase in EMG activity in the paraspinal muscles of individuals with low back pain is not due to guarding; rather, it results from changes in motor control.^{4,5}

Deep Paraspinal (Spinotransverse)

The spinotransverse muscles extend the vertebrae from which they arise. They are not able to rotate the spine because of the longitudinal orientation of the fibers.¹ Lee et al⁶ found that the multifidus muscle in the thoracic spine is variably active with rotation in either or both directions, thereby contributing to control segmentally or through coupling of motions. The multifidus muscle can control intervertebral shear and torsion without generating torque.⁷ It is also part of the feed forward activity during arm movements.^{8,9} The lumbar multifidus muscle is activated more during the abdominal bracing maneuver versus the abdominal drawing-in maneuver.¹⁰ The lumbar multifidus muscle is also more active with fast walking,^{11,12} with the deep fibers of the multifidus muscle having a greater postural function than the superficial fibers.¹²

2.3. Functional Unit

The functional unit to which a muscle belongs includes the muscles that reinforce and counter its actions as well as the joints that the muscle crosses. The interdependence of these structures is functionally reflected in the organization and neural connections of the sensory motor cortex. The functional unit is emphasized because the presence of a TrP in one muscle of the unit increases the likelihood that the other muscles of the unit will also develop TrPs. When inactivating TrPs in a muscle, one must be concerned about TrPs that may develop in muscles that are functionally interdependent. Box 48-1 grossly represents the functional unit of the thoracolumbar paraspinal muscles.¹³

Box 48-1 Functional unit of the paraspinal muscles

Action	Synergists	Antagonists
Thoracic and lumbar extension	Quadratus lumborum, thoracolumbar paraspinals	Rectus abdominus, internal and external oblique
Lateral trunk flexion	Ipsilateral quadratus lumborum, ipsilateral thoracolumbar paraspinals	Contralateral quadratus lumborum, contralateral thoracolumbar paraspinals

The thoracolumbar paraspinal muscles function not only to stabilize the spine but also to assist with force transmission. With their multiple angles of origin and insertion, as well as their fascial connections, the paraspinal muscles can work in concert with the abdominal (internal and external oblique and transversus abdominis muscles), latissimus dorsi, gluteal, rhomboid, and middle and lower trapezius muscles. They function to transfer load from the ground into the trunk and vice versa from overhead work. When functioning in a stabilizing role, the paraspinal muscles, along with the transverse abdominis muscle via the paraspinal fascia, assist with stability in the transverse plane.¹⁴

When there is breakdown in the kinetic chain from injury/trauma, muscle weakness or length/strength imbalances, inhibition, poor biomechanics of the upper or lower quarter, etc, the paraspinal muscles tend to overcompensate in the sagittal plane. They often compensate for weak hip extension or abdominal control when handling heavy loads or with repeated movements in this plane.

3. CLINICAL PRESENTATION

3.1. Referred Pain Pattern

Trigger points in the thoracolumbar paraspinal muscles are one of the most common causes of back pain (see Chapter 53 for more clinical considerations on causes of back pain). The referred pain patterns illustrated for these back muscles at specific segmental levels are common examples, but TrPs may develop at any segmental level.

Superficial Paraspinal (Erector Spinae)

In the thoracic spine, the two muscles that are most likely to develop TrPs are the longissimus thoracis and the iliocostalis thoracis muscles. The iliocostalis thoracis muscle refers pain both cephalad and caudad, while the longissimus thoracis muscle refers pain mainly caudad.¹⁵

The pattern of referred pain from TrPs in the iliocostalis thoracis muscle at the mid-thoracic level (Figure 48-3A) is up toward the shoulder and laterally to the chest wall. This pain could be mistaken for pleurisy on either side or cardiac angina if present only on the left.¹⁶⁻¹⁸ At the lower thoracic level (Figure 48-3B), iliocostalis thoracis and lumborum TrPs may refer pain upward across the scapula, around to the abdomen, and downward over the lumbar area.^{15,19} This pain referred to the abdomen may be mistaken for visceral pain.^{18,-20,21} Iliocostalis lumborum TrPs at the upper lumbar level (Figure 48-3C) refer pain strongly downward, concentrating on the mid-buttock, and is a frequent source of unilateral posterior hip pain.^{15,-21,22}

Figure 48-3. Examples of referred pain patterns (essential reference zones are solid red, spillover areas are stippled red) at several levels in the erector spinae muscles. A, The midlevel of the right iliocostalis thoracis muscle. B, The caudal portion of the right iliocostalis thoracis muscle. C, The upper end of the right iliocostalis lumborum muscle. D, The lower thoracic (right) and upper lumbar (left) longissimus thoracis muscles.

Trigger points in the lower thoracic level of the longissimus thoracis muscle (Figure 48-3D, on right of figure) refer pain strongly low in the buttock.^{15,19} This remote source of buttock pain is easily and often overlooked. Longissimus thoracis TrPs in the most caudal

portion of the muscle fibers, which are located in the upper lumbar area, usually refer pain several segments caudally but still within the lumbar region (Figure 48-3D, on left of figure).^{15, 19} This pain is another muscular source of “lumbago.”

Kellgren mapped experimentally induced referred pain patterns of the erector spinae muscles by injecting hypertonic saline solution into normal muscles.²³ He reported that the superficial erector spinae muscles at the mid-lumbar level referred pain to the upper part of the buttock. In a similar study, hypertonic saline injection of the structures along the edge of the interspinous ligament at the L1 level referred pain characteristic of renal colic to the loin, inguinal, and scrotal areas, causing retraction of the testicle.²⁴ At the T9 level, the posteriorly injected hypertonic saline caused palpable rigidity and deep tenderness of the lowest part of the abdominal wall.²⁵

Deep Paraspinal (Spinotransverse)

Although the semispinalis thoracis muscle is classified anatomically as the outermost (most superficial) of the deep paraspinal muscles, it is thought that its pain patterns correspond to those of the longissimus fibers at the same segmental level.

The next deeper layer of the deep group of paraspinal muscles, the multifidi muscles, refers pain primarily to the region around the spinous process of the vertebra adjacent to the TrP (Figure 48-4A). Multifidus TrPs located from L1 to L5 may also refer pain anteriorly to the abdomen, which is easily mistaken as visceral in origin (Figure 48-4B on the right).^{15, 19} The multifidus muscle at L5 can also refer to the posterior thigh and/or leg^{23, 26} and, less frequently, to the anterior thigh.²⁶ Multifidus TrPs at the S1 level project pain downward to the coccyx (Figure 48-4B) and render the coccyx hypersensitive to pressure (referred tenderness). The condition is often identified as coccydynia.

Figure 48-4. Referred pain patterns (red) from the deep paraspinal muscles. Pain referred by the rotatores muscles is felt essentially in the midline. A, Examples of local patterns characteristic of TrPs at the mid-thoracic level and in multifidi muscles at the low sacral level. B, Local and projected pain patterns of TrPs in these muscles at the intermediate L2 and S1 levels, respectively.

When Kellgren injected hypertonic saline experimentally into normal deep paraspinal muscles, he concluded that these deep muscles were more likely than the superficial group to refer pain anteriorly to the abdomen.²³ Pain patterns similar to those observed in adults were reported from TrPs in the longissimus and multifidus muscles of children.²⁷

Involvement of the deepest paraspinal muscles, the rotatores muscles, throughout the length of the thoracolumbar spine produces midline pain and referred tenderness to tapping on the spinous process adjacent to a TrP. Only deep palpation of the muscles can determine from which side the midline pain arises. This spine tenderness is used as an osteopathic sign of articular-dysfunction involvement of that vertebra.

3.2. Symptoms

The chief report by patients with active TrPs in the thoracolumbar paraspinal muscles is pain in the back and sometimes in the buttock and abdomen. This pain markedly restricts spinal motion and the patient's activity. The patient will report pain with most spinal motions, especially when controlling forward motion of the trunk against gravity.

When the longissimus muscles are involved bilaterally, often at the L1 level, the patient has difficulty rising from a chair and climbing stairs if he or she faces forward in the usual manner.

When a patient has iliocostalis lumborum TrPs, the patient commonly draws an up-and-down pattern to represent the pain referred from iliocostalis TrPs but a crosswise pattern in the same region of the back to demonstrate the pain referred from TrPs in the lower rectus abdominus muscle.

When the report of "lumbago" is due to TrPs in the deep lumbar paraspinal muscles, patients report the pain usually is a unilateral, extremely aggravating, and steady ache deep in the spine. It becomes bilateral as the muscles on both sides become involved. The patient may point to a one-sided bulging of the long muscles of the lumbar spine. The patient finds little relief by changing position and is often convinced by the way it feels that the pain originates in the bony spine, not in the muscles.

3.3. Patient Examination

After a thorough subjective examination, the clinician should make a detailed drawing representing the pain pattern that the patient has described. This depiction will assist in planning the physical examination and can be useful in monitoring the progression of the patient as symptoms improve or change. The type, quality, and location of the pain should be carefully assessed, and standardized outcome tools should be utilized. A detailed medical screening is also necessary because there are several medical conditions in the cardiovascular, pulmonary, gastrointestinal, hepatic, and biliary and urologic systems that can present with similar types of pain presentations as those from the thoracolumbar paraspinal muscles.²⁸

Observation of posture in standing should be carried out with attention to spinal

curvature and lower extremity biomechanical alignment. It is important to incorporate assessment for functional and structural scoliosis, presence of a hemipelvis, iliac upslip,²⁹ and leg length discrepancy. The skin overlying involved lumbar paraspinal muscles often exhibits superficial tenderness and resistance to skin rolling (panniculosis) or trophedema, which disappears after therapeutic skin rolling and inactivation of the underlying TrPs.^{30, 31}

Assessment for a leg length discrepancy is necessary because a difference of 0.6 cm (a quarter of an inch) can place strain on the thoracolumbar muscles. If a discrepancy is found, the corrective lift must be worn whenever the patient is on her feet. Additionally, assessment for a short pelvis (hemipelvis) should also be performed and appropriate corrections made if found. While the patient sits on a flat level wood seat (Figure 48-5B), pelvic tilt is estimated and corrected by placing enough pages or sheets of paper under the ischial tuberosity on the shorter side to level the pelvis exactly (Figure 48-5C). A hard surface requires less correction than a well-padded seat, because the softness of the seat allows the body to tilt to the short side. This shifts more weight to that side and increases the pelvic tilt (Figure 48-5D). The patient may also try to compensate for a small hemipelvis by crossing one knee over the other to cantilever up the low side (Figure 48-5A).

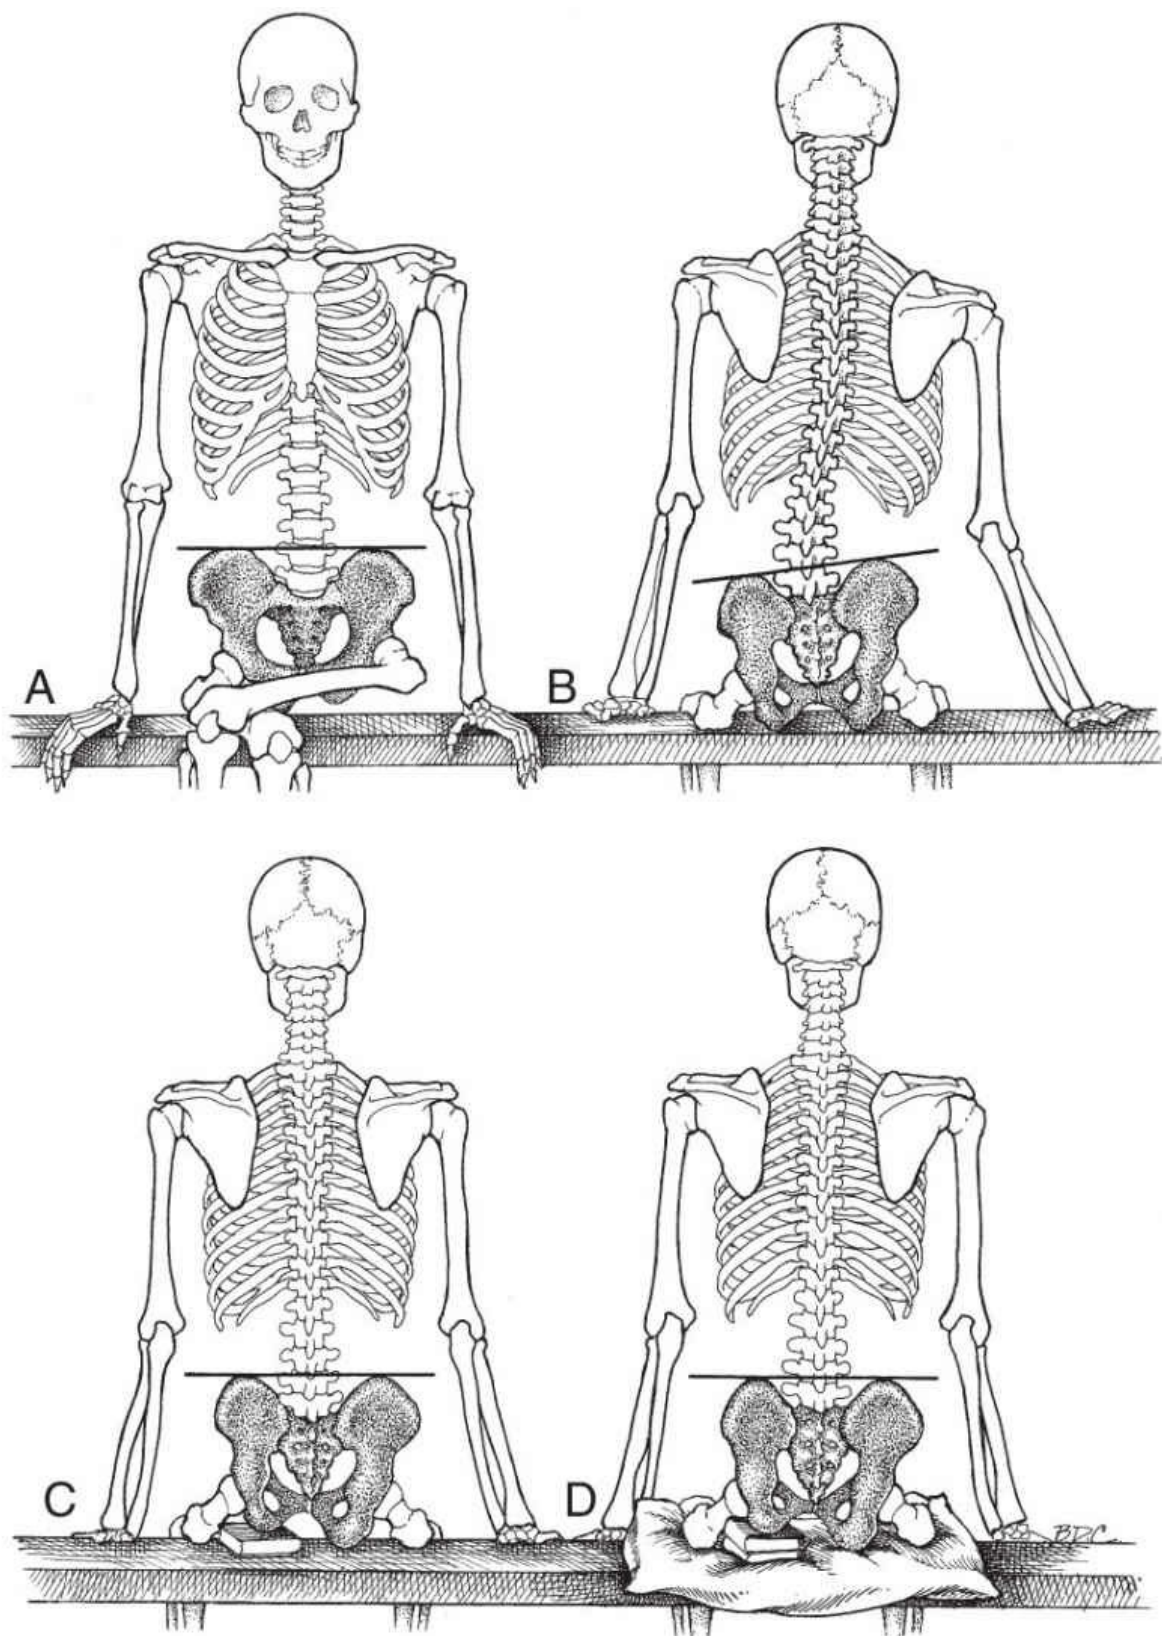

Figure 48-5. Effects of skeletal asymmetry due to a smaller left hemipelvis are demonstrated by sitting on a flat-level wood bench. A, Crossing the leg on the shorter side over the other knee helps level the pelvis. B, The tilted pelvis causes compensatory scoliosis, which tilts the shoulder-girdle axis. C, A small ischial lift levels the pelvis on a hard surface. D, On a soft

cushioned surface, a thicker ischial lift is required to provide the same correction as that obtained on a hard surface.

Accessory joint motion should be tested in the thoracic spine, lumbar spine, sacroiliac joint, and thoracic rib cage because joint hypomobility is typically present with paraspinal muscle dysfunction. Additionally, sacroiliac and iliosacral movements should be assessed in the standing and seated position.²⁹ It is important for the clinician to consider the use of the sacroiliac joint special tests cluster developed by Laslett et al.³² These tests have high clinical utility in identifying sacroiliac joint dysfunction. Clinically, we have found that in the presence of active TrPs in the deep paraspinal muscles, these provocative tests may be false positive due to peripheral sensitization.

Superficial Paraspinal (Erector Spinae)

Patients with nonspecific low back pain have increased numbers of latent TrPs compared with their healthy counterparts, and those with a greater number of active TrPs have a higher pain intensity. The most prevalent muscles involved include the iliocostalis lumborum, along with the quadratus lumborum, and gluteus medius muscles.³³

Assessment of active range of motion of the lumbar spine in all planes will give clues of superficial paraspinal (erector spinae) muscle involvement. Frequently, range of motion will be limited in flexion to no more than a few degrees. Functional mobility assessment, as stated previously, will reveal difficulty with transitioning from sit to stand.

Deep Paraspinal (Spinotransverse)

Deep lumbar paraspinal TrPs are likely to occur in patients with either an excessive or absent lumbar lordosis, while deep thoracic paraspinal TrPs tend to occur in patients with marked thoracic kyphosis. Active range of motion testing will commonly be guarded and can restrict all motions of the lumbar spine, especially if involved bilaterally.

Trigger points in the spinotransverse muscles impair movement between two vertebrae during flexion or side bending of the spine. During flexion, a hollow or flat area develops in the smooth curve formed by the spinous processes. The flattening usually spans one to three vertebrae. Involvement of a multifidus muscle or a rotator muscle on either side produces midline tenderness over the adjacent spinous process. This tenderness is easily located by tapping each spinous process in succession. Tenderness disappears after inactivation of the responsible TrPs, which may be located on either or both sides of the spine. Dry needling to the lumbar multifidus muscle has been shown to improve nociceptive sensitivity and increase the contraction of the multifidus muscle.³⁴

3.4. Trigger Point Examination

Superficial Paraspinal (Erector Spinae)

Palpation of specific paraspinal muscles is less effective with the patient in standing because of postural muscle tension and protective splinting by normal muscles. The clinician must obtain relaxation of the patient's back muscles so that abnormally taut muscle fibers are distinguishable.

Historically, the reliability of palpating for TrPs in the muscles of the lumbar spine has been accepted as generally poor,³⁵⁻³⁷ although it may be minimally improved with modified criteria.³⁷ These findings are not consistent with more recent studies looking at the reliability of identifying TrPs in muscles in other body regions.³⁸⁻⁴²

To assess the superficial paraspinal (erector spinae) muscles, the patient should be placed in prone (with a pillow under the trunk as needed) and the arms resting comfortably (Figure 48-6A and B). If the patient is unable to lie in prone, the patient can be placed in side-lying with the spine supported in neutral alignment. A small towel roll may be needed to keep the spine aligned (Figure 48-6C and D).

Figure 48-6. Examination of the left erector spinae muscles for TrPs. The longissimus thoracis, iliocostalis thoracis, and iliocostalis lumborum muscles are palpated with a cross-fiber flat palpation. A, The longissimus thoracis muscle. B, Iliocostalis lumborum muscle. C, Palpation of longissimus thoracis muscle with patient side-lying and clinician behind the patient. D, Palpation of iliocostalis lumborum muscle with the patient side-lying and the clinician in front of the patient.

The longissimus thoracis, iliocostalis thoracis, and lumbar iliocostalis muscles are palpated with a cross-fiber flat palpation. The longissimus thoracis muscle is identified by

finding the “hill” muscle that is just lateral to the spinous processes on each side (Figure 48-6A). This muscle is frequently “ropey” in nature; therefore, it is essential to compare bilaterally and several segments above and below to ensure proper identification of a TrP. The thoracic iliocostalis muscle is a thinner muscle, lateral to the longissimus thoracis muscle, travelling along the rib angles. The more caudal portion of the muscle travels medially to blend with the iliocostalis lumborum muscle. The iliocostalis lumborum muscle is the “hill” muscle in the lumbar spine, just lateral to the spinous processes (Figure 48-6B).

Deep Paraspinal (Spinotransverse)

With the patient positioned as described above, the clinician taps or presses on the tips of successive spinous processes to elicit tenderness. When a spinous process in the flatter area of the spine is hypersensitive, the deep musculature on each side of it is palpated by firm pressure in the groove between the process and the longissimus muscle. A deep cross-fiber flat palpation is directed along the side of the spinous process to exert pressure on the rotatores muscles against the underlying laminae to locate a spot of maximum tenderness. Because of the depth of the muscles in this region, a taut band is rarely found; however, in the area where a TrP is present, the tissue will feel denser than the areas above and below it. If two or three spinous processes are tender, one expects to find adjacent TrPs on at least one side at each level of tenderness. A filiform needle can be utilized to accurately identify a TrP in these deep muscles that can't be reliably manually palpated.

4. DIFFERENTIAL DIAGNOSIS

4.1. Activation and Perpetuation of Trigger Points

In any part of the paraspinal muscles, TrPs may be activated by unaccustomed eccentric loading, eccentric exercise in the unconditioned muscle, or maximal or sub-maximal concentric loading.⁴³ Trigger points may also be activated or aggravated when the muscle is placed in a shortened or lengthened position for an extended period of time. For example, prolonged immobility, as when sitting for hours in an aircraft or vehicle, may activate TrPs in the paraspinal muscles. Similarly, occupational overload, such as sitting at a computer, can contribute to the development of TrPs. Yoo et al⁴⁴ found that there was increased EMG activity in the T10 and L4 paraspinal muscles after 20 and 40 minutes of sitting at a computer workstation. Hoyle et al⁴⁵ reported that regardless of the high or low visual or postural stresses, TrPs developed within an hour of sitting.

A quick awkward movement that combines bending and twisting of the back, especially when the muscles are fatigued or chilled, is likely to activate TrPs in the iliocostalis muscle, even though no additional loading (lifting) is involved. This activation may be caused by disproportionate loading of one group of muscle fibers as a result of poor coordination.

Caution should also be exercised when performing exercises. Some exercises are more likely to load the paraspinal muscles than others. Exercises like a bilateral free weight row are more likely to activate the erector spinae muscles than a bilateral machine row or a

unilateral free weight row.⁴⁶ Additionally, exercises like a side crunch on an exercise ball, side bridge on the toes, and side bridge on the knees are more likely to activate the lumbar paraspinal muscles versus a prone leg extension on an exercise ball or a prone plank on an exercise ball.⁴⁷

The whiplash mechanism of injury that causes sudden acceleration or deceleration is likely to rapidly stretch protectively stiffened spinal muscles, which in turn is likely to activate TrPs in them.

Trigger points in the paraspinal muscles can also be activated or perpetuated by any mechanical factor that disturbs axial symmetry, such as a scoliosis from a leg length discrepancy or pelvic asymmetry.⁴⁸ Paraspinal muscle activity will be greater on the side of the convexity of a scoliosis.^{49, 50} Usually, the vertical dimension of the pelvis is smaller on the side of the shorter leg. This situation tilts the pelvis when sitting, just as the leg length discrepancy tilts it when standing, resulting in the same musculoskeletal effects (Figure 48-5B).

4.2. Associated Trigger Points

Associated TrPs can develop in the referred pain areas of a primary TrP⁵¹; therefore, muscles in the referred pain areas should also be considered during examination. For TrPs in the iliocostalis thoracis muscle, associated TrPs can develop in several other muscles, including other portions of the iliocostalis muscles, the longissimus, the trunk portion of the latissimus dorsi, serratus posterior inferior, lumbar multifidus, quadratus lumborum, pectoralis major, infraspinatus, supraspinatus, rectus abdominus, abdominal obliques, and psoas major muscles. An iliocostalis thoracis TrP may result from TrPs in the latissimus dorsi, infraspinatus, rhomboid major and minor, serratus posterior superior, scalene, serratus posterior inferior, lower trapezius, middle trapezius, serratus anterior, and/or the rectus abdominus muscles, depending on which portion of the muscle is affected. Therefore, to effectively improve pain from the iliocostalis muscle, these muscles must also be examined and treated.

For TrPs in the iliocostalis lumborum muscle, associated TrPs can develop in the trunk portion of the latissimus dorsi, quadratus lumborum, gluteus maximus, gluteus medius, gluteus minimus, piriformis, and deep hip lateral rotator muscles. A TrP in the iliocostalis lumborum muscle can be caused by a TrP in the rectus abdominus, longissimus thoracis, iliocostalis thoracis, and/or psoas major muscles.

Trigger points in the longissimus thoracis muscle can contribute to the development of associated TrPs in the iliocostalis lumborum, lumbar multifidus, quadratus lumborum, gluteus maximus, piriformis, proximal hamstring, and proximal adductor magnus muscles. A TrP in the longissimus thoracis muscle can result from a TrP in the rectus abdominus, serratus posterior superior, scalenes, rhomboid major and minor, and/or infraspinatus muscles, depending on which portion of the muscle is affected.

Thoracic multifidus TrPs can contribute to associated TrPs in the iliocostalis thoracis and longissimus thoracis muscles. Clinically, this muscle has been seen to refer anteriorly;

therefore, the pectoralis major muscle may also develop associated TrPs. A TrP in the thoracic multifidus muscle can be due to a TrP in the rectus abdominus, middle trapezius, and/or iliocostalis thoracis muscles, depending on which region is affected.

Lumbar multifidus TrPs can contribute to associated TrPs in the iliocostalis lumborum, quadratus lumborum, rectus abdominus, abdominal obliques, and psoas major muscles. A TrP in the lumbar multifidus muscle can result from a TrP in the rectus abdominus, longissimus thoracis, and/or psoas major muscles.

Sacral multifidus TrPs can contribute to associated TrPs in the gluteus maximus, gluteus medius, piriformis, hamstrings, psoas major, and abdominal oblique muscles. A TrP in the sacral multifidus muscle can result from a TrP in the rectus abdominus, gluteus maximus, gluteus medius, and/or quadratus lumborum muscles.

The spinotransverse muscle group is more likely to demonstrate isolated muscle involvement, whereas the more superficial paraspinal muscles are likely to accumulate associated TrPs in functionally related muscles, especially the contralateral superficial muscles.

Not uncommonly, articular dysfunction of the thoracolumbar junction will be associated with active TrPs in the adjacent erector spinae, psoas muscle, and the quadratus lumborum muscles. Remarkably, if one treats the dysfunction of the thoracolumbar junction, or TrPs in one of the three muscles, the treatment often relieves TrPs in another one of the muscles.⁵²

4.3. Associated Pathology

Some medical conditions give rise to symptoms that can appear confusingly similar to those produced by TrPs in the thoracolumbar paraspinal muscles or may be present concurrently. For pain that presents in the trunk, either anteriorly or posteriorly, screening for visceral disease is of critical importance. Jarrell⁵³ reported that the presence of an abdominal wall TrP predicted evidence of visceral disease in over 90% of subjects, and if a TrP was not present, it was associated with not having visceral disease in 64% of subjects. As a result, if TrPs in the muscles of the trunk continually return, a thorough medical screening and possible referral to the physician may be warranted. There are several conditions related to the cardiovascular, pulmonary, gastrointestinal, endocrine, hepatic and biliary, and urologic systems that can refer pain to the thoracic region, lumbar region, interscapular, or sacral region, depending on the viscera involved.²⁸ Knowledge of these pain referrals and symptomology are essential in the differential diagnosis of musculoskeletal pain.

Segmental dysfunction associated with TrPs in the thoracolumbar paraspinal musculature may occur anywhere in this region. The number of segments involved depends on the muscles involved. For example, TrPs in the rotatores muscles can induce a concurrent single level dysfunction. Trigger points in the multifidi muscles are more likely to induce articular dysfunction involving two or three adjacent segmental levels. Semispinalis TrPs at any level will usually be associated with four to six segmental levels of dysfunction. The apex segment is often exquisitely tender to palpation. The most

superficial and longest muscles are the iliocostalis and longissimus muscles and their TrPs are associated with group dysfunctions. If the patient compensates proximally to level the shoulders, he or she can present with a double curve (S curve) that is easily misinterpreted as a primary scoliosis. Trigger points in the iliocostalis lumborum muscle are also associated closely with pelvic obliquity secondary to tension applied to the muscle's insertional aponeurosis onto the sacral base.

Schneider⁵⁴ emphasized that the symptoms caused by multifidus TrPs mimic those of lumbar facet or sacroiliac syndromes and that an L4-L5 lateral disc herniation produces tightness of the left L4-L5 multifidus muscle, causing a segmental motion block. Clinically, TrPs in the lumbar multifidus muscle have been seen to mimic facet joint dysfunction.

The pain referral patterns of the thoracic zygapophyseal joints^{55,56} and costotransverse joints⁵⁷ have been established. The referred pain patterns from these joints have overlap with pain referral patterns of the thoracic paraspinal and multifidus muscles.

Any patient with chronic low back pain and additional widespread pain should be examined for central sensitization or fibromyalgia. Trigger points are frequently associated with these conditions,⁵⁸⁻⁶⁰ with active TrPs reproducing familiar pain of patients.⁶⁰ Symptoms of fibromyalgia are also associated with rheumatic diseases such as rheumatoid arthritis, spondyloarthritis, psoriatic arthritis, and connective tissue disorders.⁶¹

Radicular pain and/or radiculopathy may be caused by pressure on a nerve root from a herniated disc, by encroachment within the spinal foramen as from osteoarthritis, or by a tumor. Lumbar radicular reference of pain usually causes pain that radiates into the lower extremity, paraspinal TrPs alone rarely do. However, when active TrPs in the back muscles induce associated TrPs in the gluteal muscles, the latter TrPs often refer myofascial pain down the lateral or posterior aspect of the thigh or leg, sometimes extending to the foot.^{15,22,62-65} Radiculopathy is characterized by neurologic deficits including decreased tendon reflexes, impaired cutaneous sensation, and/or motor weakness with atrophy. Trigger points typically do not cause such neurologic deficits.

Myositis ossificans is a benign condition where heterotopic ossification occurs in muscles, typically in the extremities, rarely in the trunk muscles, and more frequently after trauma.⁶⁶ Two cases of myositis ossificans are reported in the literature occurring in the paraspinal muscles, one in the lumbar⁶⁷ and one in the thoracic paraspinal muscles.⁶⁸

Another condition to be aware of that causes soft tissue swelling in the paraspinal muscles is fibrodysplasia ossificans progressive.⁶⁹⁻⁷¹ It is a rare genetic disease that is autosomal dominant. There is congenital malformation of the great toes, tissue swelling that occurs after a trauma that leads to heterotopic ossification.⁷²⁻⁷⁵

Another rare condition to consider is acute paraspinal compartment syndrome, which is an increase in interstitial pressure in the paravertebral compartment that typically occurs after some type of strenuous exercise or activity. It typically presents with severe low back pain,⁷⁶⁻⁷⁹ but may also present with additional symptoms in the abdomen,⁷⁶ testicle,^{78,79} legs,⁷⁹ groin,⁷⁸ and flank.⁷⁶ Differential diagnosis of this condition is essential because it can mimic an acute lumbar muscle strain, disc herniation, vertebral fracture, inflammatory

low back pain, or renal colic.⁷⁹ It has also been mistaken as ureteral colic.⁷⁶

5. CORRECTIVE ACTIONS

The patient with paraspinal TrPs should modify activities that induce stress when bending over forward. Bending to pick up heavy items should not be done from bending at the waist but by squatting with the legs. The patient should also avoid holding his or her breath, or twisting while lifting or pulling.

To minimize strain to the thoracolumbar paraspinal muscles, proper mechanics should be utilized when rising from or sitting down to a chair with the “Sit-to-stand” and “Stand-to-sit” Technique (Figure 50-13). To rise from the chair, the hips are moved forward to the front of the chair seat before starting to rise. The body and hips are then turned somewhat to the side and one foot is placed beneath the front edge of the chair. Finally, the torso is held erect while the knees and hips are straightened, lifting the body. The process is reversed in stand-to-sit by turning to the side and placing one foot under the front edge of the chair, keeping the torso erect, and aiming the buttocks at the front edge of the chair seat rather than at the rear of the seat. The person then slides backward on the seat to meet the backrest. This procedure again maintains the back in an erect position and transfers the load from the paraspinal muscles to the hip and thigh muscles.

The paraspinal musculature can be relieved of unnecessary strain by modifying the chair, backrest, armrests, and/or computer so they are ergonomically correct. Refer to Chapter 76 on posture and ergonomics.

When sleeping on the side, a patient with TrPs in the thoracolumbar paraspinal muscles is usually more comfortable with a pillow, or two, placed in between the knees. This prevents the rotary torsion of the lumbar spine that occurs when the knee drops forward onto the bed.

To stretch the thoracolumbar paraspinal muscles, three different types of stretches can be performed. The first is a single knee to chest stretch. In the supine position, the patient draws one knee to the chest while the opposite leg is straight out (Figure 48-7A). Next, the lower extremity is returned to the straight-leg starting position, and the other thigh is flexed to the chest and returned.

Figure 48-7. Stretches for the paraspinal muscles. A, Single knee to chest. Flexion of one thigh at a time by rhythmically and gently bringing the knee toward the armpit on the same side. B, Double knee to chest. Flexion of both thighs together, brought tight onto the chest. The thighs, rather than the knees, may be grasped to avoid forced knee flexion if discomfort is felt. C, Starting position for the prayer stretch. D, Ending position of the prayer stretch. A pillow should be placed under the forehead to keep neutral neck alignment while allowing the head to rest comfortably and minimize spine muscle activation.

A second way to stretch the thoracolumbar paraspinal muscles is with a double knee to chest stretch. In the supine position, both legs are pulled to the chest until a gentle stretch is felt in the back (Figure 48-7B).

A third way to stretch the muscles is in the “prayer position.” The patient starts in the quadrupedal position (Figure 48-7C). While keeping the hands in place, the hips rock back toward the heels as if going to sit on them. The muscles on both sides of the spine will be equally stretched when the arms are directly in front of the patient (Figure 48-7D). To focus the stretch more on one side, the patient should walk the hands away from the side to be stretched, making sure not to lift the hips and buttocks off the heels.

Self-pressure release of the thoracolumbar paraspinal muscles can be performed utilizing a homemade or purchased TrP release tool. With a commercially available rigid tool, the edge of the device can be pressed into the portion of the muscle that refers pain for several seconds (Figure 48-8A). This release can be repeated up and down the muscle group for maximum relief. A homemade tool can also be made with a long sock and a lacrosse or

tennis ball (Figure 48-8B top left corner). The patient places the ball in the sock and positions the ball between the wall and his back at the point where pain is referred. Holding the open end of the sock with both hands, the patient may reposition as needed for maximum relief (Figure 48-8B main picture).

Figure 48-8. Trigger point self-pressure release. A, self-pressure release with a commercially available TrP release tool. B, A lacrosse or tennis ball and sock can make a simple and effective low-cost self-pressure release tool. Using the sock to position and stabilize the lacrosse ball, the patient can adjust the pressure by leaning into the ball to achieve an effective release.

Abdominal Muscles

“Limbo Limiters”

César Fernández de Las Peñas, Joseph M. Donnelly, and Margaret M. Gebhardt

1. INTRODUCTION

The abdominal musculature consists of five different muscles: the rectus abdominis, internal oblique, external oblique, transversus abdominis, and pyramidalis. These muscles perform several functions including flexion, sidebending, and rotation of the trunk, but most important is their role in trunk stability during walking, heavy lifting, and movement of the extremities, particularly the transversus abdominis muscle. In addition, the abdominal muscles protect the abdominal viscera. Trigger points (TrPs) in the abdominal musculature can mimic visceral disease symptomatology (appendicitis, peptic ulcer, gallstone colic, colitis, dysmenorrhea, chronic pelvic pain, and urinary tract disease) because they can refer pain to the abdominal area but also reproduce symptoms such as burning, fullness, bloating, swelling, or gas. It is also possible that TrPs in the abdominal muscles can be related to motor control disturbances in the deep abdominal muscles (transversus abdominis and internal oblique) especially in patients with low back pain. Symptoms from TrPs may be exacerbated by stress, direct trauma, repetitive overload, or most importantly, with visceral pathology. In fact, the activation of TrPs in these muscles can be directly related to viscerosomatic or somato-visceral reflex. Differential diagnosis should include differentiation between abdominal pain from TrP origin or from visceral disease. Careful clinical examination of abdominal wall muscles can assist with differential diagnosis. Corrective actions should include postural reeducation, a progressive strengthening exercise program, self-stretch and TrP self-pressure release, and reeducation of diaphragmatic breathing.

2. ANATOMIC CONSIDERATIONS

The external and internal abdominal oblique muscles, like the external and internal intercostal muscles have a diagonal crisscross arrangement and the two groups of muscles

have corresponding orientation. Clinicians should consider which layer runs in which direction (Figure 49-1). Figure 49-2 illustrates a mnemonic for the fiber directions. The fingers of the left hand on the right side of the abdomen against the skin represent the fiber direction of the right internal abdominal oblique (and intercostal) muscles, whereas the right hand on top of the left hand represents the fiber direction of the right external abdominal oblique (and intercostal) muscles. The transversus abdominis fibers run radially around the abdomen as their names imply.

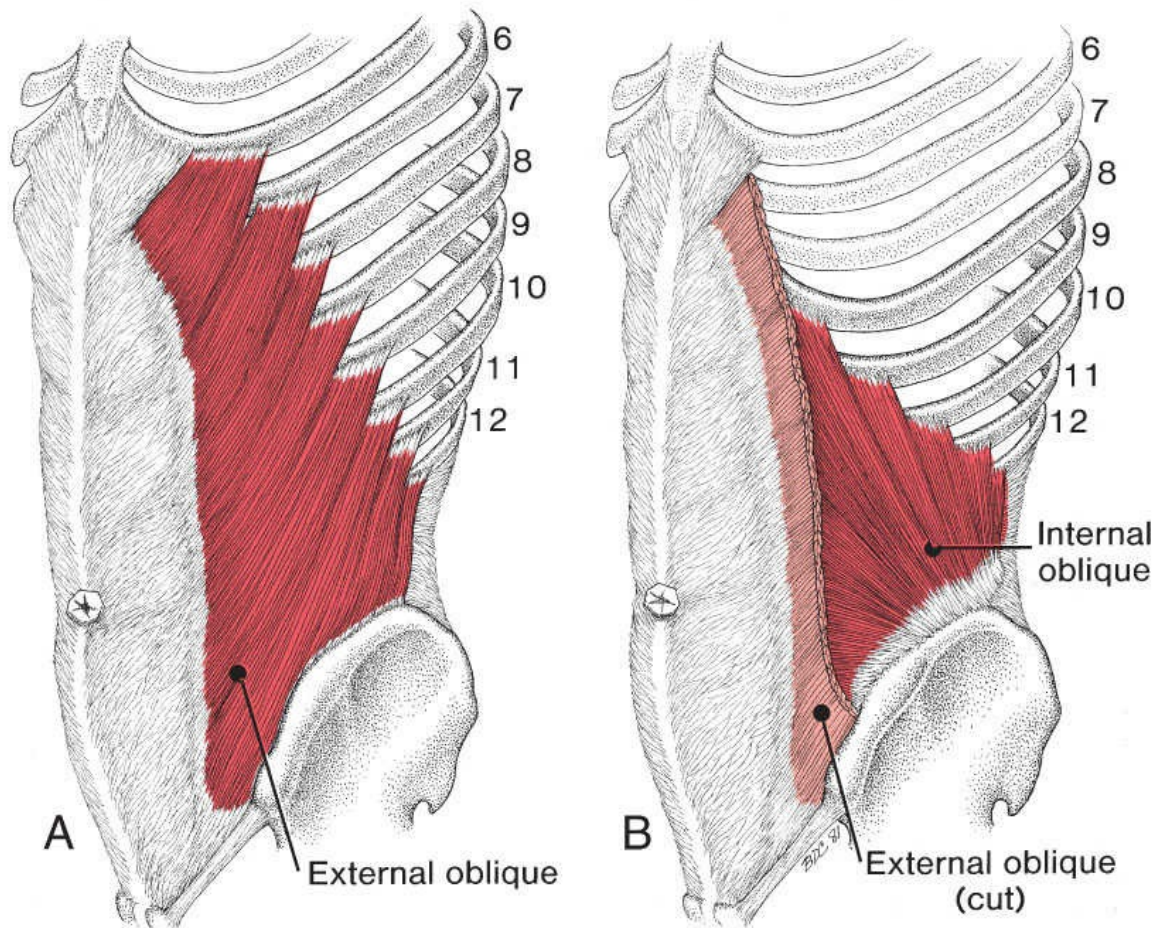

Figure 49-1. Attachments of two lateral abdominal wall muscles. A, External oblique muscle (light red). B, Internal oblique muscle (dark red); the external oblique muscle (light red) is cut.

Figure 49-2. Technique for remembering the fiber direction of the oblique abdominal muscles. The top hand represents the fiber direction of the external abdominal oblique and external intercostal muscles. The bottom hand represents fiber direction of the internal abdominal oblique and internal intercostal muscles.

The pattern of relative muscle thickness of abdominal wall muscles is rectus abdominis > internal oblique > external oblique > transversus abdominis.¹ Symmetry for total absolute thickness of all three lateral muscles has been reported to be 8% to 9% (mean), but for individual muscles there was an asymmetry of absolute size from 13% to 24% with a symmetrical relative thickness.¹ In general, men show significantly larger muscles than women,¹ and there are no significant differences between the middle-aged and young men.²

External Oblique Abdominis

The external oblique muscle is the most superficial muscle of the abdominal wall. Laterally and proximally, the muscle arises from the external surfaces and inferior borders of the lower eight ribs.³ The lower three rib attachments of the external oblique muscle interdigitate with the latissimus dorsi muscle, and the upper five rib attachments interdigitate with the serratus anterior muscle. Although these three muscles appear in anatomy books to be quite separate, in dissection, the external oblique muscle appears to form with the other two as an unbroken sheet of muscle. The fasciculi from the lowest two ribs lie nearly vertical and are parallel and adjacent to those fibers of the quadratus lumborum muscle that also connects the iliac crest and the twelfth rib.³ The fibers run diagonally downward and forward to join the abdominal aponeurosis that attach anteriorly to the linea alba in the midline and to the anterior half of the iliac crest (Figure 49-1A).

Internal Oblique Abdominis

The direction of the fibers in the fan-shaped internal oblique muscle, in the upright body, ranges from nearly vertical posteriorly, through a diagonally upward and medial direction among its intermediate fibers, to horizontal for the most caudal fibers (Figure 49-1B). Laterally, all fibers converge onto the lateral half of the inguinal ligament, the anterior two-thirds of the iliac crest, and the lower portion of the lumbar aponeurosis.³ Above, the nearly vertical fibers attach to the cartilages of the last three or four ribs. Above and medially, diagonal fibers attach to the linea alba through the anterior and posterior rectus sheath. Medially, the horizontal fibers from the inguinal ligament attach to the arch of the pubis through the conjoint tendon, which this muscle forms with the transversus abdominis muscle.³

Transversus Abdominis

Transversus abdominis muscle fibers run nearly horizontal across the abdomen and attach anteriorly to the midline linea alba via the rectus sheath (Figure 49-3), which surrounds the rectus abdominis muscle above the arcuate line and attaches to the pubis through the conjoint tendon.³ Below that line, the sheath occurs only anterior to the rectus abdominis muscle. Laterally, the transversus muscle attaches to the lateral one-third of the inguinal ligament, the anterior three-quarters of the crest of the ilium, the thoracolumbar fascia, and the inner surface of the cartilages of the last six ribs, where it interdigitates with the fibers of the diaphragm muscle.³

Figure 49-3. Attachments of the transversus abdominis muscle (red), which lie deep to the external and internal oblique muscles.

Rectus Abdominis

The rectus abdominis muscle attaches along the crest of the pubic bone (Figure 49-4). The fibers of the paired muscles interlace across the symphysis. Above, the muscle attaches to the cartilages of the fifth, sixth, and seventh ribs.³ The fibers of the rectus abdominis muscle are usually interrupted by three or four, more or less complete, transverse tendinous inscriptions.⁴ Of the three most constant tendinous inscriptions, one is found near the tip of the xiphoid process, one close to the level of the umbilicus, and one midway between them.⁴ The abdominal section of the pectoralis major muscle (Figure 42-2) may overlap fibers of the upper portion of the rectus abdominis muscle, and thus may account for the

occasional reference of pain to the anterior chest from TrPs in this region. The loss of the dorsal half of the rectus sheath below the arcuate line is clear as seen in Figure 49-3.

Figure 49-4. Attachments of the rectus abdominis muscle (light red), which connects the anterior rib cage to the pubic bone close to the symphysis, and attachments of the variable pyramidalis muscle (dark red), which lies just above the symphysis pubis within the anterior rectus sheath.

Pyramidalis

The pyramidalis muscle is a variable muscle that attaches below to the anterior surface of the ramus of the pubis and above to the linea alba approximately midway between the symphysis and the umbilicus.³ It lies within the anterior rectus sheath (Figure 49-4). Beaton and Anson⁵ observed that the pyramidalis muscle was absent in 17.7% when analyzing 430 sides. Anson et al⁶ described the usual and variant anatomy of this muscle in great detail.

2.1. Innervation and Vascularization

The lateral abdominal wall muscles, the external and internal obliques, and the transversus abdominis muscles are innervated by branches of the 8th through the 12th intercostal nerves from T8 to T12, showing a segmental innervation.³ The internal oblique and transversus abdominis muscles are also supplied by branches of the iliohypogastric and ilioinguinal nerves that stem from L1. The ilioinguinal and iliohypogastric nerves emerge through the internal oblique muscle medially and inferiorly to the anterior superior iliac spine.⁷

The external oblique muscle is also innervated by the subcostal nerve.³ The subcostal nerve lies subcostally and caudal to the rib. The main branches are located between the internal oblique and transversus abdominis muscles. These nerves branches vary widely in the abdominal wall.⁸

The rectus abdominis muscle is innervated by the 7th through the 12th intercostal nerves derived from the corresponding thoracic nerves (T8-T12), and different segmental nerves usually innervate fibers between different tendinous inscriptions, especially in the upper half of the muscle.³ The nerves pass inferomedially between the internal oblique and transversus abdominis muscles before entering the lateral confluence of the anterior and posterior rectus sheath or in some cases the posterior rectus sheath.⁹ The nerves, which contain varying numbers of sensory, motor, and autonomic fibers, pass under the rectus abdominis muscle and became intramuscular at varying points, with most of them entering into the muscle in the lateral third.⁹ Finally, the pyramidalis muscle also receives innervation by a branch of the 12th thoracic nerve.

The internal oblique muscle gets its blood supply from the lower posterior intercostal and subcostal arteries, the superior epigastric artery, the inferior epigastric artery, the superficial and deep circumflex arteries, and the posterior lumbar arteries.³ Ramasastry et al¹⁰ described a flap in the internal oblique muscle where a single ascending branch of the deep circumflex iliac artery enters the undersurface of the muscle, arborizing within the muscle.

The blood flow of the cranial part of the external oblique muscle is supplied by the lateral and anterior branches of the intercostal arteries.³ The lateral branches of the intercostal artery run on the surface of the external oblique muscle, whereas the anterior branches of the arteries enter into the muscle. In addition, the caudal part of the muscle

derives its main blood supply from one or two branches of the deep circumflex iliac artery (94.7%) or the iliolumbar artery (5.3%).¹¹ Yang et al¹² reported the presence of a huge variability ranging from 9% to 22% in the vascular supply of the external oblique muscle.

Blood supply for the rectus abdominis muscle is provided by more than one source. Mathes and Nahai¹³ describe two pedicles: the inferior epigastric artery runs superiorly on the posterior surface of the muscle, enters the muscle, and provides the supply to the lower part of the muscle; the superior epigastric artery supplies the blood flow to the upper portion of the muscle.¹³

The transversus abdominis muscle receives supply from the following arteries: lower posterior of intercostal and subcostal arteries, superior epigastric artery, inferior epigastric artery, superficial and deep circumflex arteries, and posterior lumbar arteries.³

2.2. Function

The four abdominal wall muscles (rectus abdominis, external oblique, internal oblique, and transversus abdominis) play a variety of essential roles in human function. These muscles create the forces necessary to flex, twist, and side-bend spine¹⁴; stiffen the abdominal cavity and lumbar spine during simple tasks such as standing, sitting, and locomotion¹⁵ as well as during demanding tasks such as dynamic loading and heavy lifting^{16,17}; and finally, assist the expiration of air in challenged breathing. Regarding respiratory function, Kim and Kim¹⁸ found that smokers have a higher degree of dependence on internal oblique muscles than transversus abdominis muscles during forceful expiratory conditions as compared with that in nonsmokers. An overreaction of the internal oblique muscle may cause problems in efficiently diffusing loads of the spine. Special functions of the abdominal muscles, particularly as related to respiratory activities, are covered in Chapter 45.

From a biomechanical perspective, the abdominal wall muscles have two primary roles. First, they create movement, both forceful and controlled, of the upper and lower quarters.¹⁹ Second, they play a stabilization role for the thoracic and lumbosacral spine as well as the pelvis.²⁰ The use of stability generated from the abdominal wall muscles is thought to allow for increased force generation from the extremities. The rectus abdominis muscle is thought to be more a force-producing muscle, whereas the transversus abdominis muscle is the main stabilizing muscle. The external and internal oblique muscles participate in both roles.^{19,20} The transversus abdominis, internal and external oblique, and the pelvic floor musculature function together as a unit for stabilization of the lumbosacral spine and pelvic girdle in conjunction with the thoracolumbar fascia.^{20,21} In addition, the abdominal wall musculature increases intra-abdominal pressure, an important function for maintaining overall spinal stability.²⁰ The contraction of the abdominal musculature in conjunction with the contraction of the diaphragm muscle is thought to enhance spinal stability through the production of forces that create a rigid cylinder in the abdominal cavity.

There is scientific evidence supporting a feed-forward action of the lateral abdominal wall muscles in the motor control of the lumbar spine, particularly the transversus

abdominis muscle.²² Several studies have reported that the transversus abdominis (which always starts its contraction first), the internal oblique, the external oblique, rectus abdominis, and the lumbar multifidus muscles are activated in a feed-forward manner before any upper or lower limb movement.^{23–25} In fact, this feed-forward response was independent of the movement of the extremity but related to speed of the movement, suggesting that this is not a response to reactive forces but is linked to control of the stability of the spine against potential external perturbations.^{25,26} Furthermore, it seems that a codependent mechanism exists involving balanced tension between the transversus abdominis and internal oblique muscles and the lumbar paraspinal muscles throughout the aponeurotic components of the thoracolumbar fascia.²¹ This lack of feed-forward can be related to the overload of the superficial trunk muscles. For instance, Ghamkhar and Kahlaee²⁷ have recently reported that individuals with chronic low back pain had higher global activity of the superficial trunk muscles, such as erector spinae or rectus abdominis muscles.

Lateral Abdominal Wall Muscles

The internal and external oblique muscles function bilaterally to increase intra-abdominal pressure (eg, for urination, defecation, emesis, parturition, and forced exhalation) and to flex the vertebral column. Unilaterally, they bend the vertebral column toward the same side and assist to rotate the vertebral column.^{14,28} The external oblique muscle rotates the vertebral column toward the contralateral side, whereas the internal oblique muscle rotates the vertebral column toward the same side. Therefore, the contralateral external oblique and the ipsilateral internal oblique muscles rotating the trunk in the same direction are probably related to the fact that abdominal muscle afferents activate similar pathways to muscles on both sides of the body.²⁹ An increase in intra-abdominal pressure is also assisted by the contraction of the transversus abdominis muscle.

All lateral abdominal wall muscles help complete exhalation quickly during rapid breathing, and this action is different depending on the position and the presence of load. For instance, activity of the lateral abdominal wall muscle varies depending on the gravity: the internal oblique muscle is more active during both inspiration and expiration in the standing position, whereas the activity of the external oblique muscle is higher in the sitting-with-elbows-on-the-knee position.³⁰ Similarly, the activation of transversus abdominis, internal oblique, and external oblique musculature was higher with load than without it.³¹

The external and internal oblique muscles show some activity during walking, but they can exhibit a sudden increase in activity with a sudden or sustained increase in intra-abdominal pressure, eg, during an active straight leg raise.³² In fact, this activity depends on each particular muscle because the activity is increased in the transversus abdominis muscle, but decreased in the external oblique muscles during lifting.³³ The fibers of both transversus abdominis and internal oblique muscles in the region of the inguinal canal are activated continuously during standing because they demonstrate a larger increase in motor

unit discharges during activities that would increase intra-abdominal pressure.³² Selective activation of the internal oblique and transversus abdominis muscles doubles when a sit-back exercise (Figure 49-5A) is performed with the feet unsupported as compared with when the feet are supported, which emphasizes recruitment of other muscles, ie, the iliopsoas.³⁴

Figure 49-5. A, The sit-back exercise is a progressive uncurling that starts in the sitting position and ends in supine. Knees and hips should be bent and the feet fixed. From this initial sitting position, the patient leans back slightly. After a few degrees of uncurling, the patient returns to the starting position. Progressive uncurling, with assisted return to the starting position, is repeated until uncurling reaches the full supine position. B, Abdominal curl with fist below the chin to support the neck. C, Arm stretched out to decrease the demand on the abdominal muscles. D, Hands placed at side of the head to maximally challenge the abdominal muscles.

The cyclical swings in abdominal pressure produced by breathing and by the activity of the abdominal muscles help pump the venous blood out of the abdomen at rest and during exercise. Relaxation of the abdominal wall during inhalation increases blood flow into the abdominal veins from the lower limbs. As the abdominal wall muscles contract for exhalation, the blood is forced upward toward the heart if the valves of the lower extremity veins are competent. A recent study observed that during exercise, the abdominal and diaphragm muscles might play the role of an “auxiliary heart.”³⁵

Rectus Abdominis

The rectus abdominis muscle is the prime mover for spinal flexion, particularly of the lower thoracic and lumbar spine, and it also tenses the anterior abdominal wall to increase intra-abdominal pressure for trunk stability.³⁶ Electromyographically, the rectus abdominis muscle is active when a weight is carried on the back but not when the weight is carried anterior to the thigh. In fact, this muscle does not exhibit fatigue during submaximal efforts like the lumbar paraspinal muscles do.³⁷ Furthermore, the rectus abdominis muscle is

inactive during 14 static upright postures.³⁸ Sit-ups generate much more electrical activity in the rectus abdominis muscle than sit-backs.^{39,40} The muscular activity was greatest during the initial phase of the sit-up between 15° and 45° or between scapular lift and hip lift from the floor.^{39,40} A small difference was observed in the rectus abdominis muscle electrical activity whether the knees were bent to 65° or were straight.³⁹ Flexing the knees and anchoring the feet during a sit-up increased the activity of the abdominal muscles as compared with the rectus femoris muscle.⁴⁰ Recording of four levels of difficulty of abdominal muscle testing (elevating progressively more of the weight of the lower extremities in the supine position) showed that the lower half of the rectus abdominis muscle was the most active, followed by the upper half of the muscle.⁴¹

Pyramidalis

The pyramidalis muscle tenses the linea alba.

2.3. Functional Unit

The functional unit to which a muscle belongs includes the muscles that reinforce and counter its actions as well as the joints that the muscle crosses. The functional interdependence of these structures is reflected in the organization and neural connections of the sensory motor cortex. The functional unit is emphasized because the presence of a TrP in one muscle of the unit increases the likelihood that the other muscles of the unit also develops TrPs. When inactivating TrPs in a muscle, one should be concerned about TrPs that may develop in muscles that are functionally interdependent. Box 49-1 grossly represents the functional unit of the abdominal muscles.⁴²

Box 49-1 Functional unit of the abdominal muscles

Action	Synergists	Antagonist
Trunk flexion	Rectus abdominis Psoas major	Thoracolumbar paraspinals (longissimus thoracis)
Trunk rotation	Ipsilateral internal oblique abdominis Contralateral external oblique abdominis Ipsilateral internal intercostals Contralateral external	Contralateral internal oblique abdominis Ipsilateral external oblique abdominis Contralateral internal intercostals Ipsilateral external

	intercostals	intercostals
Trunk sidebending	Ipsilateral internal oblique abdominis	Contralateral internal oblique abdominis
	Ipsilateral external oblique abdominis	Contralateral external oblique abdominis
	Ipsilateral quadratus lumborum	Contralateral quadratus lumborum
	Ipsilateral thoracolumbar paraspinals	Contralateral thoracolumbar paraspinals

For spinal rotation and flexion, the external oblique muscle anatomically appears synergistic with the external intercostals and serratus anterior muscles with which the external oblique also interdigitates, as well as the vertical costal fibers of the latissimus dorsi with which the lower part of the external oblique muscle interdigitates and forms a continuous line of pull.³

For lumbar spinal rotation, the external oblique muscle on one side is synergistic with the ipsilateral deepest (diagonal) paraspinal muscles and with the contralateral serratus posterior-inferior and internal oblique muscles.

To increase intra-abdominal pressure for nonrespiratory reasons, the four muscles of the abdominal wall are synergistic with the quadratus lumborum and diaphragm muscles. Functions of the abdominal muscles as related to respiration are covered in Chapter 45.

3. CLINICAL PRESENTATION

3.1. Referred Pain Pattern

Abdominal TrPs may cause as much distress as pain stemming from visceral dysfunction. In fact, symptoms referred from abdominal TrPs commonly confuse the diagnostic process by mimicking visceral abdominal pathology.⁴³ Muscolino⁴⁴ described a patient with a clinical history of Crohn's disease who developed TrP in the abdominal muscles responsible for his pain symptoms. The pain pattern from TrPs in the abdominal musculature, particularly the internal and external oblique muscles, is less consistent from patient to patient than the patterns for most other muscles. Referred pain from abdominal muscles has little respect for the midline; abdominal TrPs on one side frequently cause bilateral pain. In an older study, Gutstein⁴⁵ observed that the patient is likely to describe pain caused by abdominal TrPs as "burning," "fullness," "bloating," "swelling," or "gas." The referred pain patterns from abdominal TrPs have been also reported by Melnick.⁴⁶

Abdominal Oblique Muscles

Trigger points in the abdominal oblique muscles have potential referred pain patterns that may reach up into the chest, may travel straight or diagonally across the abdomen, and may extend downward. Whether this variability represents different characteristics of consecutive deeper layers of muscles or less consistency in the patterns of pain referred from TrPs in this musculature, it is not clear. This variability is also possibly related to the fact that the internal oblique muscle is extremely difficult, if not impossible, to palpate directly.

Active TrPs in the external oblique muscle can produce “heartburn” (Figure 49-6A) and other symptoms commonly associated with abdominal hernia. The referred pain from this muscle can also produce deep epigastric pain that occasionally extends to other parts of the abdomen.⁴⁷

External oblique

Figure 49-6. Referred pain patterns (red) and visceral symptoms associated with TrPs in the internal and external oblique (and possibly transverse) abdominis muscles. A, “heartburn” associated with external oblique TrPs. B, Groin and/or testicular pain, as well as chiefly lower quadrant abdominal pain, referred from TrPs in the lower lateral abdominal wall musculature, particularly the external oblique muscle.

Active TrPs located in the musculature of the lower lateral abdominal wall, possibly in any one of the three layers of muscle, refer pain into the groin and testicles and may project pain to other parts of the abdomen (Figure 49-6B). The experimental injection of hypertonic saline into the external oblique muscle near the anterior superior iliac spine induced referred pain over the lower portion of that quadrant of the abdomen, along the inguinal ligament, and into the testicle.⁴⁸ An external oblique TrP in a 10-year-old child referred severe pain from the upper quadrant to the inguinal region.⁴⁹

Trigger points in the lower portion of the abdominal muscles, over the pubis or the lateral half of the inguinal ligament, may lie in the internal oblique muscle and possibly in the lower rectus abdominis muscle. These TrPs can increase irritability and spasm of the detrusor and urinary sphincter muscles, producing an increase in urinary frequency, retention of urine, and groin pain. When needled, abdominal wall TrPs often refer pain to the urinary bladder area. Melnick⁴⁷ described that TrPs in the lower portion of the abdominal muscles could be a source of chronic diarrhea.

Transversus Abdominis

The transversus abdominis muscle cannot be directly palpated. Trigger points in the transversus abdominis muscle refer pain as a band across the upper abdomen between the anterior costal margins. Sometimes the pain concentrates on the region of the xiphoid process. This pain can be distressing when coughing.

Rectus Abdominis

The symptoms caused by TrPs in this muscle are varied, but largely dependent on the portion of the muscle where they would appear. Symptoms are considered in three groups, those due to TrPs in the upper portion of the muscle (above the umbilical region), those caused by periumbilical TrPs, and those from TrPs in the lower rectus abdominis muscle.

Upper Portion

Trigger points in the upper portion of the rectus abdominis muscle can refer pain to the mid-back bilaterally, which is described by the patient as running horizontally across the back on both sides at the thoracolumbar level (Figure 49-7A).⁵⁰⁻⁵² Gutstein⁴⁵ also noted that treatment of tender spots in abdominal wall muscles relieved back pain. Unilateral backaches at this level, however, more frequently originate in TrPs of the latissimus dorsi muscle. In addition to back pain, TrPs in the upper portion of the rectus abdominis muscle

can also refer pain to the xiphoid process. Melnick⁴⁷ described symptoms from TrPs in the upper rectus abdominis muscle as abdominal fullness, “heartburn,” indigestion, and sometimes nausea or vomiting. These TrPs can also refer pain across the upper abdomen between the costal margins. Injection of hypertonic saline into the rectus abdominis muscle at about 2.5 cm (1 in) above the umbilicus caused brief referred pain throughout the same quadrant of the abdomen and on the same side in the back.⁴⁸ It has also been reported in a case report that TrPs in the upper portion of the left rectus abdominis muscle produced precordial pain.⁵³ When it has been identified that chest pain is myofascial and not cardiac in origin, it can be related to pain from TrPs in the pectoralis major and/or sternalis muscles; a rectus abdominis muscle source of the pain is easily overlooked. Finally, TrPs in the upper portion of the rectus abdominis muscle were observed to refer pain to the same abdominal quadrant and to simulate the symptoms of cholecystitis, gynecological disease, and peptic ulcer.⁵³

Rectus abdominis

McBurney's point

Figure 49-7. Referred pain patterns (red) and visceral symptoms of TrPs in the rectus abdominis muscle. A, Bilateral pain across the back, precordial pain, and/or a feeling of abdominal fullness, nausea, and vomiting can be caused by TrPs in the upper portion of

the rectus abdominis muscle. A similar pattern of bilateral low back pain is referred from what is often seen with TrPs in the caudal end of the rectus abdominis muscle. B, Lower right quadrant pain and tenderness may occur in the region of McBurney's point due to nearby TrPs in the lateral border of the rectus abdominis muscle. C, Dysmenorrhea may be greatly intensified by TrPs in the lower portion of the rectus abdominis muscle. D, Referred pain pattern of the pyramidalis muscle.

Periumbilical Portion

Trigger points in the lateral border, periumbilical portion of the rectus abdominis muscle, are likely to produce sensations of abdominal cramping or colic.⁴⁷ The patient often bends forward for relief. Application of cold spray to the abdomen has been reported as effective for infants who burp and cry persistently with colic.⁵⁴ Lateral TrPs in the rectus abdominis muscle near the umbilicus may evoke diffuse abdominal pain that is accentuated by movement.⁵⁵

Lewis and Kellgren⁵⁶ found that experimentally induced irritation of this muscle can mimic pain of intestinal colic. Injection of a hypertonic saline into the rectus abdominis muscle induced a familiar colic-like pain, which was stronger anteriorly than toward the back and extended diffusely over several segments in front.⁵⁷

Lower Portion

Trigger points in the lower part of the rectus abdominis muscle may refer pain bilaterally to the sacroiliac and low back region.^{50–52} The patient portrays this pain with a crosswise motion of the hand (Figure 49-7A), rather than the up-and-down pain pattern characteristic of the iliocostalis thoracis muscle, other superficial paraspinal muscles, and psoas major muscle. In some patients, TrPs in the lower rectus abdominis muscle may mimic symptoms associated with dysmenorrhea (Figure 49-7C).

Several authors have noted that a TrP in the lateral border of the right rectus abdominis muscle in the region of McBurney's point, which is halfway between the anterior superior iliac spine and the umbilicus (Figure 49-7B), is likely to produce symptoms simulating those of acute appendicitis.^{58,59} This pain pattern was reported as occurring when the patient was tired, worried, or premenstrual.⁶⁰ In one patient, the TrP for this "pseudo-appendicitis" pain was located in the rectus abdominis muscle just above the level of the umbilicus.⁵⁸

Other authors have also observed that TrPs in the region of McBurney's point may refer pain to the same lower quadrant of the abdomen and to the right upper quadrant area.^{46,–59,60} These TrPs also may refer sharp pain to the iliac fossa, the iliacus muscle, and to the penis.⁶⁰

Pyramidalis

The pyramidalis muscle refers pain close to the midline between the symphysis pubis and

the umbilicus (Figure 49-7D).

3.2. Symptoms

It has been recognized since the 1920s that persistent abdominal pain is as likely to originate in the abdominal wall muscles or be referred from chest wall muscles as it is to originate in abdominal viscera.⁶¹ Trigger points in the diaphragm muscle can also cause chest pain.⁶² The differential diagnosis of diseases that produce symptoms that are commonly caused by, or may mimic pain caused by, abdominal TrPs includes joint dysfunctions, fibromyalgia, appendicitis, peptic ulcer, gallstone colic, colitis, painful rib syndrome, intractable dysmenorrhea, pelvic pain syndromes, chronic pelvic pain, and urinary tract disease.

Abdominal symptoms are commonly enigmatic and often a source of diagnostic confusion. The pain pattern of a number of abdominal diseases is mimicked by TrPs in the abdominal wall muscles.⁶³ Montenegro et al⁶⁴ have proposed that abdominal myofascial syndrome should be considered in the differential diagnosis of chronic pelvic pain. Trigger points in the abdominal muscles may produce referred abdominal pain and induce visceral disorders (somato-visceral effects). Conversely, visceral disease can also influence somatic sensory perception and can activate TrPs (viscero-somatic effects) that may perpetuate pain and other symptoms long after the patient has recovered from the initiating visceral disease.⁶⁵ Understanding the reciprocal somato-visceral and viscero-somatic effects of TrPs helps unravel some of this uncertainty. It has been found that abdominal TrPs have a 93% positive predictive value for visceral disease, particularly chronic pelvic pain syndrome.^{66,67} These studies found that the presence of abdominal TrPs, along with abdominal and perineal cutaneous allodynia, discriminated visceral from somatic sources of pain.⁶⁷ Furthermore, Anderson et al⁶⁸ found that TrPs in the external oblique (80%) and rectus abdominis (75%) muscles were highly prevalent in men with chronic prostatitis or chronic pelvic pain. Different studies have reported the effectiveness of pelvic TrP treatment for relief of abdominal wall and chronic pelvic pain,⁶⁹⁻⁷¹ as well as for primary dysmenorrhea.⁷² It is important to consider that the European Association of Urology published guidelines suggesting that TrPs should be considered in chronic pelvic pain diagnosis.⁷³

Additional differential diagnostic considerations for abdominal wall TrPs should include hiatal hernia (gastroesophageal reflux), gastric carcinoma, chronic cholecystitis or ureteral colic, inguinal hernia, hepatitis, pancreatitis, gynecologic pathology (such as ovarian cysts), diverticulosis, umbilical hernia, thoracic radiculopathy, upper lumbar radiculopathy, costochondritis, ascariasis, epilepsy, and rectus abdominis hematoma.

Melnick⁴⁶ has reported the relative frequency of serious symptoms arising from TrP areas in the abdominal muscles among 56 patients (Table 49-1). Long⁵⁹ distinguished the “anterior abdominal wall syndrome” from visceral diseases. The syndrome was attributed to TrPs in the abdominal wall muscles. Its distinguishing feature was nearly continuous pain that might relate to movement but not to the ingestion of food or to evacuation. On careful

inquiry, some of his patients localized the pain to the abdominal wall. Good⁶⁰ observed that referred pain from TrPs in the lateral border of the rectus abdominis muscle was aggravated by bending over when lifting (an activity which shortens and often causes contraction of that muscle). In the experience of the authors of this manual, prolonged vigorous activity that requires forceful abdominal breathing may also increase referred pain from abdominal wall TrPs.

Table 49-1 Frequency of Serious Complaints among 56 Patients with Abdominal Trigger Points ^a		
Symptoms	Number of Patients	Prevalence ^b (%)
Pain	40	71
Pressure and bloating	14	25
Heartburn	6	11
Vomiting	6	11
Diarrhea	2	4

^a Adapted from Melnick J. Treatment of trigger mechanisms in gastrointestinal disease. *NY State J Med.* 1954;54:1324-1330.

^bPercentage and numbers total more than 100% because some patients had more than one symptom.

Kelly⁷⁴ noted that individuals with myalgic lesions (described like TrPs) of the abdominal wall musculature were likely to report abdominal discomfort or distress, rather than of pain per se. In the authors' experience, active TrPs of the abdominal muscles, especially in the rectus abdominis muscle, may cause a lax, distended abdomen with excessive flatus. Contraction of the abdominal muscles is inhibited by the presence of TrPs; therefore, the patient cannot "pull the stomach in." This apparent distension is readily distinguished from ascites by physical examination.

Feinstein et al⁷⁵ injected hypertonic saline into paraspinal musculotendinous tissues 1.3 to 2.5 cm from the midline at each segmental level. The abdominal pain patterns referred from paraspinal muscles at the T7-T12 levels were similar but without the precise degree of segmental correspondence that was previously suggested by Melnick.⁴⁶

Kellgren (along with Lewis in one of their two studies) described referred pain to the abdomen from interspinous ligaments when they injected hypertonic saline.^{56,57} Hockaday and Whitty⁷⁶ subsequently found that pain was referred from interspinous ligaments only to dorsal areas. The more extensive pain patterns observed by Kellgren⁵⁷ may have been due to injection of paraspinal (nonmidline) structures, which Hockaday and Whitty⁷⁶ scrupulously avoided.

Abdominal pain in an upper quadrant may be attributed to Tietze's syndrome of the costal cartilages (reported as also affecting the xiphisternal joint) or to abnormal mobility of the lower intercostal joints, which has been variously referred to as the "slipping rib syndrome," or the "rib-tip syndrome".^{77,78} These conditions have been diagnosed by the

“hooking maneuver,” in which the fingers are hooked under the costal margin to pull the ribs forward, demonstrating their abnormal mobility and reproducing the patient’s pain.⁷⁹ There is a strong likelihood that many of these patients were suffering from enthesitis of muscle attachments to the chondral cartilages. The chondral intercostal muscles, pectoralis major, and transverse abdominal musculature are likely candidates for TrPs that could contribute to the enthesitis.

Right upper quadrant pain due to TrPs in either the internal or external oblique muscles or in the lateral border of the rectus abdominis muscle of the same quadrant is easily confused with the pain of gallbladder disease. Pain simulating appendicitis was projected from “fibrositic nodules” (described like palpable bands and TrPs) in the region covered by the costal portion of the external oblique muscle, and from TrPs in the lateral border of the rectus abdominis muscle in the right lower quadrant.⁵⁸

Abdominal pain, particularly in the lower quadrant of the abdomen, may be referred from TrPs in the para-vertebral muscles (Chapter 48). Trigger points in the lower portion of the rectus abdominis muscle can cause pain in the thoracolumbar region, and a similar pain in that region can also be caused by an avulsion injury of the lumbar multifidus and rotator muscles or from zygapophyseal joints.^{50–52, 80} Urinary frequency, urinary urgency, and “kidney” pain may be referred from TrPs in the lower abdominal muscles. A TrP high in the adductor muscles of the thigh may refer pain upward into the groin and to the lower lateral abdominal wall as well.⁸¹

3.3. Patient Examination

The lateral abdominal wall may be injured in a variety of endeavors with occasional acute injuries in the setting of high-energy trauma such as motor vehicle collisions. Injuries to the lateral abdominal wall may result in lumbar hernia formation and also Spigelian hernias.⁸² After a thorough subjective examination the clinician should make a detailed drawing representing the pain pattern that the patient has described. This depiction will assist in planning the physical examination and can be useful in monitoring the progression of the patient as symptoms improve or change. Any patient with primary reports of abdominal pain should alert the clinician to perform a thorough systems review. Any concerns regarding the involvement of the cardiovascular, respiratory, or gastrointestinal systems as a source of symptoms should result in an immediate referral to a physician.

The clinician should observe the patient’s posture in sitting, standing, walking, and reaching. Articular dysfunctions associated with abdominal muscle TrPs include pubic and innominate dysfunctions, as well as depressed lesions of the lower half of the rib cage. Movement restriction of the thoracolumbar junction is sometimes associated with a shortened rectus abdominis muscle with palpable TrPs. Similar involvement of the psoas and quadratus lumborum muscles is also commonly associated with these joint dysfunctions.⁸³ All these structures should be carefully examined by the clinician.

Several authors have noted the value of increasing the abdominal muscle tension during examination to help distinguish the pain that is due to TrPs from that due to underlying

visceral disease. To conduct the abdominal tension test according to Long,⁵⁹ the sensitive area is compressed with sufficient pressure to cause steady pain with the patient in a supine position. When the patient then raises the legs high enough to bring both heels a few inches above the table, the tensed abdominal muscles lift the palpating finger away from the viscera while the digital pressure on the muscle itself is increased. If the pain increases, it suggests that pain may originate from the abdominal wall musculature. If the pain decreases, it more likely originates inside the abdomen. The similar Carnett's technique (the patient is in a supine position, crosses the arms and sits halfway forward) reliably distinguished abdominal wall tenderness from visceral tenderness.⁸⁴ Other possibilities for increasing the contraction of the abdominal wall muscles include asking the patient to lift both heels off the bed alone or in combination with lifting the head. By having patients raise only the head and shoulders free of the table, the test can be performed by those unable to do a sit-up, and they can confirm the test for themselves, assuring themselves of no visceral origin of the pain.⁸⁵

The examiner should observe the displacement of the patient's umbilicus during various activities, such as laughing, coughing, raising one leg up from the bed, or having the patient lift their head off a pillow from a supine position. If there is abdominal muscle imbalance, a umbilicus deviates away from a weaker (or inhibited) muscle and toward a stronger (or more hyperactive) muscle. This deviation indicates a positive Beever's sign.⁸⁶ Simply observing the umbilicus while the patient rests quietly may reveal a deviation toward a muscle with TrP shortening or away from an abdominal muscle that is inhibited by TrPs.

The double leg lowering test and the lower abdominal muscle progression are also two common tests of abdominal muscle performance. A strong association between rectus abdominis muscle activity and external oblique muscle activity was observed with both tests. The association between the internal oblique and transversus abdominis muscles was moderate and weak on each test, respectively.⁸⁷

These tests may measure different qualities of abdominal wall muscle performance. Proper assessment of abdominal wall muscle endurance is clinically significant in these patients because the abdominal muscle fatigue after sustained exercise is primarily due to peripheral mechanisms,⁸⁸ suggesting a potential role of TrPs in muscle fatigue.

Abdominal Oblique Muscles

To ensure contraction of the lateral wall abdominal muscles while performing the abdominal tension test, the supine patient should elevate the heels or elevate the head and shoulders high enough to lift both scapulae off any support on the table. When the patient elevates only the head, it is the rectus abdominis muscle that is mainly contracted, not the abdominal oblique muscles. The patient can also rotate the trunk during the head elevation for increasing the diagonal tension of the ipsilateral internal oblique and the contralateral external oblique muscles. Clinical assessment of abdominal oblique muscles is highly relevant in patients with low back pain, because patients with chronic low back pain

demonstrated significantly higher activation of the external oblique and rectus abdominis muscles.⁸⁹ This overactivity can be a promoting factor for developing TrPs in these muscles.

Transversus Abdominis

There is clear evidence suggesting that patients with low back pain demonstrate a delayed activation of the transversus abdominis muscle; however, this temporal change is not directly associated to related-disability.²² In fact, patients with low back pain exhibit delayed activation of transversus abdominis and internal oblique muscles, absence of abdominal core muscle coactivation, and impairments in the temporal timing between transversus abdominis and internal oblique muscle onsets.⁹⁰ Additionally, the transversus abdominis muscle also exhibits lower activation during weight-bearing tasks.⁹¹ Because direct palpation of the transverse abdominis muscle for the presence of TrPs is difficult, assessment of its function is clinically important in patients with low back or abdominal pain.

Rectus Abdominis

When a patient with TrPs in the rectus abdominis muscle stands, the abdomen is likely to sag and become pendulous. Clinically, TrPs in this muscle inhibit its supportive function. Janda⁹² classified the rectus abdominis muscle as prone to inhibition and weakness. The palpable taut band associated with TrPs would shorten only a segment of the rectus abdominis muscle (between fascial delineations) in which it lies. The rectus abdominis muscle has no parallel muscle, except its contralateral partner, that could contract and unload it to provide protective splinting. Nevertheless, recent studies have found increased activation of the rectus abdominis muscle in individuals with chronic low back pain.²⁷

If asked to take a deep breath, patients with rectus abdominis TrPs are likely to exhibit paradoxical breathing. Although during quiet respiration, exhalation is essentially performed by the elasticity of the lungs and requires little muscular assistance, the threat of pain due to stretching of the involved rectus abdominis muscle apparently could subconsciously inhibit the normal diaphragmatic contraction on inspiration. This pattern may be a rectus abdominis–diaphragmatic reflex inhibition. When the patient inhales deeply with the diaphragm muscle, protruding the abdomen, referred pain due to rectus abdominis TrPs may be exacerbated. In these patients, the bilateral, transverse, mid-back referred pain from TrPs in the upper portion of the rectus abdominis muscle is usually aggravated by taking a deep breath, especially when the back is arched in marked lumbar lordosis, which further stretches the rectus abdominis muscle. Back pain from paraspinal TrPs is not usually influenced by respiration. Herniation through the abdominal musculature is detected in some cases only when the patient is standing rather than recumbent.

3.4. Trigger Point Examination

Examination of the superficial external oblique and rectus abdominis muscles is easier than examination of the deeper internal oblique and transversus abdominal muscles, because these two are not reliably accessible for diagnostic palpation.

When the abdominal muscles are examined for TrPs, the patient lies supine, taking a deep breath using diaphragmatic (abdominal) breathing and holding the breath to passively stretch the muscles (it helps relax them) and to increase their pressure sensitivity to palpation. To optimize palpation of lateral abdominal TrPs, the patient lies on the contralateral side and holds a similar deep breath.

External Oblique

The external oblique muscle can be examined with a cross-fiber pincer palpation. The most accessible fibers are those located on the lower border of the rib cage and along the line where this muscle attaches to the iliac crest (Figure 49-8A and B). The patient's hips may be flexed to slacken the abdominal muscles; the abdominal wall in the flank area (external and internal oblique and transversus muscles) can then be grasped between the fingers and the thumb. When the TrP or the taut band is strummed with the pincer grasp, the muscle fiber usually responds with a vigorous and visible local twitch response. Cross-fiber flat palpation may also be utilized to identify TrPs in the external oblique muscles (Figure 49-8C).

Figure 49-8. Palpation of the right external oblique muscle. A, Cross-fiber pincer palpation with the patient supine; B, Cross-fiber pincer palpation with the patient side-lying. C,

Internal Oblique

The internal oblique muscle cannot be directly palpated. Tender areas in this muscle can be located along the inferior margins of the tips of the six lower ribs or close to the pubic bone. In our experience, to find them, the clinician should press down against the upper edge of the pubic arch, not on the flat anterior surface of the pubis. These TrPs feel like small buttons or short bands at the region of attachments of the internal oblique muscle.

Rectus Abdominis

Trigger points in the rectus abdominis muscle are easily accessible to a cross-fiber flat palpation. Trigger points can be found in either portion of the muscle (Figure 49-9A and B). The patient's hips may be flexed to slacken the rectus abdominis muscle, which is helpful for palpation of the lower portion of the muscle. When the TrP or the taut band is identified with cross-fiber flat palpation, the muscle fiber usually responds with a visible local twitch response.

Figure 49-9. Cross-fiber flat palpation of the rectus abdominis muscle with the patient supine. A, Upper portion of the muscle; B, Lower portion of the muscle.

4. DIFFERENTIAL DIAGNOSIS

4.1. Activation and Perpetuation of Trigger Points

A posture or activity that activates a TrP, if not corrected, can also perpetuate it. In any part of the abdominal muscles, TrPs may be activated by unaccustomed eccentric loading, eccentric exercise in an unconditioned muscle, or maximal or submaximal concentric loading.⁹³ Trigger points may also be activated or aggravated when the muscle is placed in a shortened or lengthened position for an extended period of time. A posture or activity that activates a TrP, if not corrected or if continued, can also perpetuate it. In addition, many structural and systemic factors (refer to Chapter 3) perpetuate a TrP that has been activated by an acute or chronic overload. Abdominal TrPs are likely to develop in muscles that lie in

the zone of pain referral from visceral structures. In general, TrPs may develop in response to visceral disease; direct trauma; and to mechanical, toxic, or emotional stress. These mechanisms are particularly relevant for abdominal wall muscles. For instance, TrP activity may persist long after the initiating acute visceral disease has resolved. If the visceral lesion is long-lasting and persists (eg, peptic ulcer, neoplasm, or intestinal parasites), treatment directed only to the TrPs provides merely transient or partial relief.

4.2. Associated Trigger Points

Associated TrPs can develop in the referred pain areas caused by TrPs.⁹⁴ Therefore, musculature in the referred pain areas for each muscle should also be considered. Although the clinician first considers TrPs in the abdominal musculature to explain non-visceral abdominal pain, there are other TrP sites to be considered. Epigastric pain suggestive of a duodenal ulcer may arise from TrPs in the diaphragm or serratus anterior muscles.

Trigger points in the lower portion of the lateral abdominal wall muscles are often associated with TrPs high in the adductor muscles of the thigh, which may refer pain upward inside the abdomen. Trigger points in the pelvic floor musculature may often coexist with TrPs in the abdominal wall muscles and can help differentiate pelvic and abdominal pain of visceral versus somatic origin.⁶⁶

Similarly, TrPs in the psoas or iliacus muscles can also refer pain to the abdominal region, contribute to flatulence, or mimic other visceral symptoms.

4.3. Associated Pathology

As mentioned earlier, visceral diseases can be associated with abdominal wall TrPs. Abdominal wall TrPs are especially likely to develop with any inflammatory visceral disease as a result of the viscerosomatic reflex. In fact, the presence of abdominal TrPs and abdominal cutaneous allodynia each had a positive predictive value of 93% for the presence of visceral dysfunction.⁶⁷ The relationship between TrPs and visceral problems is bidirectional because modification of the sensory input to the central nervous system in somatic areas of pain referral from visceral nociceptive input can modify the perception of pain. In fact, viscera tissues exhibit similar pain referral areas as TrPs. In healthy subjects, stimulation of the splenic flexure of the small intestine by acute distention induced referred pain to the upper abdomen. In individuals with an irritable colon, this stimulus projected pain also to the precordium, left shoulder, neck, and arm.⁹⁵ The upper and lower gastrointestinal tract of 21 patients with “functional” abdominal pain with no organic cause was systematically explored using an inflatable balloon.⁹⁶ The authors found referred pain elicited by areas in the esophagus, small intestine, and colon that produced the patients’ symptoms. Giamberardino et al⁹⁷ studied the responses to ureteral stone implants in rats for as long as 10 days. These authors observed a direct linear correlation between severity of visceral pain episodes and hyperalgesia of the ipsilateral external oblique muscle. In this study, the amount of referred muscle hyperalgesia was a direct function of the amount of colic pain experienced.

Trigger points in the rectus abdominis muscle can simulate the symptoms of appendicitis. Physicians who are unaware of TrPs responsible for lower right abdominal quadrant pain can be frustrated by the poor correlation between the patient's symptoms and the pathological state of the excised appendix.⁹⁸ In fact, nearly 40% of the appendices removed in one large series were normal.⁹⁹ Therefore, it is important to differentiate if pain in the lower right abdominal quadrant pain is related or not to abdominal wall TrPs. On the opposite, a real appendicitis could also activate TrPs in the abdominal wall muscles, particularly after surgery, provoking persistent pain after the surgery. It has been previously documented that pain responding to medical treatment for a duodenal ulcer became persistent until TrPs in the abdominal musculature were inactivated.⁴⁷ The leucocyte count and erythrocyte sedimentation rate are usually normal in myofascial pain syndromes but are elevated in acute appendicitis and other inflammatory visceral diseases.

Similarly, TrPs can also refer pain to the urinary bladder area with associated sphincter spasm and residual urine. Some patients have received urethral dilation and urethrotomy without relief. The referred TrP sensations can also mimic symptoms compatible with cystitis.¹⁰⁰ Urinary tract symptoms indicating prostatitis can be and often are caused by intrapelvic TrPs. Again, somatic activation of TrPs in any abdominal wall muscle or paraspinal muscle can be provoked by repetitive or long-lasting urinary infections. In fact, patients with a diagnosis or who were surgically operated for endometriosis exhibited TrPs in the abdominal and pelvic floor muscles.¹⁰¹

The abdominal wall muscles may exhibit dysfunction from a variety of causes because they are highly sensitivity to physical or mental stress. Several commonly encountered stress factors may activate abdominal wall TrPs: fatigue, emotional tension, cold exposure, viral infections, visceral problems, straining due to constipation, and poor posture (such as sitting and leaning forward for hours on a bed or at a desk with the abdominal muscles shortened and tense, with the back not supported). However, some postural disturbances such as forward head or rounded shoulder postures (refer to Chapter 76) can sometimes be the result of the TrP shortening in the upper portion of the rectus abdominis muscle. Structural biomechanical malalignment such as a leg length discrepancy, scoliosis, or small hemipelvis may add unnecessary overload and their effects may be cumulative over time. The external oblique muscle is vulnerable to a sustained twisted position (sitting at a desk, turned sideways because of lighting). This muscle also is vulnerable in sports activities that require a vigorous twisting body motion (ball throwing or racquet swinging).

Acute trauma and chronic occupational strain are important activating factors. Anecdotally, TrPs are likely to occur close to an abdominal scar, as such after an appendectomy or hysterectomy. The initiating stresses during surgery may be the combination of excessive stretch on the muscles by retractors and associated ischemia. The skin and muscles around an incision can be easily infiltrated effectively with procaine at the time of suturing the wound to prevent the development of TrPs following surgery and to reduce postoperative incisional discomfort. In another example, rectus abdominis TrPs may be initiated in conjunction with an abdominal operation and perpetuated by paradoxical breathing that develops as a result of postoperative abdominal soreness. The development

of these TrPs also discourages abdominal muscle activity, which could contribute to paradoxical breathing. An unusual source of continuous severe lower abdominal pain is hematoma of the rectus abdominis muscle.¹⁰²

5. CORRECTIVE ACTIONS

When seated, the patient should use a small pillow for lumbar support and should lean against the backrest of the chair. This maintains the natural lumbar lordosis and raises the thoracic cage anteriorly, which places the more longitudinal abdominal wall muscles on gentle stretch. A very tight elastic belt or girdle may compress the abdominal muscles, interfering with their circulation.

Helpful exercises for the abdominal musculature include regular diaphragmatic (abdominal) breathing, the pelvic-tilt and the sit-back/sit-up exercises, and laughter.

Diaphragmatic (Abdominal) Breathing

The most effective active stretch exercise for these muscles is diaphragmatic breathing.³⁹ Diaphragmatic breathing, with the patient in hook-lying, stretches the lateral abdominal wall muscles (Figure 45-11).

Pelvic Tilt

The pelvic-tilt exercise is a gentle and effective exercise for the lower portion of the rectus abdominis muscle. The exercise is performed as illustrated and described in Figure 49-10.

Figure 49-10. The pelvic-tilt exercise engages the abdominal muscles and stretches the lumbar spinal muscles. A, Starting position. B, Patient contracts the abdominal muscles to flatten the lumbar spine against the floor, gently tilting the front of the pelvis toward the nose.

Sit-back/Abdominal-curl/Sit-up

The sit-back/abdominal-curl/sit-up exercise is the smooth combination of three exercises (Figure 49-5). This combination exercise should always begin with the sit-back exercise. It results in a lengthening, not shortening, contraction of the abdominal musculature. The lengthening contraction of the sit-back places relatively less load on the involved abdominal

muscles because of the greater strength and efficiency of a lengthening, as compared with a shortening contraction. First, the patient pushes himself or herself up into the sit-up position with the arms and then does a slow sit-back (Figure 49-5A). The curl-down movement of the sit-back should be made smoothly and slowly, without jerks. The pause between each cycle of the exercise is as important as the movement and should be equally long. A full inspiration and expiration at the end of each sit-back helps reestablish complete relaxation of the muscles and paces the exercise. The patient starts by doing the exercise on alternate days or, if the abdominal muscles are still sore, skipping 2 days. Then, the number of sit-backs is gradually increased to a goal of 10 per daily session. Only when the sit-back goal is reached does the patient proceed to the abdominal curl (Figure 49-5B), which is a partial sit-up. This is done as a “peel-up” with the spine bending forward, so that each successive vertebra leaves the floor in turn (Figure 49-5C and D).

Laughter

Laughter is a vigorous isometric exercise for all the abdominal muscles.

If the exercise program induces fatigue or self-perception of shortening of the muscles, the patient can be also gently stretch the abdominal musculature (Figure 51-5A and B).

Quadratus Lumborum Muscle

“Joker of Low Back Pain”

Joseph M. Donnelly and Deanna Hortman Camilo

1. INTRODUCTION

The quadratus lumborum muscle is a broad, quadrilateral muscle that is located within the posterior abdominal wall. The muscle has a broader attachment at the ilium as compared with its attachment onto the lumbar spine and lower ribs. The three groups of quadratus lumborum muscle fibers consist of nearly vertical fibers that form the posterior portion of the muscle (iliocostal), the diagonal fibers that create the middle muscle layer that travels from the iliac crest to the transverse processes of the lumbar vertebrae (iliotransverse), and the diagonal fibers that form the anterior portion of the muscle that extend from the lumbar vertebrae transverse processes to the lower ribs (costotransverse). It functions to side-bend, extend, and stabilize the lumbar spine. Trigger points (TrPs) in the quadratus lumborum muscle generate local pain in the lateral trunk between the iliac crest and 12th rib. Referred pain extends ipsilaterally to the pelvis or sacroiliac joint (SIJ), buttocks, groin, and anterior thigh. Symptoms may be exacerbated by repetitive activities that involve bending and lifting and compensatory gait mechanics due to gluteal muscle weakness or a leg length discrepancy. Due to the location of pain referral, differential diagnosis should include SIJ dysfunction or pathology, greater trochanteric bursitis, and lumbar radicular pain. Corrective actions for quadratus lumborum TrPs should address postural alignment; sleeping positions; ergonomics with bending, lifting, and twisting; self-pressure release techniques; and self-stretching techniques.

2. ANATOMIC CONSIDERATIONS

The quadratus lumborum muscle is a thin flat quadrilateral-shaped muscle located in the posterior aspect of the abdominal wall. It occupies the area of the iliac crest deep to the erector spinae and multifidus muscles.^{1,2} The muscle is comprised of an anterior, middle, and posterior layer of intersecting bundles of muscle fibers which vary in size and

The iliocostal fibers form the most evident portion of the quadratus lumborum muscle. These fibers travel medially and superiorly from their attachment on the uppermost portion of the posterior iliac crest and iliolumbar ligament toward their attachment on the lower ribs² (Figure 50-1).

Figure 50-1. Attachments of the quadratus lumborum muscle (red). The intertransversarii lateralis muscle and iliolumbar ligament are uncolored, dorsal view. From Eisler P. *Die Muskeln des Stammes*. Jenna: Gustav Fischer; 1912:654, color added.

The iliotransverse and costotransverse portions have more variable diagonal bundles of fibers that attach on the tips of the transverse processes of the upper four lumbar vertebrae. The iliotransverse diagonal fibers connect proximally to the transverse processes of L1-L4 and the lateral aspect of T12 and attach distally to the crest of the ilium and often the iliolumbar ligament. The small costotransverse diagonal fibers, which are often not discernable, attach proximally to the 12th rib and distally to the lumbar transverse processes.² Both sets of diagonal fibers of the quadratus lumborum muscle may be thought of as guy wires that provide stabilization forces for the lumbar spine (Figures 50-2 and 50-3).

Figure 50-2. Attachments of the quadratus lumborum muscle (red). The iliotransverse, iliocostal, and costotransverse fibers can be visualized, anterior view.

Figure 50-3. Quadratus lumborum (red) and intertransversarii laterales (uncolored) muscles, anterior view. The two halves of the figure are drawn from two different cadaver specimens. 12, 12th thoracic nerve; I, first lumbar nerve. From Eisler P. *Die Muskeln des Stammes*. Jena: Gustav Fischer; 1912:654, 655, color added.

The iliotransverse diagonal fibers are consistently shown in dorsal view (Figure 50-1).^{5,6} This portion of the quadratus lumborum muscle is not under the cover of the erector spinae musculature; it lies deep to the thoracolumbar fascia where the internal abdominal oblique, transversus abdominis, and the latissimus dorsi muscles attach to the thoracolumbar fascia.² Emphasis should be placed on this anatomic arrangement, especially when palpating for TrPs or muscular tenderness, particularly near the attachments on the iliac crest (Figure 50-4).² The diagonal iliotransverse and costotransverse fibers comprise the medial border of the muscle, and the more nearly vertical iliocostal fibers form the lateral border, with increasing overlap and interdigitation as fibers approach their iliac and

costal attachments. These diagonal fibers frequently interdigitate between layers of the more lateral longitudinal (vertical) fibers and are most apparent from the posterior view.

Figure 50-4. Regional anatomy of the right quadratus lumborum muscle (dark red). Neighboring muscles are light red. The thoracolumbar fascia, which lies anterior to (deep to) the quadratus lumborum muscle, is seen between the quadratus lumborum muscle and the cut edge of the transversus abdominis muscle. The transverse abdominis, latissimus dorsi, and internal oblique muscles have been cut and portions removed. The external oblique muscle has also been cut and a portion reflected.

The iliolumbar ligament lies in the region between the fourth and fifth lumbar transverse processes and the iliac crests, immediately inferior and medial to the quadratus lumborum muscle (Figures 50-1 and 50-3).² The fibers of the iliolumbar ligament blend with the intertransverse ligaments of the lumbar spine and the anterior sacroiliac (SI) ligaments. Together, these ligaments provide stability to the SIJ and the L5-S1 vertebral segment by limiting side-bending and protecting against anterior shear of L5 on S1.²

2.1. Innervation and Vascularization

The quadratus lumborum muscle is supplied by branches of the anterior primary rami of T12 and L1-L4.¹

Vascular supply of the quadratus lumborum muscle is provided by branches of the lumbar arteries, branches from the sacral artery, the iliolumbar artery, and branches from the subcostal artery.¹

2.2. Function

The quadratus lumborum muscle has, historically, been considered a “hip hiker,” elevating the ipsilateral hip during unilateral contraction with a fixed spine. Although the quadratus lumborum muscle does perform this function during ambulation when attempting to compensate for a longer limb,² recent research concludes that its primary functions are lateral flexion, extension, and stabilization of the trunk and lumbar spine in the frontal and horizontal planes.^{1, 2, 7-9}

When acting unilaterally with a fixed pelvis, the quadratus lumborum muscle functions as an ipsilateral lateral flexor of the spine (Figure 50-5A and B).^{1, 7-9} Studies conducted with electromyography (EMG) have shown that the posterior portion of the quadratus lumborum muscle has greater activation during ipsilateral lateral flexion (side-bending) than the anterior portion of the muscle; however, it is during this movement that peak activity of the anterior portion of the quadratus lumborum muscle is achieved.^{7, 9} Unilateral contraction of the quadratus lumborum muscle has a stabilizing effect on the spine when a person is carrying a load in the contralateral upper extremity.⁷ Studies have also shown that the quadratus lumborum muscle is active during contralateral lateral flexion. Thus, the quadratus lumborum muscle on one side of the body serves a stabilizing role, whereas the quadratus lumborum muscle on the contralateral side of the body laterally flexes (side-bends) the spine.^{7, 9} Lateral trunk motions require both concentric and eccentric contractions between the right and left quadratus lumborum muscles in addition to other trunk muscles to achieve postural stability.

Figure 50-5. Tracings of lumbar radiographs (black) with quadratus lumborum fibers (red lines) added to show their attachments and directions. A and B, Anteroposterior view; C, D, and E, Lateral view. An X locates the center of rotation between two vertebrae; an open circle locates the tip of a transverse process. Solid red lines mark the longitudinal iliocostal fibers; dashed red lines indicate the diagonal iliotransverse and costotransverse fibers. A, Superficial lateral iliocostal fibers that laterally flex the lumbar spine toward the same side. B, Medial, deep diagonal iliotransverse, and costotransverse fibers produce the same effect. C, D, and E, All fibers extend the lumbar spine when the subject stands with the lumbar spine in the flexed, neutral, or extended posture, respectively.

Waters and Morris¹⁰ reported EMG activity in the quadratus lumborum muscle during walking. All recordings were made from the right side of the body. A burst of EMG activity in the right quadratus lumborum muscle occurred in all subjects at moderate and fast walking speeds, preceding and through right and left heel contact.¹⁰ Knapp¹¹ concluded from clinical observations that, without apparent gluteal muscle weakness, dropping of the pelvis on the swing side when walking in place may be caused by weakness of the oblique fibers of the quadratus lumborum muscle on the opposite side. This supports the

biomechanical theory that the quadratus lumborum muscle and the hip abductor muscles serve as guy wires in the frontal plane during the gait cycle.²

When contracting bilaterally, the quadratus lumborum muscle extends the spine.⁸ In a computer analysis¹² of the lever arms and cross-sectional areas of the regional muscles in two cadavers, the quadratus lumborum muscle was calculated as producing approximately 9% of the muscular force exerted in lateral flexion of the spine and 13% (in one cadaver) or 22% (in the other cadaver) of the extension power of the lumbar spine. This study confirms the extension function deduced from Figure 50-5C, D, and E in all positions of the lumbar spine from full flexion to full extension. In spinal rotation to the contralateral side, the quadratus lumborum muscle was calculated as contributing 9% or 13% of the power.¹²

Bilateral quadratus lumborum muscle contraction also serves a large stabilizing role during spinal compression when the subject is in a standing position,⁸ such as when carrying a load with bilateral upper extremities. As the carrying load is increased gradually, the activity of the quadratus lumborum and abdominal oblique muscles increases because more trunk stability is required. To further support the concept of the quadratus lumborum muscle's role in spinal stabilization, researchers have found that stabilization exercises on a Swiss ball in the elderly significantly increases muscle activation in the quadratus lumborum muscle.¹³

Acting bilaterally, the anterior portion of the quadratus lumborum muscle braces the 12th rib and provides support for contraction of the diaphragm muscle, serving as a secondary muscle of inspiration.^{1,9} It is also identified as fixing one to two ribs in forced exhalation.¹⁴⁻¹⁶

The quadratus lumborum muscle can also compensate for a weak gluteus medius muscle during hip abduction. Investigators have studied muscle activation of the quadratus lumborum muscle during hip abduction and found that it compensates for an inadequate gluteus medius muscle, and this compensation is followed with lateral pelvic tilting.^{17,18} Recruitment imbalance between the gluteus medius and quadratus lumborum muscles during hip abduction should be considered as a contributing factor to clinical conditions.¹⁷ Recent research has found that utilization of a pelvic compression belt during side-lying hip abduction significantly decreases quadratus lumborum muscle activation and improves gluteus medius muscle activation.¹⁹

2.3. Functional Unit

The functional unit to which a muscle belongs includes the muscles that reinforce and counter its actions as well as the joints that the muscle crosses. The functional interdependence of these structures is reflected in the organization and neural connections of the sensory motor cortex. The functional unit is emphasized because the presence of a TrP in one muscle of the unit increases the likelihood that the other muscles of the unit also develops TrPs. When inactivating TrPs in a muscle, one should be concerned about TrPs that may develop in muscles that are functionally interdependent. Box 50.1 grossly

represents the functional unit of the quadratus lumborum muscle.²⁰

Box 50-1 Functional unit of the quadratus lumborum muscle

Action	Synergists	Antagonist
Trunk ipsilateral lateral flexion (side-bending)	Ipsilateral internal abdominal oblique Ipsilateral external abdominal oblique Ipsilateral erector spinae Ipsilateral latissimus dorsi	Contralateral quadratus lumborum Contralateral internal abdominal oblique Contralateral external abdominal oblique Contralateral erector spinae Contralateral latissimus dorsi
Trunk extension	Erector spinae Multifidi Latissimus dorsi	Rectus abdominis Internal abdominal oblique External abdominal oblique

During gait, the quadratus lumborum muscle works in conjunction with the hip abductor and adductor muscles to create frontal plane stability during the swing phase of the gait.²

3. CLINICAL PRESENTATION

3.1. Referred Pain Pattern

Trigger points may be found within any portion of the quadratus lumborum muscle; however, many portions of the muscle are not accessible by manual palpation. Trigger points are commonly found in four locations: in the superficial (lateral) and deep (medial) portions, each with a cephalad and a caudal TrP area. The superficial (lateral) TrPs refer pain more laterally and anteriorly than the deep TrPs. The caudal TrPs tend to refer pain more distally. The pain from these TrPs is often reported as deep and aching but may be stabbing during movement.

Trigger points in the superficial location (Figure 50-6A) are likely to refer pain along the crest of the ilium and sometimes to the adjacent lower quadrant of the abdomen. The pain may extend to the outer upper aspect of the groin. They are responsible for referred pain to the greater trochanter and outer aspect of the upper thigh. The greater trochanter can be so “sore” (tender to pressure) that the patient cannot tolerate lying on that side, and pain may prevent weight-bearing by the lower extremity on the involved side. The referred pain from these TrPs often result in a misdiagnosis of trochanteric bursitis (Figure 50-6A).

Figure 50-6. Referred pain patterns (bright red) of TrPs in the quadratus lumborum muscle (red). Solid bright red denotes an essential pain pattern, and stippled red, a spillover pattern. A, Pain patterns of superficial (lateral) TrPs that are palpable below and close to the 12th rib and just above the iliac crest. B, Pain patterns of deep (more medial) TrPs close to the transverse processes of the lumbar vertebrae. The more cephalad deep TrPs refer pain to the sacroiliac joint; more caudal TrPs refer pain low in the buttock. C, Trigger

points can exist in any part of the muscle. Due to its location, examination may be performed with the use of a filiform needle or with a TrP injection.

Deep quadratus lumborum TrPs have been shown to refer pain to the front of the thigh, extending from the anterior superior iliac spine to the lateral side of the upper part of the patella in a narrow band about the width of a finger. The more cephalad of the deep TrPs (Figure 50-6B) refer pain strongly to the area of the SIJ; bilaterally, these TrPs frequently may refer pain that extends across the upper sacral region. The caudal deep TrPs refer pain to the lower buttock.

Authors have identified the quadratus lumborum muscle as a source of lumbago,^{21–23} backache,^{24–28} and lumbar myalgia.²¹ More specifically, they have identified the quadratus lumborum muscle as referring pain to the SI region,^{29–31} the hip or buttock,^{29–31} the greater trochanter,^{29,31} the abdomen,^{26,27,30,32,33} and the groin.^{29,31} Additional areas of pain referral from the quadratus lumborum muscle were reported in the anterior thigh²⁷ and in the testicles and scrotum.²⁴

Tucker et al³⁴ investigated the nociceptive effects of a hypertonic saline injection into six muscles in the low back. Fifteen subjects were injected with hypertonic saline solution into the longissimus lumborum, quadratus lumborum, and superficial and deep multifidus muscles at L4 and L5. The injections were performed with ultrasound guidance to locate the specific muscles. Participants reported the depth, location, intensity, size, and quality of pain for up to 14 minutes following the injection. The most common descriptors of pain caused by injection of the quadratus lumborum muscle were aching, cramping, dull, sore, and tight. One subject reported paresthesias in the anterolateral thigh that lasted 2 days. The most common referred pain pattern from the quadratus lumborum muscle was to the lateral trunk, lower back, anterior iliac crest, and pelvis, which was very similar to the referred pain pattern from the deep multifidus muscle. The deep and superficial multifidus muscle had an annoying quality and higher cramping and dull ache as compared with the other muscles. The longissimus lumborum muscle was described primarily as aching and annoying. The referred pain patterns were not consistent to that of referred nerve root pain, therefore the authors conclude that there is a diffuse mechanism of referred pain from these six muscles. They also conclude that the individual may not experience pain at the level or location of the nociceptive stimuli.³⁴ The referred pain pattern noted for the quadratus lumborum muscle in this study was very similar to the referred pain patterns described earlier by Travell and Simons.³⁵

3.2. Symptoms

When patients report nonspecific low back pain (LBP), the quadratus lumborum muscle is typically found to be a contributing factor to the patient's report of pain. Trigger points in the quadratus lumborum muscle are common in LBP, but this source is commonly overlooked. Trigger points in the quadratus lumborum muscle should be considered as a potential source of symptoms when the patient reports unilateral LBP, SIJ and buttock

pain, pain over the greater trochanter, and groin pain.

Patients with TrPs in the quadratus lumborum muscle may report a persistent, deep, aching pain at rest²⁹ that increases in the unsupported upright position and in positions that require stabilization of the lumbar spine. Arising from the supine position or getting up out of a chair may be difficult or impossible without help from the upper limbs.

The patient may also experience acute pain over the greater trochanter which is aggravated with sit-to-stand, walking, ascending, and descending stairs. They may also report having significant issues with lying on the affected side, especially at night. These individuals may have had a failed cortisone injection of the greater trochanter bursa.

In addition to back pain distributed in the primary referred patterns of this muscle (Figure 50-6), pain may extend to the groin, testicle, scrotum, or in a sciatic nerve distribution.²⁴ Patients have reported heaviness of the hips, cramping of the calves, and burning sensations in the legs and feet.³⁰ The patient may also report increasing difficulty with walking for long periods of time, especially when the strength of the gluteus medius muscle is inadequate to support the pelvis in the mid stance phase of gait.

Utilizing a cross-sectional design, Iglesias-González³⁶ investigated the difference in the presence of TrPs in 42 patients with nonspecific LBP and 42 age-matched controls. The quadratus lumborum, iliocostalis lumborum, psoas, piriformis, gluteus minimus, and gluteus medius muscles were examined for TrPs. The numeric pain rating scale (NPRS), Roland-Morris Low Back Questionnaire, and the Pittsburgh Sleep Quality Index were used as outcome measures. Patients with nonspecific LBP had a mean of 3.5 active TrPs and two latent TrPs as compared with the control group participants who did not have any active TrPs. Active TrPs in the quadratus lumborum muscle were most prevalent (55%), followed by the gluteus medius muscle (38%), and iliocostalis lumborum muscle (33%) in patients with nonspecific LBP. A greater number of active TrPs was associated with worse sleep quality and higher pain intensity ($P < 0.001$) in the nonspecific LBP group. There was also a significant difference in the presence of latent TrPs in subjects with nonspecific LBP compared with the control group with the quadratus lumborum, iliocostalis lumborum, psoas, piriformis, and gluteus medius muscles being most affected.³⁶

3.3. Patient Examination

After a thorough subjective examination, the clinician should make a detailed drawing representing the pain pattern that the patient describes. This depiction will assist in planning the physical examination and can be useful in monitoring the progression of the patient as symptoms improve or change. The type, quality, and location of the pain should be carefully assessed and utilization of standardized outcome tools is imperative while examining patients with LBP and/or lower extremity dysfunctions.

The patient with active TrPs in the quadratus lumborum muscle exhibits muscle guarding that restricts movement between the lumbar vertebrae and the sacrum during walking, lying down, turning over in the bed, getting up from the bed, or when arising from a chair. A vigorous cough may evoke the characteristic pain distribution.

Observation of the posture in standing should be carried out with attention to spinal curvature and lower extremity biomechanical alignment. It is important to incorporate assessment for functional and structural scoliosis, presence of a hemipelvis, iliac upslip,³⁷ and leg length discrepancy. Due to the quadratus lumborum muscle's attachments to the pelvis and lumbar spine, shortening of the quadratus lumborum muscle can contribute to apparent scoliosis and leg length discrepancies. If there is shortening of the quadratus lumborum muscle (potentially, due to TrPs) in standing, the pelvis is slightly elevated on the affected side or depressed on the side opposite to the affected muscle. The lumbar spine usually exhibits a functional lumbar scoliosis that is convex away from the side of the involved quadratus lumborum muscle.²² The normal lumbar lordosis is likely to appear flattened due to the vertebral rotation that accompanies the scoliosis, despite the fact that the quadratus lumborum muscle is an extensor and lateral flexor of the spine.

Iliac crest heights and PSIS and ASIS bony landmarks should also be assessed for asymmetry in the seated position.³⁷ The seated position the patient prefers should also be assessed. Clinically, it is common for the patient to lean toward the affected side while seated when there are active TrPs in the quadratus lumborum muscle. A hemipelvis may be more apparent in this position than in standing.

In supine or prone lying, TrPs may shorten the muscle and can thus distort pelvic alignment, elevating the pelvis on the side of the tense muscle (Figure 50-7). Bony landmarks should also be palpated in this position to differentiate an iliosacral dysfunction³⁷ from quadratus lumborum TrPs or shortening of the muscle.

Figure 50-7. Distortion of apparent leg length discrepancy due to a taut quadratus lumborum muscle. A, At the medial malleolus in the prone position, the right lower limb appears shorter than the left due to TrPs and tension in the shortened right quadratus lumborum muscle (dark red). B, True leg length discrepancy becomes apparent when the TrPs in the right quadratus lumborum muscle are eliminated and the muscle returns to its normal resting length (light red). The S-curve functional scoliosis of the spine, seen in A, is also eliminated.

Assessment of lumbar spine active range of motion likely reveals limitations in flexion, extension, and lateral flexion (side-bending). Lateral flexion (side-bending) is typically restricted toward the pain-free side and sometimes bilateral restrictions may be noted.

Seated or standing rotation of the thoracolumbar spine is usually most restricted toward the side of the involved muscle when its iliocostal fibers are affected.

Sacroiliac and iliosacral movements should also be assessed in standing and seated positions.³⁷ It is important for the clinician to consider the use of the SIJ special tests cluster developed by Laslett et al.³⁸ These tests have high clinical utility in identifying the SIJ dysfunction. Clinically, however, in the presence of active TrPs in the quadratus lumborum muscle, these provocative tests may be false positive due to peripheral sensitization.

Strength of only the quadratus lumborum muscle is difficult to assess because of the parallel force generated by the lateral portions of the external and internal abdominal oblique muscles. Quadratus lumborum muscle strength may be tested using the side plank position. Figure 50-8A and B depicts two different positions to test the quadratus lumborum muscle. This test position allows the clinician to assess the patient's ability to utilize the quadratus lumborum muscle to stabilize the lumbar spine.

Figure 50-8. Quadratus lumborum muscle strength test using the side plank position. A and B, The knees are bent, giving the patient more stability. C and D, Legs and hips are straight, placing a greater demand on the quadratus lumborum muscle.

The quadratus lumborum muscle compensates for gluteus medius muscle weakness during gait, and therefore it is important to assess gluteal muscle strength in patients who exhibit quadratus lumborum TrPs or a Trendelenburg gait pattern. The muscle activation pattern and the position of the pelvis during side-lying hip abduction should be observed

(Figure 50-9A). Firm stabilization of the pelvis inhibits the quadratus lumborum muscle from compensating for a weak gluteus medius muscle as seen in Figure 50-9B.¹⁹

Figure 50-9. Side-lying hip abduction muscle activation pattern and strength test. A, Muscle activation pattern observing hip and pelvic motion. Note elevation of the left iliac crest as indicated by the solid white line demonstrating compensation by the quadratus lumborum muscle for inadequate strength or inhibition of the gluteus medius muscle. B, Stabilization of the pelvis to inhibit the quadratus lumborum muscle for accurate assessment of gluteus medius muscle inhibition or strength deficits. Note the change in the observed hip abduction range of motion.

Accessory joint motion should be tested in the lumbar spine, SI joint, and lower ribs as joint hypomobility is typically present with quadratus lumborum muscle dysfunction.

Lower rib mobility should also be assessed due to the attachment of the quadratus lumborum muscle on the lower ribs and its role in forced respiration such as coughing.

Raising the arm of the side to be examined onto the top of the table behind the head elevates the thoracic cage (Figure 50-10A). Dropping the knee of that side toward the examining table behind the other knee, pulls that side of the pelvis distally and lowers the iliac crest. This position creates adequate space for examining the muscle (Figure 50-10A) and adds the tension necessary for palpation. A bolster or towel roll positioned under the waist line may also be utilized to create more access to the quadratus lumborum muscle (Figure 50-10B). However, when the quadratus lumborum muscle is especially tight and tender, this position places the quadratus lumborum muscle under painful tension. The pelvis cannot pull away from the rib cage and the knee on the side being examined does not reach the table. The leg needs to be supported using a pillow placed between the legs or under the leg of the affected side (Figure 50-10A and B).

Figure 50-10. Patient positioning for examination of TrPs in the quadratus lumborum muscle. A, Partial opening of the space between the lowest ribs and ilium by having the patient reach overhead with the arm to elevate the rib cage. B, For some patients, especially women, full opening of the space may be provided by the addition of a supporting lumbar roll or pillow. This wider opening permits palpation of the quadratus lumborum muscle. C and D, The arrows indicate the direction in which pressure is applied to elicit spot tenderness. Downward pressure is exerted just above (adjacent to) the crest of the ilium and anterior to the long paraspinal muscle mass at the L4 level. E, To locate the deep, more cephalad TrPs, deep pressure is applied just caudal to the 12th rib and again anterior to the paraspinal muscles.

3.4. Trigger Point Examination

Trigger points in the quadratus lumborum muscle are common in patients reporting LBP, SI, or lateral proximal thigh pain.³⁶ For examination of TrPs in the quadratus lumborum muscle, positioning is extremely important. Unless the patient is properly positioned lying on the uninvolved side, the TrPs in this muscle are very difficult to palpate.^{39–41} The position that the patient ordinarily assumes in side-lying may not permit adequate palpation for deep tenderness of the quadratus lumborum muscle because of inadequate space between the 10th rib and the crest of the ilium.

One reason why TrPs in the quadratus lumborum muscle are so easily overlooked is the

location of the muscle, which lies anterior to the paraspinal muscle mass and is inaccessible from the posterior approach (Figure 50-11) of a routine back examination. Examination for quadratus lumborum TrPs begins by palpating for the lateral edge of the paraspinal mass, the 12th rib, and the crest of the ilium. In many patients, the only part of the latissimus dorsi muscle that overlies the quadratus lumborum muscle is its aponeurosis, which presents little obstruction to palpation. In some, however, a thick column of overlying fibers of the latissimus dorsi muscle extends to the crest of the ilium (Figure 50-11).

Figure 50-11. Serial cross sections of the quadratus lumborum muscle, dark red; other muscles, light red. Attachment of the muscle to the 12th rib is seen in the T12 and L1 sections; attachment to a transverse process is seen in the L2 section, and attachment to the ilium is seen in the L4 section. The next lower section (not included) would show only the iliolumbar ligament, and no quadratus lumborum muscle. The latissimus dorsi is one muscle usually interposed between the palpating finger and the quadratus lumborum muscle. Only at the L4 level is the muscle directly palpable beneath the skin. Adapted from Carter BL, Morehead, Wolpert SM, et al. *Cross-sectional Anatomy*. New York, NY: Appleton-Century Crofts; 1977:31-34.

Three regions in this muscle are examined for TrPs. The first region is deep at the angle where the crest of the ilium meets the paraspinal muscle mass (Figures 50-4 and 50-10C and D). As seen in Figures 50-4 and 50-11, this is the thickest part of the quadratus lumborum muscle, near the level of the L4 transverse process. This location is just cephalad to the point where many vertical iliocostal fibers and diagonal iliointertransverse fibers anchor by intertwining with fibers of the iliolumbar ligament. As shown in Figure 50-10C and D, the muscle is examined for tenderness by applying deep pressure superior to the crest of the ilium and anterior to the paraspinal muscles. The pressure is directed toward the tips of the lumbar transverse processes. One should press gently at first because remarkably little pressure on these TrPs can be exquisitely painful. Here, pressure is applied primarily to the diagonal lower iliointertransverse fibers of the quadratus lumborum muscle. These fibers are too deep for one to feel their taut bands or to elicit local twitch responses manually.

The second region examined for quadratus lumborum TrPs extends along the inner crest of the ilium where many of the iliocostal fibers attach. The tip of the finger is applied across the direction of the fibers shown in Figure 50-4. This cross-fiber flat palpation locates taut bands with tender spots in those fibers (Figure 50-10E). Local twitch responses are rarely visible unless the individual is thin and has few latissimus dorsi fibers extending this far.

If one progresses too far laterally, the fingers encounter the lateral border of the external abdominal oblique muscle; these fibers run nearly parallel to the lateral iliocostal fibers of the quadratus lumborum muscle. The external abdominal oblique fibers may have taut bands and TrPs that can easily be mistakenly ascribed to the quadratus lumborum muscle (Figure 50-4). Taut bands of the external abdominal oblique muscle angle from the tip of the 12th rib down and forward to the anterior aspect of the crest of the ilium (see Figure 49-1A).⁴² The adjacent quadratus lumborum fibers are nearly parallel but are usually at an angle from the middle and posterior portions of the 12th rib to the posterior aspect of the crest of the ilium.

The third region lies in the angle where the paraspinal muscle mass and the 12th rib meet. As seen in Figures 50-2, 50-4, and 50-11, deep fingertip pressure applied in the direction of the L1-L2 transverse processes transmits pressure to the cephalad attachment of the iliocostal and costotransverse fibers of the quadratus lumborum muscle. In some patients, the attachments of the iliocostal fibers extend laterally far enough along the 12th

rib to be felt by cross-fiber flat palpation in a manner similar to that described for the second region above. With the patient in the position shown in Figure 50-10C to E one can also apply pressure caudad to L2 seeking tenderness over the L3 transverse process between regions one and three. Only tenderness is elicited because these fibers are too deep to permit palpation of taut bands.

With sustained pressure on any one of these TrPs, one may elicit its pattern of referred pain, although penetration of the TrP with a needle is a more reliable way of eliciting pain referred by TrPs in this muscle.

4. DIFFERENTIAL DIAGNOSIS

4.1. Activation and Perpetuation of Trigger Points

Any posture or activity that activates a TrP, if not corrected, can also perpetuate it. In any part of the quadratus lumborum muscle, TrPs may be activated by unaccustomed eccentric loading, eccentric exercise in unconditioned muscle, or maximal or submaximal concentric loading.⁴³ Trigger points may also be activated or aggravated when the muscle is placed in a shortened or lengthened position for an extended period of time.

Quadratus lumborum TrPs can be activated acutely by awkward lifting of an unusually heavy load such as a TV set, a child, or a large dog or by a quick bending movement when the torso is twisted or turned somewhat to one side, often to reach for an object on the floor.³¹ Another version of the latter stress is that of angling sideways while bending forward to rise from a deep-seated chair, a low bed, or a car seat. Many patients report the onset of pain when putting on pants while standing half stooped and leaning sideways or after losing balance as the feet become entangled in the clothing.

The quadratus lumborum muscle often develops TrPs from an auto accident. Baker⁴⁴ investigated the occurrence of TrPs in 34 muscles of 100 occupants (drivers and passengers) who sustained a single motor vehicle impact. The quadratus lumborum muscle was involved more frequently than any other muscle in impacts from the driver's side (81% of subjects) and in impacts from behind (79% of subjects). It was the second most commonly injured muscle (81%) when the impact was from the front and the third most common (63%) when the impact was on the passenger's side. In this study,⁴⁴ no distinction could be made between preexisting TrPs that were activated by the accident and TrPs that were initiated by this gross trauma.

Quadratus lumborum TrPs can also be activated by obscure, sustained, or repetitive strain (microtrauma) from activities such as gardening, scrubbing the floor, lifting cement blocks,²⁵ or by walking or jogging on a slanted surface, as on a beach or along a crowned road. In addition, when one quadratus lumborum muscle becomes involved, the shortening of that muscle at rest tends to overload its contralateral mate and usually results in the development of TrPs in this antagonist but with pain of less intensity.

The introduction of a walking cast or boot can activate quadratus lumborum TrPs, as has been demonstrated experimentally.³² When quadratus lumborum pain appears

immediately after an ankle fracture that required application of a walking cast, the TrP was probably activated by the strain of the fall that also caused the fracture; whereas, if the muscle pain appears a week or two after the application of the cast, the chronic strain of the newly imposed leg length discrepancy most likely activated the TrPs. This pain is relieved (or prevented) by wearing (on the contralateral foot) a shoe with sufficient lift to match the length of the immobilized lower extremity.

Mechanical factors that predispose to the activation of quadratus lumborum TrPs or that perpetuate those TrPs are: a leg length discrepancy,³¹ a small hemipelvis,³¹ short upper arms,⁴² a soft bed with a hammock-like sag, leaning forward with poor elbow support over a desk (frequently caused by wearing eyeglasses with too short a focal length), standing and leaning over a low sink or work surface, and deconditioned or weak abdominal muscles.

The relative importance of a leg length discrepancy and of a small hemipelvis as perpetuating factors in LBP of quadratus lumborum muscle origin is often revealed by a patient's relative tolerance to standing versus sitting and by the way he or she stands. When the patient stands with one foot forward, weight on the other foot (shorter side), or stands with feet wide apart and the pelvis shifted to one side (shorter side), and has pain when standing and walking, the problem is probably due to a leg length discrepancy. When only sitting aggravates the pain, either short upper arms or a small hemipelvis is more likely to be the culprit. When symptoms are present in both positions, a patient may have both a small hemipelvis and a leg length discrepancy on the same side; that is, one side of the body is smaller.

4.2. Associated Trigger Points

It has been shown that associated TrPs can develop in the referred pain areas caused by primary TrPs.⁴⁵ Therefore, muscles in the referred pain areas for each muscle should also be considered. Clinically, the muscles most likely to develop associated TrPs due to TrPs in the quadratus lumborum muscle are the contralateral quadratus lumborum, ipsilateral iliopsoas, iliocostalis between T11 and L3, longissimus, piriformis, superficial and deep multifidus,³⁶ external oblique, and, occasionally, latissimus dorsi muscles.

The two quadratus lumborum muscles work as a team bilaterally to stabilize the lumbar spine, which explains why TrPs on one side are frequently associated with less active TrPs in the quadratus lumborum muscle on the opposite side. The psoas major and lumbar paraspinal muscles help the quadratus lumborum muscle to stabilize the lumbar spine. Both the quadratus lumborum and lumbar paraspinal muscles are spinal extensors. The posterior fibers of the external oblique muscle are nearly parallel to the iliocostal quadratus lumborum fibers, have similar attachments to the rib cage and pelvis, and also are likely to have TrPs if the quadratus lumborum muscle does. In patients with nonspecific LBP in addition to TrPs in the quadratus lumborum muscle, other back muscles, such as the longissimus thoracis and multifidi muscles, can also project pain to the low back, buttock, and SIJ.⁴² Iliopsoas TrPs²⁹ refer LBP that patients describe as radiating unilaterally up and down along the lumbosacral spine rather than horizontally across the back. The TrPs in the

lower rectus abdominis muscle⁴² refer bilateral LBP, which is described as traveling horizontally at the level of the SIJs. Pain from these other TrPs should be distinguished from quadratus lumborum TrP pain by the history, pain pattern, motions that are restricted and by physical examination and palpation of the muscles.

The gluteus medius and gluteus minimus muscles commonly develop associated TrPs because they lie in the referred pain zones of the quadratus lumborum muscle. Patients sometimes report pain in the reference zones of the gluteus medius and minimus muscles in response to pressure on quadratus lumborum TrPs. With inactivation of the gluteal TrPs, pressure on the quadratus lumborum TrP then refers pain only to its characteristic gluteal and pelvic distribution.

Roach et al⁴⁶ examined the prevalence of TrPs in the gluteus medius and quadratus lumborum muscles in patients with patellofemoral pain syndrome (PFPS) in a randomized controlled study with 26 patients with PFPS and 26 matched controls with no history of PFPS. The prevalence of TrPs in the gluteus medius and quadratus lumborum muscles was significantly higher in the PFPS group than in the control group. The prevalence of unilateral TrPs in the quadratus lumborum muscle on the opposite side to the PFPS was 93%. Eighty percent of patients with PFPS had TrPs in the quadratus lumborum muscle bilaterally, whereas the control group had 35% unilaterally and 15% bilaterally. All patients in the PFPS group had at least one quadratus lumborum TrP. They also found a significant decrease in force production in hip abduction strength in the PFPS group as compared with controls. Following one treatment session with pressure release techniques there was no improvement in force production in hip abduction.

Conversely, TrPs can develop in the quadratus lumborum muscle as a consequence of TrPs in other muscles. Jull and Janda⁴⁷(pp253-278) noted that the quadratus lumborum muscle is subject to overload when used to substitute for weak hip abductor muscles in walking. Trigger points in the gluteus medius and gluteus minimus muscles are one of many causes of such weakness.

Lewit⁴⁸ related hypomobility at the thoracolumbar junction to TrPs in the iliopsoas, erector spinae, quadratus lumborum, and abdominal muscles. The importance of articular dysfunction as a perpetuating factor for TrPs in these muscles is relatively unexplored and promises to be a fertile area for investigation. However, TrP tension in these muscles can reinforce hypomobility at the thoracolumbar junction.

4.3. Associated Pathology

Differential diagnosis of symptoms caused by TrPs in the quadratus lumborum muscle primarily consists of SIJ dysfunction, trochanteric bursitis, sciatica, spinal stenosis, thoracolumbar (facet joint) articular dysfunction, and lumbar disc derangement. Thoracolumbar articular dysfunction characteristically causes asymmetrical restriction of rotation, side-bending, flexion, or sometimes extension of the thoracolumbar region. Involvement of the quadratus lumborum muscle alone can restrict primarily side-bending away from the involved side, as well as rotation and flexion of the lumbar spine.

In acute LBP with or without radicular symptoms, active TrPs in the quadratus lumborum muscle may present as a flattened lumbar lordosis and/or a lateral shift consistent with the presentation of an acute disc derangement.

Additional diagnoses to consider include spinal tumors; myasthenia gravis; gallstones and liver disease; kidney stones and other urinary tract problems; intra-abdominal infections; intestinal parasites and diverticulitis; abdominal aortic aneurysm; and multiple sclerosis.

5. CORRECTIVE ACTIONS

When major weight-bearing and postural muscles develop TrPs, patients should be instructed in techniques to address the source of symptoms and contributing factors. Often, patients would need to learn to perform their usual activities in a manner that does not stress the implicated muscle. Sleeping conditions such as the mattress and sleeping position can have a profound influence on quadratus lumborum TrPs. A sagging, hammock-like, mattress puts the quadratus lumborum muscle in the shortened position when one lies on the opposite side. If the patient's mattress is too soft or older than 10 years, the patient should consider investing in a new mattress. Sleeping flat on the back with knees straight places the quadratus lumborum muscle in a relatively shortened position by causing the pelvis to tilt forward and lumbar lordosis to increase. This position can be avoided by placing a small pillow or other support under the knees or by sleeping on one side with proper support of the lumbar spine and lower extremities (Figure 50-12A and B). With a pillow placed appropriately, the lumbar spine can retain its normal curvature, protecting both the quadratus lumborum muscle and the lumbar discs. (If the patient's problem is one of a posterior disc derangement, the preferred position is prone.) The patient with a persistent quadratus lumborum muscle problem needs to learn how to slide and roll the hips rather than to lift them when turning over in bed at night.

Figure 50-12. Proper sleeping position. A, The patient's uppermost hip is in slight flexion with a pillow between the knees to keep the pelvis level and lumbar spine in a neutral position. A pillow is also placed under the upper most arm and in front of the trunk to reduce rotation. B, Patient is positioned as previously described in A; however, a towel roll is placed under the waist (arrow) to keep the lumbar spine in a neutral position. Note the increased support between the patient's knees to keep the pelvis in a neutral position.

The combined flexion–rotation movement of bending forward and sideways to lift or pull something should be avoided. This is a hazardous maneuver for anyone but especially for the person with quadratus lumborum TrPs. One should turn the entire body to face the task squarely and then perform a pure flexion–extension movement without twisting the trunk. When turning to reach behind, the patient should learn to keep the back erect, avoiding any trunk flexion during rotation.

Sustained flexion and forceful extension of the spine should be avoided. If the lower limb muscles and knees are free of problems, one can lift objects from the floor by bending the knees while keeping the torso erect. Unfortunately, people find this movement difficult; not only does it require additional efforts to lift the entire torso and hip region instead of

only the head, neck, and shoulders, but it also throws the load on the quadriceps femoris muscles, which, in this position, are at a mechanical disadvantage.⁴⁹

Learning to avoid unnecessary bending can play a critical role. The importance may not be so much in what is done, but in how it is done. One learns to make up a low bed while kneeling, rather than standing and bending over to reach the bed. Brushing the teeth is done while standing up straight and avoiding leaning over the sink, except to clear the mouth, while supporting the body weight with the free hand or by placing one foot in the vanity shelf or on a stool under the sink if available.

The muscular strain of a near fall, or injury from a fall, is avoided by sitting down to put on socks, pantyhose, skirt or trousers, and so on or by leaning against a wall or heavy furniture so that balance is assured.

A common example of unnecessary forward leaning is the usual way of rising from a chair without arm support (Figure 50-13). When rising with the buttocks at the rear of the chair seat, the body is pitched forward in a stooped position to place the center of gravity over the feet. This heavily loads the extensor muscles of the back as the person straightens up.

Figure 50-13. The sit-to-stand and stand-to-sit techniques minimize strain on the neck and back muscles and on the intervertebral discs. Start position while seated in a chair, the patient should move the buttocks to the front of the seat and then turn the body to a 45° angle. This positioning permits the spine to stay erect with a neutral lumbar lordosis between sitting to standing. The reverse, stand-to-sit technique, is accomplished by first turning the body, by keeping the trunk erect, if needed using the hands on the thighs to support the trunk while sitting down on the front of the seat, and then sliding the buttocks backward, still keeping the spine erect.

The correct manner of rising from a chair order to spare the back muscles is shown in Figure 50-13. The buttocks are first slid forward to the front of the seat; then, the body is turned sideways about 45° and one foot is placed under the front edge of the seat and under the center of gravity of the body. The body is then lifted with the torso held erect such that the load is placed mainly on the quadriceps femoris muscles. A push by the hands against

the thighs assists the lift if the quadriceps muscles are weak. To return to the seated position, the sequence is reversed with the use of the hands on the thighs to lower to the chair.

The patient may inactivate quadratus lumborum TrPs with the application of TrP self-pressure release by utilizing TrP release tools or a tennis ball. Utilizing a TrP release tool, the patient can lie on their back placing the end of the tool on the muscle and the tool across the body. On the tool, both hands are utilized to provide pressure over the tender area for 15 to 20 seconds and repeat up to six times (Figure 50-14A). The patient can also perform a similar technique in the seated position (Figure 50-14B). Another option is standing against the wall with a TrP release tool or a tennis ball using the same principles above (Figure 50-14C).

Figure 50-14. Trigger point self-pressure release using TrP release tools. A, Supine. B, Seated. C, Standing.

The quadratus lumborum supine self-stretch exercise (Figure 50-15) is most effective for the diagonal iliotransverse fibers of that muscle. The exercise begins in the supine position with the hips and knees flexed (Figure 50-15A). The thigh on the side of the quadratus lumborum muscle to be stretched is adducted to the point of taking up all the slack in the muscle and the other leg is crossed over the thigh to provide overpressure (Figure 50-15B). The patient then relaxes to allow the pelvis on the involved side to drop down toward the table. With a slow inhalation, the quadratus lumborum muscle contracts isometrically, creating tension. The patient can slowly and gradually stretch the quadratus lumborum muscle by providing a gentle overpressure with the other limb. During slow exhalation, the patient concentrates on relaxing the muscles to be elongated and the uppermost limb helps pull the pelvis caudally by further adducting the thigh on the treatment side to take up all slack that develops (Figure 50-16C). Contraction and relaxation are repeated slowly three to five times until no additional range of motion is

achieved. Then, the patient slips the uppermost, assisting limb off the treated limb to help in pushing the latter back to the neutral position. This maneuver avoids overloading the elongated muscles while still under full stretch (a position of vulnerability).

Figure 50-15. Supine self-stretch exercise for the left quadratus lumborum muscle. A, Starting position, supine with the hips and knees bent. B, Preparatory position with the controlling right leg crossed over the left thigh. C, The patient takes a deep breath that contracts the quadratus lumborum muscle and as the patient slowly exhales, the right leg gently pulls the left thigh downward, which rotates the pelvis. Large arrow indicates the direction of applied pressure. Small arrow indicates the pelvic rotation. Steps B and C may be repeated until no further increase in range of motion is achieved. Release the stretch by slipping the controlling (right) leg off the left knee, releasing tension, and assisting the left leg back to the starting position.

Figure 50-16. Self-stretch of the right quadratus lumborum muscle in the quadruped position (“on all fours”). A, Starting position. B, Preparatory position with the arm forward and across the midline of the body. C, Full stretch with arrows emphasizing the option of

reaching the arm forward and pushing the hips down and back to elongate the trunk, further stretching the quadratus lumborum muscle.

The same principle applies to walking upstairs or climbing a ladder. If the body is turned 45° to one side, it is much easier to keep the back straight while ascending or descending.

Patients who enjoy gardening activities should sit on a low box or other seat that is 8 to 10 inches high while transplanting and weeding. This low-seated position helps them avoid bending over. In the house, small objects need to be placed on a chair or table rather than on the floor.

Any problem in foot mechanics, such as pronation of the foot and ankle, that produces an asymmetrical gait pattern may contribute to selective muscular overload,⁵⁰ including the overuse of the quadratus lumborum muscle. Appropriate corrective shoes or shoe inserts are indicated in these cases.

Asymmetries that produce a painful functional (compensatory) scoliosis that depend on muscular contraction to be maintained should be corrected in patients with a persistent quadratus lumborum myofascial pain syndrome. If appropriate examination has identified a pelvic asymmetry, an effort should be made to level the sacral base. Any existing lower extremity dysfunction, as well as any pelvic torsion and lumbar joint dysfunction, should be corrected to ensure that treatment of quadratus lumborum TrPs last.

An alternative stretch position for a patient with highly irritable quadratus lumborum TrPs is in the quadruped (“on all fours”) position (Figure 50-16A). The arm on the side to be stretched is placed forward and across the midline of the body (Figure 50-16B). The patient shifts the buttocks backward and down toward the heels while keeping the arm across the midline of the body (Figure 50-16C). This position is commonly referred to as the prayer stretch or child’s pose position with the modification of the arm placed forward and across the body instead of straight ahead.

Psoas Major, Psoas Minor, and Iliacus Muscles

“Hidden Pranksters”

Jennifer Marie Nelson and Michelle Finnegan

1. INTRODUCTION

The iliopsoas muscles are functionally important in both the trunk and the lower extremity. The psoas major muscle is divided into an anterior and posterior mass and lies on each side of the vertebral column. The anterior mass of the psoas major muscle has two different sets of attachments. The first part consists of five digitations of muscle that attach to the bodies of two adjoining vertebrae and the associated intervertebral disc. The second part is a series of tendinous arches that extend across the narrow portions of the bodies of all five lumbar vertebrae between the digitations of the first part. Distally, this muscle is joined by the iliacus on its way to attach to the lesser trochanter of the femur. The psoas minor muscle arises from the sides of the bodies of the T12 and L1 vertebrae and the disc in between, and it inserts onto the pectin pubis, the iliopubic ramus, and iliac fascia. The iliacus muscle originates from the upper two-thirds of the inner surface of the iliac fossa, inner lip of the iliac crest, the iliolumbar and ventral sacroiliac ligaments, and the upper surface of the lateral portion of the sacrum. In addition to attaching to the lesser trochanter of the femur with the psoas major muscle, some fibers also attach to the femur inferior and anterior to the lesser trochanter. The psoas major muscle is innervated by the ventral rami mainly of L1 and L2, with some contribution from L3, whereas the psoas minor muscle is innervated by a branch of the first lumbar spinal nerve. The iliacus muscle is innervated by branches of the femoral nerve from L2 and L3. The primary function of the psoas and iliacus muscles is hip flexion. The psoas major and minor muscles also play a role in trunk stability. Trigger points (TrPs) in the iliopsoas muscles refer pain into the low back, anterior hip, groin, and anterior lateral thigh. Differential diagnosis includes lumbar disc pathology, hematoma, bursitis, femoral acetabular impingement, pelvic pain, malignant tumors, abscess, sports hernias, and nerve entrapments. Corrective actions include appropriate sleeping and sitting postures, stretching, and diaphragmatic breathing.

2. ANATOMIC CONSIDERATIONS

Psoas Major

The psoas major muscle (Figure 51-1) is a long muscle that is divided into an anterior and posterior mass and lies on each side of the lumbar vertebral column and the pelvic brim.^{1,2} The posterior mass of the psoas major muscle attaches to the anterior surface of all lumbar vertebrae as well as the lower borders of the transverse processes.^{1,2} The anterior mass of the psoas major muscle has two different sets of attachments.¹ The first part is comprised of five digitations of muscle that attach to the bodies of two adjoining vertebrae and the associated intervertebral disc. The highest portion attaches at the T12-L1 segment and the lowest at the L4-L5 segment. The second part is a series of tendinous arches that extend across the narrow portions of the bodies of all five lumbar vertebrae between the digitations of the first part. Here, the roots of the lumbar plexus are lodged within the psoas major muscle, with branches of the plexus emerging from the surface and the borders of the muscle.

Figure 51-1. Attachments of the right psoas major, psoas minor, and iliacus muscles (red). The psoas major muscle crosses many articulations including those of the lumbar spine and the lumbosacral, sacroiliac, and hip joints. The psoas minor muscle does the same, except that it does *not* cross the hip joint. The iliacus muscle, however, crosses only the hip joint.

Fibers of the psoas major muscle are systematically overlapped by fibers from the above attachments at successively higher segmental levels. As a result, the muscle is layered with fibers from the higher levels forming the outer surface of the muscle and those of the lower levels buried sequentially more deeply within its substance.^{3,4} Fibers in the posterior portion are 3 to 5 cm long, and fibers in the anterior portion are 3 to 8 cm long.²

As the muscle continues to descend along the pelvic brim, it passes anterior to the sacroiliac joint and is joined by the iliacus muscle. Together, both muscles (together forming the iliopsoas muscle complex) travel posterior to the inguinal ligament, helping to form the floor of the femoral triangle. They then travel anterior to the hip joint capsule and attach onto the lesser trochanter of the femur.¹

The thickness of the psoas major muscle is reported to vary among different races. Hanson et al⁵ examined 21 cadavers that were black and 23 cadavers that were white and found the muscle was approximately twice as thick in black cadavers.

The iliopsoas bursa is a structure that lies beneath the iliopsoas muscle and anterior to the hip joint capsule in 98% of normal individuals. In a small percentage of the population (15%), the bursa can communicate with the hip joint because the tissues between them can be thin and weak.⁶

Early studies on the composition of muscle fiber type of the psoas major muscle suggested a predominance of type I fibers⁷⁻⁹ or an equal amount of both type I and II fibers.¹⁰ More recently, Arbanas et al¹¹ found the psoas major muscle to be composed of type I, IIa, and IIx muscles fibers, with type IIa being the most prevalent (49.77%). Type I fibers were the second most common (40.15%) followed by type IIx (10.8%). This data supports the concept of a dynamic function of the muscle. Interestingly, the composition of the fibers were found to change throughout the muscle. The percentage of type IIa and IIx fibers increased from L1 to L4, whereas the percentage of type I fibers decreased from L1 to L4. In light of these trends, it is hypothesized that the cranial portion of the muscle has a more static role (due to a higher percentage of type I fibers) and caudal portion of the muscle has a more dynamic role (due to a higher percentage of type II fibers).

The psoas major muscle also has significant fascial attachments. Superiorly, the psoas fascia forms part of the medial arcuate ligament. Laterally, it blends with the fascia of the upper portion of the quadratus lumborum muscle. More caudally, it continues with the iliac fascia, where it separates the anterior mass of the psoas major muscle from the retroperitoneal structures. The iliac fascia is indistinguishable and continues with the psoas fascia. In the upper retroperitoneum, the fascial blends with the anterior layer of the thoracolumbar fascia over the quadratus lumborum muscle. Caudally, it attaches to the inner aspect of the iliac crest and to the periosteum of the ilium at the pelvic brim.¹

Psoas Minor

The psoas minor muscle, when present, lies anterior to the psoas major muscle in the lumbar region. It arises from the sides of the bodies of the T12 and L1 vertebrae and the discs between. It has a long flat tendon that inserts onto the pectin pubis, iliopubic ramus,

and iliac fascia. The entire muscle is contained within the abdomen and does not attach to the lower extremity.¹ Neumann and Garceau¹² reported that this muscle attached firmly into the iliac fascia in all cadaver hips studied, whereas 90.5% also had a firm bony attachment to the pelvis.

The psoas minor muscle is absent in approximately 40% of people¹; however, these percentages vary among studies. Maldonado et al¹³ reported the psoas minor tendon as absent in 64.7% of unembalmed female cadavers, whereas Neumann and Garceau¹² reported this muscle being absent in 34.4% of cadavers examined. Hanson et al⁵ found notable differences in the absence of the psoas minor muscle between races. They found the psoas minor muscle was absent in 91% of black cadavers and 13% of white ones.

Iliacus Muscle

The iliacus muscle originates from the upper two-thirds of the inner surface of the iliac fossa, inner lip of the iliac crest, the iliolumbar and ventral sacroiliac ligaments, and the upper surface of the lateral portion of the sacrum. It travels anteriorly as far as the anterior superior and anterior inferior iliac spines. Most of the fibers of the iliacus muscle join the psoas major tendon, and together they insert onto the lesser trochanter of the femur. Other fibers attach to the femur anterior to the lesser trochanter, including fibers from the upper portion of the hip joint capsule.¹

Anatomic variations have been reported in the iliacus muscle. D'Costa et al¹⁴ reported a case of an accessory iliacus muscle, covered by a separate fascia, which attached at the middle third of the iliac crest and inserted on the lesser trochanter of the femur with the iliopsoas tendon. Rao et al¹⁵ reported a case of variation in the iliacus muscle bilaterally. On one side, there were two defined variant muscles, an iliacus minimus and an accessory slip of the iliacus muscle. On the other side, there was a single additional slip of the iliacus muscle that fused with the iliopsoas tendon distally. Fabrizio¹⁶ reported a unique variation of the iliacus muscle that originated from the superolateral aspect of the iliac fascia and traveled nearly horizontal to insert into the psoas major muscle, forming a blended iliacus–psoas muscle. Another unique variation of the iliacus muscle, reported by Aleksandrova et al,¹⁷ described slips missing from the middle and anterior parts of the muscle (due to not developing), and the posterior portion of the muscle originated unusually high from the iliolumbar ligament.

There are also reported variations of the iliopsoas tendon at the level of the hip joint. Philippon et al¹⁸ examined 52 cadavers and found more than one tendon present. In only 28% of cadavers were the tendons single-banded. More commonly (64.2%), they were double-banded and there was a small group (7.5%) that were triple-banded.

2.1. Innervation and Vascularization

Innervation of the psoas major muscle is mainly supplied by the ventral rami of L1 and L2, with some contribution from L3.¹ Other variations have been reported. Gibbons et al²

found through dissection that the posterior fibers of the psoas major muscle were innervated by the ventral rami of spinal nerves T12-L4, whereas the anterior fibers were supplied by branches of the femoral nerve from L2-L4. The lumbar plexus is embedded posteriorly in the substance of the psoas major muscle.¹ Similarly, Kirchmair et al¹⁹ reported that of the 32 embalmed cadavers they dissected, the lumbar plexus was contained in the psoas major muscle in 96.8% of cadavers; however, in 3.2% of the cadavers, the plexus was posterior to the psoas major muscle.

The psoas minor muscle is innervated by a branch of the first lumbar spinal nerve.¹

The iliacus muscle is innervated by branches of the femoral nerve, L2 and L3.¹ When an accessory iliacus muscle is present, the L4 root of the femoral nerve innervates it.¹⁴

The vascular supply of the psoas major muscle occurs via several arteries. The lumbar arteries supply the upper portion of the muscle, whereas the anterior branch of the iliolumbar artery supplies the mid portion of the muscle with contributions from the deep circumflex and external iliac arteries. The femoral artery and its branches supply the distal portion of the muscle.¹

Vascularization of the psoas minor muscle is mainly supplied through the lumbar arteries; however, there could be additional contributions from the arteries that also supply the psoas major muscle.¹

The primary vascular supply of the iliacus muscle is from the iliac branches of the iliolumbar artery, with additional contributions from the deep circumflex iliac and obturator arteries as well as some branches of the femoral artery.¹

2.2. Function

Hip Flexion and Stability

The primary function of the psoas major muscle is flexion of the hip.^{1,4,20–26} Interestingly, Yoshio et al²⁷ found that only when the hip was flexed from 45° to 60°, the psoas muscle functioned as a hip flexor.

There is more recent evidence that the psoas major muscle also has a stabilizing function. Yoshio et al²⁷ analyzed the function of the psoas major muscle using cadavers. They found that when the hip was flexed 0° to 15°, one primary function was to stabilize the femoral head in the acetabulum during hip flexion, another was to maintain an upright position of the lumbar column (discussed further below).

Hip Internal and External Rotation

Contradictory evidence exists exploring the psoas major muscle's ability to externally rotate the hip. Electrophysiologic studies revealed that neither the iliacus nor the psoas muscles are activated during the internal rotation of the hip, but both muscles were often active during external rotation.^{28,29} Electrical stimulation of either muscle with the subject in a standing or a supine position produces a slight external rotation.³⁰ Skyrme et al²⁶ found

that in six cadaveric specimens, hip external rotation was produced only when traction to the iliopsoas was performed with the hip in abduction. Contrary to these studies, Hooper³¹ reported that the iliopsoas muscle does not play a significant role in rotation of the normal femur because its tendon is aligned with the axis of rotation in most cases. There is no contemporary electromyographic (EMG) research to support the iliopsoas muscles performing either hip internal or external rotation in adults.¹

Trunk Movement and Stability

When present, the psoas minor muscle is most likely a weak flexor of the trunk.¹ In a recent cadaveric study, Neumann and Garceau¹² reported that due to the muscle's attachment to the iliac fascia, the psoas minor muscle might partially contribute to control of the position and mechanical stability of the iliopsoas muscles as they cross the femoral head.

The psoas major and iliacus muscles, when acting from below and contracting bilaterally, are able to bend the trunk and pelvis forward against resistance, as when performing a sit-up.¹ Historical studies agree that, after the first 30° of upward movement of a sit-up, the iliacus muscle is vigorously active.^{28, 32, 33} LaBan et al³³ saw no activity in five subjects through the first 30° when the legs were straight but did observe activity when the knees were bent. Flint³² found mild to moderate activity in three subjects throughout that 30° angle. Interestingly, some individuals depend on the rectus femoris muscle without help from the iliacus muscle, while other individuals use both muscles, when initiating a sit-up. More recent studies of the psoas major muscle, using magnetic resonance diffusion weighted images³⁴ and EMG,²³ showed that the psoas major muscle is more active in full sit-ups than in curl-ups, but they have not looked at the exact degrees at which the psoas major muscle initiates activation.

Earlier,⁴ it was thought that the psoas major muscle was able to produce a small net extensor torque on the three upper lumbar vertebrae, whereas on the lower two vertebrae, the muscle was able to produce a small net flexor torque. More recently, Park et al³⁵ reported that differences in function exist between two portions of the muscle—the fascicles that arise from the transverse processes and those from the vertebral bodies, not from the higher against the lower levels. The activity of the fascicles of the psoas major muscle that attach to the transverse processes were greater in extension of the trunk against trunk flexion or hip flexion to 90°. The fascicles from the portion of the psoas major muscle attaching to the vertebral bodies had greater activity in hip flexion than flexion of the trunk.

There is growing evidence that the psoas major muscle has a role in stabilization of the trunk. This function stems, in part, from its attachments to the diaphragm and pelvic floor musculature.^{2, 36}

The role of the psoas major muscle in spinal stability seems to vary on the activity being examined as well as the study setup. Yoshio et al²⁷ found that the psoas major muscle acts primarily as a spinal stabilizer when the hip is flexed 0° to 45°. Hu et al²⁰ utilized EMGs to

assess activity of the right psoas major, iliacus, rectus femoris, and adductor longus muscles during an active straight leg raise. Interestingly, the iliacus, rectus femoris, and adductor longus muscles activated ipsilaterally before the psoas major muscle. The psoas major muscle activated ipsilaterally and contralaterally at the same time with no difference in amplitude from side to side, supporting the theory that the psoas major muscle acts primarily as a stabilizer.

In sitting, the psoas major muscle acts to balance the trunk.¹ Andersson et al³⁷ reported that the psoas major muscle was active in sitting with a straight back and when stabilization of the spine in the frontal plane was needed. Similarly, Santaguida and McGill²⁵ agree that the psoas major muscle is capable of stabilization through bilateral activation. They also reported that changes in lordosis did not have an effect on the mechanical action of the psoas major muscle. This second finding of Santaguida and McGill²⁵ is not consistent, with recent research. Park et al³⁵ found that the fascicles of the psoas major muscle that attached to the transverse processes were more active when subjects were in a short lordosis than a flat spine. These fascicles, along with those that attach to the vertebral column, were both active with a flat spine compared with a slumped posture.

2.3. Functional Unit

The functional unit to which a muscle belongs includes the muscles that reinforce and counter its actions as well as the joints that the muscle crosses. The functional interdependence of these structures is reflected in the organization and neural connections of the sensory motor cortex. The functional unit is emphasized because the presence of a TrP in one muscle of the unit increases the likelihood that the other muscles of the unit also develop TrPs. When inactivating TrPs in a muscle, one should be concerned about TrPs that may develop in muscles that are functionally interdependent. Box 51-1 grossly represents the functional unit of the iliopsoas muscle.³⁸

Box 51-1 Functional unit of the iliopsoas muscles

Action	Synergists	Antagonist
Hip flexion	Rectus femoris Pectineus Sartorius Tensor fasciae latae Gracilis Adductor longus Adductor brevis Adductor magnus (middle portion)	Gluteus maximus Gluteus medius (posterior fibers) Semimembranosus Semitendinosus Biceps femoris

Bilaterally, the iliopsoas muscles work to synchronize their activity for functions such as stability of the spine and alternate their activity for functions such as locomotion. As part of the abdominal cylinder, the psoas muscle is also synergistic with the diaphragm, pelvic floor, transversus abdominis, and lumbar multifidus muscles.

During a sit-up, agonists to the psoas major muscle include the rectus abdominus and psoas minor muscles. If the psoas major muscle does provide an anterior shear on the lower lumbar segments, as Hadjipavlou et al³⁹ and Bogduk et al⁴ suggest, then the iliolumbar ligament is ideally situated to provide a counterforce.

3. CLINICAL PRESENTATION

3.1. Referred Pain Pattern

Pain referred from TrPs in the iliopsoas muscles forms a distinctive vertical pattern ipsilaterally along the lumbar spine. It has been reported to extend as high as the interscapular region.⁴⁰ It extends downward to the sacroiliac region and may continue inferiorly to include the sacrum and proximal medial buttock (Figure 51-2).⁴¹ The referred pain pattern also frequently includes the groin and upper anteromedial aspect of the thigh on the same side. Palpation of TrPs near the attachment of the iliopsoas muscles (mostly iliacus fibers) on the lesser trochanter of the femur may refer pain both to the back and anteriorly to the thigh.

Figure 51-2. Pattern of pain (bright red) referred from palpable myofascial TrPs in the right

iliopsoas muscle (darker red). The essential pain reference zone is solid red; the spillover pattern is stippled.

Less frequently, other referred pain patterns have been reported. Stretching the iliopsoas muscles was shown to intensify pain in the scrotum.⁴² Pain referral to the medial knee has been reported in the literature⁴³ and seen several times in clinical practice. The psoas major muscle has also been seen to refer pain into the lower abdomen.

3.2. Symptoms

Patients with unilateral iliopsoas TrPs usually report having vertical low back pain. They frequently run their hand vertically up and down the spine rather than horizontally to demonstrate the location of their pain. When the iliopsoas muscles are involved bilaterally, the patient may perceive the pain as running across the low back, similar to having TrPs in the quadratus lumborum muscle bilaterally. Pain is worse when the patient stands upright but may present as a nagging backache even when recumbent. A frequent additional report is pain in the front of the thigh. Ingber⁴² found that patients experienced increased low back pain during antigravity activity and alleviation of the pain when recumbent. The most comfortable recumbent positions were side-lying in a nearly fetal position or lying supine with hips and knees flexed. Patients are likely to have difficulty getting up from a deep-seated chair and are unable to do sit-ups.

Patient's with constipation who also have psoas TrPs may experience referred pain evoked by the passage of a bolus of hard feces that presses against the TrPs. A hypertrophied psoas muscle can compress the neighboring large bowel.⁴⁴ Tarsuslu et al⁴⁵ utilized iliopsoas muscle release along with sphincter release and bowel mobilizations as an osteopathic treatment technique for chronic constipation in children with cerebral palsy. This intervention was as effective as those who had regular medical care and osteopathic treatment.

3.3. Patient Examination

After a thorough subjective examination the clinician should make a detailed drawing representing the pain pattern that the patient has described. This depiction will assist in planning the physical examination and can be useful in monitoring the progression of the patient as symptoms improve or change. For proper examination of the iliopsoas muscles, the clinician should first start with the observation of the posture in standing. The patient with involvement of the iliopsoas muscle unilaterally demonstrates weight shifting away from the involved side, with the foot of the involved side slightly forward and the torso slightly side bent toward the involved side. Active forward bending of the trunk may reveal a deviation toward the involved side for the first 20° of trunk motion, becoming centered for the rest of the motion.³⁸ A gait with stooped posture, forward tilt of the pelvis, and hyperlordosis of the lumbar spine is a common finding.

The length of the iliopsoas muscles should be assessed because TrPs in this muscle can

cause shortening. Iliopsoas muscle length can be determined with the Thomas test (Figure 51-3).⁴⁶ This test can also be utilized to differentiate between iliopsoas, rectus femoris, and/or tensor fascia latae length deficits. To differentiate between muscle tightness and altered neurodynamics, the patient can lift his or her head up in chin tuck position. If there is a change in the patient's symptoms or hip range of motion with cervical motion, it is an indicator there is a femoral nerve involvement.⁴⁷⁻⁴⁹ The position of the limb to test the tensor fascia latae muscle length also puts more stretch through the saphenous nerve. If dorsiflexion of the foot changes the hip tightness or patient's symptoms, then the saphenous nerve is also likely a contributing factor in the hip range of motion limitation.

Figure 51-3. Thomas test position for hip flexor length. A, One-joint muscles. B, Two-joint muscle. Adapted from Kendall FP, McCreary EK. *Muscles: Testing and Function, with Posture and Pain*. 5th ed. Baltimore, MD: Lippincott Williams & Wilkins; 2005:376-377.

Muscle imbalance can change body mechanics. The iliopsoas muscles work in harmony with the rectus abdominus muscle; if this abdominal muscle is weak, the psoas muscle is likely to develop problems trying to compensate. Full function of the abdominal musculature is confirmed if the patient can do a curl-up with the knees bent and without foot support.⁵⁰

Trigger points in a number of muscles other than the iliopsoas muscle refer pain in patterns that may be confused with the pain referral pattern arising from iliopsoas TrPs. Low back pain can also be caused by TrPs in the quadratus lumborum, lowest section of

the rectus abdominus, longissimus thoracis, multifidus, and gluteus maximus and medius muscles. Iliopsoas TrPs do not cause pain on coughing and deep breathing as do those in the quadratus lumborum muscle.⁴¹ When the patient reports that pain spreads horizontally across the low back, the pain is much more likely to be referred from TrPs bilaterally in the quadratus lumborum muscles or from the lowest portion of the rectus abdominus muscle (Figure 49-7A).⁵¹ These rectus abdominus TrPs are often associated with TrPs in the iliopsoas muscles. Thigh and groin pain may also be due to TrPs in the tensor fascia latae, pectineus, vastus intermedius, adductor longus and brevis, or the distal parts of the adductor magnus muscles. Of these, only the pectineus muscle and tensor fasciae latae should restrict extension at the hip. Physical examination readily distinguishes the more superficial TrP tenderness of the last two muscles from the deep tenderness of the iliopsoas muscles.

3.4. Trigger Point Examination

Trigger points in the psoas major and iliacus muscles can be detected with a cross-fiber flat palpation in three locations (Figure 51-4). In two of the three locations, the muscle fibers can be palpated beneath the skin without other muscles intervening. To palpate both the psoas major and iliacus muscles, the patient should relax the abdominal muscles. If the patient is ticklish, this task may be difficult. To help the patient relax, place the patient's hand between your two hands as you palpate. Commonly, when TrPs are present in one iliopsoas muscle group, the contralateral iliopsoas muscles need to be examined because they function together. Usually, TrPs are more active in one iliopsoas muscle than in the other, but the contralateral muscle frequently requires treatment as well.

Figure 51-4. Palpation of TrPs in the right iliopsoas muscle at three locations. A, Palpation of the distal iliopsoas TrP region deep along the lateral wall of the femoral triangle, just above the distal attachment of the muscle to the lesser trochanter of the femur. B, Palpation of iliacus TrPs inside the brim of the pelvis behind the anterior superior iliac spine. C, Digital pressure on proximal psoas TrPs applied first downward beside, and then medially, beneath, the rectus abdominis muscle toward the psoas muscle.

Iliopsoas Common Tendon

With the patient in the supine position and the hip in slight abduction, TrPs can be identified with a cross-fiber flat palpation on the psoas musculotendinous junction and on iliacus muscle fibers against the lateral wall of the femoral triangle, as depicted in Figure 51-4A. If the iliacus muscle is significantly tight, it may be necessary to flex the thigh slightly by supporting it with a pillow. To find the iliopsoas common tendon, the clinician should find the femoral artery within the femoral triangle and then palpate one to two fingers widths laterally over the femoral nerve to the muscle. To confirm that the clinician is palpating the iliopsoas muscle, the patient should be asked to think about lifting the leg. If the patient contracts too strongly, it will most likely push the clinician off the TrP, so a gentle contraction is required. A local twitch response is rarely elicited by digital examination at this site and even less frequently at the other two sites.

Iliacus

The proximal fibers of the iliacus muscle can be examined through the aponeurosis of the external oblique muscle using cross-fiber flat palpation along the muscle fibers that lie inside the iliac crest of the pelvis (Figure 51-4B). The fingers reach inside the crest of the ilium starting in the region behind the anterior superior iliac spine and slide back and forth parallel to the iliac crest while pressing against the bone, palpating across the fibers of the iliacus muscle. Occasionally, palpation reveals taut bands and their associated spot tenderness. Pain elicited from these TrPs are more likely to refer to the low back and sacroiliac region than to the thigh. The patient should relax the abdominal muscles in a position that allows the skin of the abdominal wall to slacken.

Psoas Major

Palpation of the psoas major muscle is performed indirectly through the abdominal wall (Figure 51-4C). The patient should be comfortable and the abdominal wall relaxed. With the patient in supine or side-lying, the palpating fingers are placed on the abdominal wall with the fingertips just lateral to the lateral border of the rectus abdominus muscle. Downward pressure is slowly, gradually, and gently exerted to depress the fingers below the level of the rectus abdominus muscle. If the pressure is exerted directly downward with no medial component, it elicits only tenderness of other abdominal contents. Therefore, the clinician exerts slowly increasing pressure medially toward the spinal column. The intervening abdominal contents transmit the pressure to the psoas major muscle against the lumbar spine. The psoas major muscle is examined for tenderness along the entire length of the lumbar spine. If present, tenderness can usually be revealed at approximately the level of the umbilicus or slightly lower. Minimal pressure can elicit a significant amount of pain when the psoas major muscle has TrPs. Pain elicited from this part of the psoas major muscle refers chiefly to the low back.

4. DIFFERENTIAL DIAGNOSIS

4.1. Activation and Perpetuation of Trigger Points

A posture or activity that activates a TrP, if not corrected, can also perpetuate it. In any part of the psoas major, psoas minor, and iliacus muscles, TrPs may be activated by unaccustomed eccentric loading, eccentric exercise in an unconditioned muscle, or maximal or submaximal concentric loading.⁵² Trigger points may also be activated or aggravated when the muscle is placed in a shortened and/or lengthened position for an extended period of time.⁵² For example, overloading the psoas major muscle by the repetitive vigorous concentric contraction required to perform sit-ups can perpetuate its TrPs. The muscle is more tolerant of the eccentric contraction of slow let-backs or sit-backs.⁵¹

Tightness of the rectus femoris muscle that prevents full hip extension can also perpetuate TrPs in the iliopsoas muscle.

Trigger points may also be activated when the muscle is placed in a shortened or lengthened position for an extended period of time or activated simultaneously with TrPs in these other muscles by sudden overload during a fall. For example, prolonged sitting with the hips acutely flexed such that the torso leans forward, placing the knees higher than the hips, can place the iliopsoas muscles in a shortened position. This position can occur while driving (or sitting in) a car, sitting at a desk, or sitting on bleachers. Truck drivers and office workers, in particular, are vulnerable to shortening of this muscle.

Sleeping in the fetal position, with the knees drawn up to the chest, can also activate iliopsoas TrPs. Patients often report that their first awareness of pain referred from these TrPs was when they get out of the bed in the morning.

Lewit^{53, 54} associates TrPs of the psoas major muscle with articular dysfunction in the thoracolumbar region at the levels of T10-L1. Impaired trunk rotation and side bending in this region identify the dysfunction clinically. He associates TrP tenderness of the iliacus muscle with dysfunction of the lumbosacral junction.⁵³

A leg length discrepancy or a small hemipelvis can also perpetuate TrPs in the iliopsoas muscles. The involved muscle is most commonly seen on the longer side, but not always. Involvement due to this condition is more likely to be noted when it results from trauma, surgery, or an adaptation then if it is congenital.

4.2. Associated Trigger Points

It has been shown that associated TrPs can develop in the referred pain areas of primary TrPs,⁵⁵ therefore, muscles in the referred pain area of the iliopsoas muscle, or muscles referring to the iliopsoas muscle should be considered. Iliopsoas TrPs can contribute to associated TrPs in the quadratus lumborum, multifidi, erector spinae, serratus posterior inferior, gluteus maximus, gluteus medius, adductor longus, adductor brevis, adductor magnus, pectineus, obturator externus, rectus femoris, vastus intermedius, vastus lateralis, vastus medialis, and sartorius muscles. Trigger points in the iliopsoas muscles can be activated by the referred pain from TrPs in the quadratus lumborum, rectus abdominis, pyramidalis, external and internal obliques, multifidi, and erector spinae muscles.

Rarely do the iliopsoas muscles develop TrPs alone; they are commonly involved with other muscles. Its antagonists are likely to develop associated TrPs, including the gluteus maximus, hamstrings, and adductor magnus muscles. Synergistic muscles likely to exhibit TrPs in association with iliopsoas involvement include the rectus abdominis, quadratus lumborum, rectus femoris, tensor fasciae latae, pectineus, lumbar paraspinal, and the contralateral iliopsoas muscles. When the rectus femoris muscle is shortened because of TrPs, the iliopsoas muscle also remain in a shortened position, making it more susceptible to TrPs.

4.3. Associated Pathology

Some medical conditions give rise to symptoms that can appear confusingly similar to those produced by iliopsoas TrPs or may be present concurrently. The psoas major muscle has a

close association with lumbar disc pathology. Ingber⁴² described several patients with persistent low back pain following a laminectomy for lumbar disc pathology and one with discogenic pain who had not undergone surgery. Injecting the iliopsoas TrPs and initiating extension exercises relieved their symptoms.

The cross-sectional area of the psoas major muscle frequently atrophies in patients with low back pain,^{56–60} although this is not consistent in all groups with low back pain.^{61–63}

Although a reportedly rare event, the psoas major muscle is susceptible to developing a hematoma in association with an anticoagulation therapy,^{64–68} thrombolysis after an acute myocardial infarction,⁶⁹ hypertensive emergency,⁷⁰ vitamin K antagonist therapy,⁶⁵ surgical procedures such as a lateral retroperitoneal transpsoas lumbar interbody fusion,⁷¹ and sometimes following minor trauma in teenagers.⁷² The hematoma causes local pain and swelling, difficulty in walking, and often seriously compromises femoral nerve function.

Hematomas in the iliacus muscle are also rare but can develop spontaneously when on an anticoagulation therapy alone,⁷³ from trauma when on anticoagulant therapy,^{74,75} after surgery when on long-term anticoagulants,⁷⁶ after a total hip replacement,⁷⁷ total hip revision,⁷⁸ and in healthy children after a traumatic injury.^{79–83}

Iliopsoas bursitis is an inflammation and enlargement of the iliopsoas bursa. It is typically seen in conjunction with underlying conditions such as rheumatoid arthritis,^{84–88} chronic arthritis,⁸⁹ and less frequently with hip osteoarthritis,⁹⁰ calcium pyrophosphate crystal arthritis,⁹¹ after a total hip replacement,^{92,93} and secondary to infection.⁹⁴ It can also be due to acute trauma or overuse injuries.⁹⁵ It can even mimic an iliopsoas abscess.⁹⁶ Patients often present with any or all the following symptoms: hip pain,^{95,97} groin pain,^{98,99} buttock pain,⁹⁸ snapping of the hip,^{95,–97,99} lower limb edema,^{92,95} groin mass,^{92,95} pain with hyperextension of the hip,⁹⁵ and/or pain with flexion/abduction/external rotation.^{95,98}

Femoral acetabular impingement is a change in hip morphology that leads to abnormal contact in the joint during movement. It usually presents as a deep ache in the anterior groin, the lateral thigh, or buttocks while sitting. During activity, the pain is often sharp in nature. Weakness and numbness are not common. Pain is increased with activity, especially with those involving high hip flexion angles, sustained flexion loading/rotation in the hip joints, and getting in and out of the car.¹⁰⁰

The psoas major muscle is not frequently considered part of the pathology of pelvic pain; however, spasms of this muscle have been known to contribute to chronic pelvic pain.¹⁰¹ In men with a diagnosis of chronic prostatitis, involvement of the iliopsoas muscles¹⁰² and, specifically, the psoas major¹⁰³ muscle has been reported. With fascial attachments of the psoas major muscle into the pelvic floor, this muscle should not be overlooked as a potential contributing factor to pelvic pain.

Primary malignant tumors of the iliopsoas muscles are rare and typically have a poor prognosis due to the lack of early diagnosis, large size, and difficulty accessing the tumor surgically.¹⁰⁴ Psoas abscess are primarily reported in a younger population and are most

commonly associated with Crohn's disease, appendicitis, colon inflammation, or cancer.¹⁰⁵ Delay in treatment significantly increase mortality rates;¹⁰⁵ thus, it is important to be aware of the possibility of an abscess when assessing the psoas major muscle because they can often mimic TrPs. Ushiyama et al¹⁰⁶ describe the case of an 83-year old with right groin pain, held in a flexed position, and painfully restricted in extension. Movement of the iliopsoas muscles can cause pain when any of the organs it shares a relationship with (kidney, ureter, caecum, appendix, sigmoid colon, pancreas, lumbar lymph nodes, and nerves of the posterior abdominal wall) are diseased.¹⁵

Trigger points in the iliopsoas muscles can also mimic sports hernias, which are small tears in the lower abdominal walls. The two may occur at the same time, but this author has seen several patients who have undergone sports hernia repairs and continued to have pain. The pain was reproduced and treated by manually treating the TrPs in the psoas major muscle. It is also possible that the symptomatic TrPs were in the abdominal muscles because it is not possible to palpate or treat the psoas major muscle without going through the abdominal oblique muscles.

Because the roots of the lumbar plexus are lodged within the psoas major muscle, with branches of the plexus emerging from the surface and borders of the muscle, there is a possibility of entrapment due to anatomic variations of both the psoas and the iliacus muscles.¹⁰⁷ It is possible for the muscles to entrap the femoral nerve and contribute to symptoms consistent with femoral nerve involvement. In a study of 121 cadavers yielding 242 specimens, D'costa et al¹⁴ found that 7.9% of the time, slips from the iliacus and psoas muscles either pierced or covered the femoral nerve. Tension in this accessory iliacus muscle may lead to strain on the femoral nerve and therefore cause pain to refer into the hip, knee, or L4 dermatome. The obturator nerve arises from the anterior rami of L2, L3, and L4 spinal nerves in the anterior portion of the psoas major muscle and emerges along the medial border of the psoas major muscle before passing into the pelvis. Tightness in the psoas major muscle can lead to tension or entrapment of the obturator nerve in this region.¹⁰⁸

Several nerves in the region of the psoas major and iliacus muscles can also become entrapped and cause groin, hip, or thigh symptoms for reasons other than muscular involvement. It is important to be able to recognize these symptoms and not assume that they are solely due to TrPs of the psoas major and/or iliacus muscles. The iliohypogastric nerve can become entrapped after an abdominoplasty with plication of the anterior rectus sheath,¹⁰⁹ during pregnancy,¹¹⁰ after gynecologic laparoscopy,^{111,112} or from an external oblique muscle defect because terminal branches travel through it.¹¹³ The ilioinguinal nerve can become entrapped after a hernia surgery,¹¹⁴⁻¹¹⁶ laparoscopic gynecologic surgery,¹¹² or a Cesarean section,¹¹⁷ and can even be idiopathic.¹¹⁸ The lateral femoral cutaneous nerve can become entrapped after a laparoscopic hernia repair,¹¹⁴ at the fascia lata of the thigh,¹¹⁹ and from a lipoma.¹²⁰ The femoral nerve can be entrapped due to an iliopsoas muscular amyloidoma bilaterally in a patient with multiple myeloma¹²¹ from a high-energy knee trauma,¹²² an iliopsoas hematoma,^{123,124} and/or an iliopsoas bursitis.¹²⁵

Finally, the obturator nerve can become entrapped due to fractures of the pelvic ring¹²⁶ and acetabulum,¹²⁷ endometriosis around the nerve,¹²⁸ or can be idiopathic.¹²⁹

5. CORRECTIVE ACTIONS

If a patient has low back pain that does not respond to a directional preference of either flexion or extension and has difficulty ambulating, a cane may be utilized.

When sitting, the patient should maintain an open angle such that the hips are higher than the knees. Raising the seat such that the thigh slopes downward toward the front of the seat assists with this. Leaning back against a slightly reclining backrest is also helpful. If sitting with the hips acutely flexed is unavoidable, then standing up frequently to extend the hips and stretch the iliopsoas muscle helps unload it. If taking a long drive, cruise control provides an opportunity for the driver to shift and change positions slightly to help minimize the load to the iliopsoas muscles.

Poor breathing, as in paradoxical breathing,⁵¹ can impair recovery of the iliopsoas muscles from TrPs. Patients who exhibit paradoxical breathing should practice abdominal breathing until they can regularly breathe in the normal pattern of coordinated chest and abdominal movements during inhalation and exhalation. This style of breathing should be performed in the supine/hook-lying position to provide the best pull on the psoas major muscle by maximal excursion of the fascial attachments of the psoas major muscle to the diaphragm muscle.²

For sleeping, the patient may place a small pillow under the knees when lying on the back or under the hips and belly when sleeping prone. This produces a slight hip flexion that lessens the pull of the iliopsoas muscles sufficiently to lie comfortably. The patient should avoid side-lying with the hips flexed excessively because this position shortens the iliopsoas muscles.

To stretch the iliopsoas muscle passively, the thighs and pelvis should be pressed against the table (or floor) because they hyperextend the lumbar spine and hips in a press-up position (Figure 51-5). The muscle can also be stretched in the position utilized for assessment (Figure 51-3A). To increase the stretch further, a post-isometric relaxation technique, which was described and illustrated for this muscle by Lewit,⁵³ can be effective. The lower extremity on the side of the iliopsoas muscle to be stretched is allowed to hang freely with the knee bent. If the thigh needs more support, the patient may move up on the supporting surface. The pull is increased by pulling the other knee to the chest. This position also loads a sufficiently shortened rectus femoris muscle.

Figure 51-5. Self-stretch of the iliopsoas muscles. A, Initial position for patients with irritable TrPs. B, Progression of iliopsoas stretch.

Iliopsoas muscles should not be treated for TrPs by stretching until one identifies any coexisting lumbar spine articular dysfunction. If present, both should be treated because each can prevent recovery of the other. It is important to treat iliopsoas TrPs bilaterally; the muscle on one side rarely develops TrPs without the other also doing so.

Deep massage and hip extension exercises may also be helpful in relieving the pain referred from iliopsoas TrPs.^{42, 130} Treating the other muscles in the functional unit with massage or stretching may also be beneficial.

To improve the stability function of the psoas major muscle, a consistent low-grade contraction of the muscle can be performed.² To stimulate the longitudinal action of the muscle, the patient should gently try to “pull/suck your hip into the socket without moving your back.” This is often easier to do if slight distraction of the femur is applied by someone gently pulling on the leg or with the leg dangling off a step. The patient can also lie prone and perform a gentle isometric contraction of the hip into the supporting surface without rotation of the pelvis or spine. In addition, working with a trained clinician on a spinal stabilization program is also helpful, as this has been shown to improve the cross-sectional area of the muscle.¹³¹

Pelvic Floor Muscles

“Pain in the Rear”

Timothy Douglas Sawyer and Joseph M. Donnelly

1. INTRODUCTION

The pelvic floor muscles perform multiple functions, including continence and pelvic organ support, sexual function, respiration, spinal stability, and the balancing of intraabdominal pressure. The pelvic floor muscles consist of the levator ani muscle, which has three portions (puborectalis, pubococcygeus, iliococcygeus), the coccygeus, the bulbospongiosus, the ischiocavernosus, the transverse perinei, the sphincter ani, the obturator internus, and the piriformis muscles. Both the pubococcygeus and iliococcygeus portions of the levator ani muscle support and slightly elevate the pelvic floor, resisting increased intraabdominal pressure. The bulbospongiosus, ischiocavernosus, and transversus perinei muscles are responsible for urologic and sexual function. The sphincter ani muscle is in a state of constant tonic contraction and increases its activation during straining, speaking, coughing, laughing, or weight lifting. Symptoms arising from trigger points (TrPs) in one or several of these muscles are very similar to that of coccygodynia, levator ani syndrome, proctalgia fugax, and chronic pelvic pain syndrome (CPPS). Trigger points in the pelvic floor muscles are activated and perpetuated by a severe fall, long periods of prolonged sitting, driving, bicycling, an automobile accident, or by surgery in the pelvic region. A thorough pelvic examination should consist of an external examination and intrapelvic examination both vaginally and rectally. Trigger points of the pelvic floor muscle may be identified in as many as 85% of patients suffering from urologic, colorectal, and gynecologic pelvic pain syndromes and can be responsible for some, if not all, symptoms related to these syndromes. In 2009, the European Association of Urology published guidelines suggesting that TrPs should be considered in the diagnosis of CPPS. Several studies demonstrating the relationship between CPPS and TrPs are highlighted in this chapter.

2. ANATOMIC CONSIDERATIONS

A thorough knowledge of the anatomy of the muscles and their relationship to each other is essential if one is to identify by palpation which muscle is responsible for the patient's report of pain. This knowledge is also valuable for treating TrPs in these muscles and is critically important if one wishes to dry-needle or inject the TrPs to inactivate them. This section first presents the major intrapelvic muscles in the sequence of the physical examination. Then, it reviews the superficial perineal muscles, and lastly, considers variable, but occasionally clinically important, intrapelvic muscles.

Sphincter Ani

The sphincter ani internus and externus muscles consist of four concentric layers or rings of muscle (Figure 52-1). The innermost ring, the sphincter ani internus muscle, comprises autonomically innervated involuntary muscle fibers of the anal wall.¹ The remaining three layers are the deep, superficial, and subcutaneous laminae of the sphincter ani externus muscle. The external sphincter ani muscle is under voluntary control. This sphincter is elliptical in shape, extending three or four times as far anteroposteriorly as it does laterally. It surrounds the last 2 cm of the anal canal. The superficial (middle) lamina of the external sphincter ani muscle contains the bulk of the muscle. This lamina is anchored posteriorly to the tendinous anococcygeal body and anteriorly to the tendinous perineal body, where it is joined by the levator ani, bulbospongiosus, and transversus perinei superficialis muscles (Figure 52-1). The deep layer of the external sphincter ani muscle is closely associated with the sling-like puborectalis portion of the levator ani muscle, which is the most posterior, lateral, and deepest section of the pubococcygeal part of the levator ani muscle (Figure 52-1).²

Figure 52-1. Pelvic floor muscles as seen from below in the supine female subject. The muscles of the pelvic diaphragm are dark red, and the associated pelvic muscles are light red. On the subject's left side, part of the deep fascia of the urogenital diaphragm has been cut and removed to reveal the transversus perinei profundus muscle.

Levator Ani

The paired levator ani muscles meet in the midline to form a muscular sheet, the pelvic diaphragm, across most of the floor of the lesser pelvis. This diaphragm is perforated by the urogenital hiatus and the anal hiatus (Figure 52-2). The levator ani muscle comprises two distinct muscles: the more anterior (lower in the pelvis) pubococcygeus and puborectalis muscles, and the more posterior (higher in the pelvis) iliococcygeus muscle.

Figure 52-2. The pelvic floor muscles are seen obliquely from above and diagonally from the left side looking down inside the pelvis. The levator ani muscle is dark red. The coccygeus muscle is medium red, and the obturator internus muscle is light red.

The pubococcygeus and puborectalis muscles attach along the dorsal surface of the

pubic bone from the symphysis to the obturator canal (Figure 52-2). They form a sling around the anus, prostate gland or vagina, and the urethra. The two halves, pubococcygeus and puborectalis muscles, meet in the midline, some at the perineal body but most at the anococcygeal body (Figures 52-1 and 52-2).² Tichy illustrates embryologically how the levator ani muscle develops as a series of telescoping rings and slings.³ The most anterior (medial) fibers of the pubococcygeus muscle that meet bilaterally at the perineal body in front of the anus are called the levator prostate in men. In women, these anterior fibers are called the pubovaginalis muscle and serve as an important sphincter of the vagina. The more posterior fibers of the pubococcygeus muscle (the puborectalis part) form a sling around the rectum. The closest that any of the pubococcygeus muscle fibers come to the coccyx is usually their attachment to the anococcygeal body.

The posterior section of the levator ani muscle, the iliococcygeus muscle, attaches above to the tendinous arch of the levator ani muscle and to the spine of the ischium. The tendinous arch of the levator ani muscle attaches to the spine of the ischium posteriorly and attaches anteriorly either to the anterior margin of the obturator membrane or to the pubic bone just medial (farther anterior) to the margin of the membrane. This tendinous arch is firmly attached to the fascia covering the obturator internus muscle. As seen from inside the pelvis, the levator ani muscle covers the lower one-half to two-thirds of the obturator internus muscle and essentially all of the obturator foramen.²

Below, the iliococcygeus muscle attaches to the anococcygeal muscle body and to the last two segments of the coccyx.⁴ The adjacent margins of the pubococcygeus and iliococcygeus muscles may be separated or may overlap. The iliococcygeus muscle may be replaced by fibrous tissue. Its upper border lies adjacent to the sacrospinous ligament and the overlying coccygeus muscle.²

Coccygeus

The coccygeus muscle, sometimes called the ischiococcygeus muscle, lies cephalad and adjacent to the iliococcygeus portion of the levator ani muscle. The two muscles often form a continuous plane (Figure 52-1). The coccygeus muscle covers (internally) the sturdy sacrospinous ligament (Figure 52-2). Laterally, the apex of this triangular muscle is attached to the spine of the ischium and to the fibers of the sacrospinous ligament. Medially, it fans out to end on the margin of the coccyx and on the side of the lowest part of the sacrum.²

Obturator Internus

Part of the obturator internus muscle that lies outside of the pelvis and attaches to the greater trochanter of the femur is considered in Chapter 57. The intrapelvic portion of the muscle covers the anterolateral wall of the lesser pelvis, where it surrounds and covers the greater part of the obturator foramen (Figure 52-2). The obturator internus muscle is fan-shaped and the direction of its fibers spans an arc of roughly 135°. Its muscle fibers form an anterior and posterior thickening, one in front of and the other behind the obturator canal. This canal allows nerves and vessels to penetrate the obturator membrane along the anterior

margin of the obturator foramen, on the side opposite to the lesser sciatic foramen.

Inside the pelvis, the obturator internus muscle attaches to the inner pelvic brim, to the margin of the obturator foramen, and too much of the obturator membrane stretched across that bony foramen. The fibers of the muscle converge toward the lesser sciatic foramen and end in four or five tendinous bands. As the muscle exits the pelvis through the lesser sciatic foramen, it makes a right-angle bend around the grooved surface between the spine and tuberosity of the ischium. This bony pulley is covered with cartilage; the passage of the tendon is also assisted by the ischiadic bursa of the obturator internus muscle.⁴ As the tendon crosses the capsule of the hip joint, it is cushioned by the subtendinous bursa of the obturator internus muscle (see Chapter 57). The exit of the obturator internus muscle from the pelvis through the lesser sciatic foramen is marked by palpable ligaments that form two borders of that foramen: the sacrotuberous ligament posteriorly and the sacrospinous ligament above.² As the fibers of the two ligaments intermingle, they cross at the upper end of the foramen; the foramen is a tightly enclosed space that leaves no room for expansion of the muscle.² The structures forming the lesser sciatic foramen are illustrated in Figure 57-3. This figure serves as a valuable reference throughout this chapter because it clarifies relations of intrapelvic muscles and ligaments.

Piriformis

The piriformis muscle forms part of the posterior wall of the true pelvis and lies posterior to the ischiococcygeus muscle. The lower portion is palpable vaginally but may be difficult depending on the length of the clinician's finger. It is attached from the undersurface of the sacrum at levels S2-S4, gluteal surface of the ilium, sacroiliac joint capsule, and in some individuals, may attach to the sacrotuberous ligament. The piriformis muscle travels inferolaterally and exits the pelvis through the greater sciatic foramen proximal to the sacrospinous ligament and attaches to the greater trochanter of the femur at the hip joint.² This muscle may be palpated with access rectally. See Chapter 57 for more on the piriformis muscle.

Bulbospongiosus, Ischiocavernosus, and Transversus Perinei

Female Anatomy

In women, the bulbospongiosus, ischiocavernosus, and transversus perinei superficialis muscles on each side of the body form a triangle (Figure 52-1). The medial leg of the triangle, the bulbospongiosus muscle (also known as the bulbocavernosus or the sphincter vaginae), surrounds the orifice of the vagina. The muscle attaches anteriorly to the corpora cavernosa of the clitoridis with a muscular fasciculus that also crosses over the body of the clitoris and compresses its deep dorsal vein. Posteriorly, the bulbospongiosus muscle anchors to the perineal body where it blends with the external anal sphincter and the transversus perinei superficialis muscles (Figure 52-2).²

The ischiocavernosus muscle in women (formerly called the erector clitoridis) forms the

lateral side of the triangle (Figure 52-1). The muscle is located along the lateral boundary of the perineum next to the bony ridge of the anterior pubic ramus, extending between the symphysis pubis and the ischial tuberosity. Above and anteriorly, the ischiocavernosus muscle ends in an aponeurosis that blends with the sides and undersurface of the crus clitoridis. Below and posteriorly, it is attached to the surface of the crus clitoridis and to the ischial tuberosity.²

The transversus perinei superficialis muscle forms the base of the triangle. The two muscles together span the perineum laterally between the ischial tuberosities, joining the sphincter ani and bulbospongiosus muscles in the midline at the perineal body (Figure 52-1). The transversus perinei profundus muscle lies deep to the transversus perinei superficialis muscle; it is a broader muscle that courses between the ischial tuberosity and the vagina (Figure 52-2).²

Male Anatomy

In men, the bulbospongiosus muscle is more complex than in women and essentially wraps around the corpus spongiosum of the penis, which is the central erectile structure through which the urethra passes. As illustrated, the two symmetrical parts of this muscle begin below at the perineal body and along the median raphe. The fibers extend outward and upward in a pennate fashion to enclose the bulk of the corpus spongiosum penis posteriorly and the corpus cavernosum penis anteriorly. Above, some of the fibers end in a tendinous expansion that covers the dorsal blood vessels of the penis.² After 5 months of fetal gestation, this muscle wraps around the bulb of the penis.⁵

The ischiocavernosus muscle in men is similar to that in women but is usually larger. On each side, the muscle attaches posteriorly to the ischial tuberosity and the ischial ramus and angles across the perineum anteriorly toward the crus penis. After coursing lateral to the bulbospongiosus muscle, it ends in an aponeurosis that blends with the sides and undersurface of the crus penis.^{1, 2, 4}

The transversus perinei profundus muscle attaches laterally to the ischial tuberosity as in women, but in men, the muscles interlace in the midline at a tendinous raphe deep to the bulbospongiosus muscle.^{1, 2}

Sacroccygeus Ventralis

The sacroccygeus ventralis (anterior) muscle is variable and was found in 102 of 110 adult bodies. It often is vestigial, consisting mainly of tendinous bands with only short muscle fibers.⁶ When well developed, it extends vertically from the sides of the 4th and 5th sacral vertebrae, from the front of the 1st coccygeal vertebra, and from the sacrospinous ligament to the 2nd to 4th coccygeal vertebrae and to the anterior sacroccygeal ligament.^{1, 6-8}

The sacroccygeus ventralis muscle may divide into medial and lateral fiber bundles. When this has happened, the lateral fibers have been identified as the sacroccygeus ventralis (depressor caudae lateralis) muscle and the medial fibers as the infracoccygeus

(depressor caudae medialis) muscle.⁶ These fibers are probably phylogenetic remnants of tail-wagging muscles.

2.1. Innervation and Vascularization

The external anal sphincter muscle is innervated by a branch of the 4th sacral nerve and by branches from the inferior rectal branch of the pudendal nerve. The internal sphincter ani muscle is innervated by the fibers of the autonomic nervous system.² The obturator internus muscle is supplied by its own nerve, which carries fibers from the L5, S1, and S2 segments² (Chapter 57). The levator ani muscle is innervated by the fibers of the S3, S4 segment and sometimes by the S5 segments via the pudendal plexus.² Stimulation of the S3 ventral root produces nearly 70% of closure pressure by the external sphincter urethrae and the remaining 30% is provided by stimulating the S2 and S4 spinal nerve roots.⁹ The coccygeus muscle derives its innervation from the fibers of the S4 and S5 segments via the pudendal plexus.² All of the perineal muscles (including the bulbospongiosus, the ischiocavernosus, and both the superficial and deep transverse perinei muscle) are innervated by the S2, S3, and S4 sacral nerves via the perineal branch of the pudendal nerve.² The fibers from the S4 and S5 segments usually innervate the sacrococcygeus ventralis muscle.⁶

The branches of the internal iliac artery constitute the major blood supply to the perineum. The only pelvic organs that don't receive their blood supply from branches of the internal iliac artery are the ovaries and the superior part of the rectum. The lymphatic drainage of the pelvic cavity is mainly to nodes located around the internal iliac vessels.

2.2. Function

The pelvic floor muscles perform multiple functions such as continence and pelvic organ support, sexual function, respiration, spinal stability, and containment of intraabdominal pressure.^{10–17} The physiologic mechanisms by which they perform their roles are not clearly understood predominately because of the lack of suitable instrumentation. The pelvic floor muscles remain, particularly from a biomechanical perspective, an understudied region of the body.

Sphincter Ani

Clinical experience shows, and electromyographical (EMG) studies confirm,¹⁸ that the sphincter ani muscle is in a state of constant tonic contraction, which is increased by straining, speaking, coughing, laughing, or weight lifting. The tonic contraction falls to a very low level during sleep and is strongly inhibited during defecation. It is strongly recruited by voluntary effort, which is accompanied by general contraction of the perineal muscles, especially the sphincter urethrae muscle.¹⁸

Levator Ani

In general, both the pubococcygeus and iliococcygeus portions of the levator ani muscle support and slightly elevate the pelvic floor muscles, resisting increased intraabdominal pressure.² In men, the more anterior (medial) pubococcygeal portion, sometimes called the levator prostate muscle, forms a sling around the prostate and specifically applies upward pressure on it. The corresponding fibers in women, also known as the pubovaginal muscle, constrict the vaginal orifice. The more posterior puborectalis fibers of the pubococcygeus muscle form a sling around the anus that is structurally continuous with the sphincter ani muscle and constricts the anus when contracted.¹⁹ Strong contraction of this part of the levator ani muscle can help eject a bolus of feces. Contraction of the more anterior periurethral fibers helps empty the urethra at the end of urination and is thought to prevent incontinence during coughing or sneezing. The levator ani muscle, like the diaphragm muscle, is also active during the inspiration phase of quiet respiration.²

A histologic comparison of the perianal and periurethral regions of the pubococcygeus muscle revealed that, although most fibers were type 1 (oxidative metabolism) fibers, in the periurethral region, only 4% were type 2 (glycolytic) fibers, whereas in the perianal region, 23% were type 2 fibers. This higher percentage of type 2 fibers in the perianal region suggests that it is used for occasional forceful contractions, when compared with more sustained contractions in the periurethral region.¹⁹ A later study by this same group²⁰ reported only type 1 fibers in the external (voluntary) sphincter urethrae muscle.

In a 1989 study,²¹ a greater proportion of type 1 (slow-twitch) fibers was associated with improved support of the pelvic viscera, especially under conditions contributing to increased intraabdominal pressure. A greater proportion of type 2 (fast-twitch) fibers improved the periurethral continence mechanism, providing increased urethral closure during mechanical pressure stress. In an EMG study of 24 normal women, about half of whom had delivered babies, none was able to relax the pubococcygeal part of the levator ani muscle in the lithotomy position, whereas some were able to relax the sphincter urethrae muscle completely.¹⁸

Coccygeus

Anatomically, the coccygeus muscle pulls the coccyx forward and is said to support the pelvic floor muscles against intraabdominal pressure and to play a primary role in achieving rectal and urinary continence.² It also stabilizes the sacroiliac joint²² and has powerful leverage for rotating this joint. Therefore, abnormal tension of the coccygeus muscle could easily hold the sacroiliac joint in a displaced position.

Obturator Internus

The obturator internus muscle is a lower extremity muscle that serves no motor function in the pelvis. As noted in Chapter 57, the obturator internus muscle is most strongly a external rotator of the thigh when the thigh is extended; the muscle becomes increasingly an abductor at the hip as the thigh is flexed.²

Piriformis

Like the obturator internus muscle, the piriformis muscle also serves no motor function in the pelvis. The muscle is an external rotator of the hip and assists in abduction of the femur when the hip is flexed (See Chapter 57).

Bulbospongiosus, Ischiocavernosus, and Transversus Perinei

Contraction of the bulbospongiosus muscle in men serves to empty the urethra at the end of urination and contracts during ejaculation.² Erection of the penis is primarily a vascular response under autonomic control,^{23,24} but the anterior and middle fibers of the bulbospongiosus and ischiocavernosus muscles contribute to erection by reflex and voluntary contraction that compresses the erectile tissue of the bulb of the penis and its dorsal vein.^{2,-25,26} In women, contraction of this voluntary muscle constricts the orifice of the vagina and contributes to erection of the clitoris by compression of its deep dorsal vein.²

In men, contraction of the ischiocavernosus muscle serves to maintain and enhance penile erection by retarding the return of blood through the crus penis. During erection, intracavernous pressure correlated strongly with the duration of voluntary EMG activity in the ischiocavernosus muscle.²⁷ Change of pressure on the glans reflexively activates the ischiocavernosus muscle. This substantiates the clinical impression that pressure stimulation of the glans penis during coitus contributes to the erectile process.²⁸

In women, the ischiocavernosus muscle acts similarly to maintain erection of the clitoris by retarding return flow from the crus clitoridis.²

The two pairs of transverse perineal muscles form a muscular sling that cradles the perineal body between the two ischial tuberosities. Bilateral contraction of the superficial and deep transversus perineal muscles serves to fix the perineal body in the midline between the anus and genitalia and to support the pelvic floor muscle. In both men and women, all of these perineal muscles are generally contracted as a unit. EMG studies indicate that selective contraction of individual perineal muscles is difficult, if not impossible.¹⁸

2.3. Functional Unit

The pelvic floor muscles, especially the anal and urethral sphincters and the levator ani, function closely together. Contractions of the genital bulbospongiosus and ischiocavernosus muscles are scarcely, if at all, voluntarily separable from sphincter activation.

The iliococcygeus and upper pubococcygeus portions of the levator ani muscle are strong flexors of the coccyx. The equally powerful antagonist to this movement is the gluteus maximus muscle; it attaches to the dorsolateral surface of the coccyx²⁹ with fibers that are directed laterally to form the gluteal cleft. Working together, the levator ani and gluteus maximus muscles provide a more powerful elevation (closure) of the anus than the levator ani muscle could provide independently. When maximum voluntary effort is required to close the anal aperture, the gluteus maximus muscle is powerfully recruited.

The obturator internus and the piriformis muscles function in concert with other external rotators of the thigh, as described in Chapter 57.

3. CLINICAL PRESENTATION

3.1. Referred Pain Pattern

Knowing the location of pain in the pelvic region is helpful in identifying which TrPs could be responsible for it. Trigger points have been associated with urogenital pain with referred pain to the penis, perineum, rectum, suprapubic area, testicles, groin, and coccyx.^{17,30} Referred pain from TrPs in the bulbospongiosus, ischiocavernosus, and anterior portions of the levator ani muscles usually project pain or discomfort to the adjacent urogenital structures, perineum, and suprapubic region (Figure 52-3A). Sphincter ani TrPs induce pain in the rectum as well as the immediate surrounding areas of the pelvic floor muscles. Trigger points in the posterior region of the pelvic floor, posterior sphincter ani, iliococcygeus, posterior part of pubococcygeus, and coccygeus muscles are likely to refer pain to the anus, the sacrococcygeal region, coccyx, and perineum (Figure 52-3B).¹⁷ This referred pain pattern is often called coccygodynia, although the coccyx itself is usually normal and not tender.^{31,32–34} Because the levator ani muscle is most commonly involved, pain in the region of the coccyx is also called levator ani syndrome.³⁴ Trigger points in the anterior portion of the levator ani muscle (puborectalis and pubococcygeus) and bulbospongiosus muscle can refer specific pain to the urogenital structures, supra pubic region, and perineum.¹⁷ The levator endopelvic fascia lateral to the prostate represents the most common location of TrPs in men with pelvic pain, often referring pain to the tip of the penis.³⁵ Vaginal pain has also been reproduced by pressure on the tender sites in the levator ani muscle³²). Trigger points in the transverse perineal muscles refer to the perineum and the medial side of the ischial tuberosities. The TrPs in the obturator internus muscle refer pain to the urogenital structures, rectum, groin, and hip, with a spillover pattern down the back of the ipsilateral thigh (Figure 52-3C). Goldstein found that injection of obturator internus TrPs relieved pain in the vagina (J. Goldstein, personal communication³⁶). The piriformis muscle can also refer into the vagina as well as the hip, ischial tuberosity, and down the back of the thigh.¹⁷

3.2. Symptoms

Patients with TrPs in the sphincter ani muscle primarily report poorly localized aching pain in the anal region and may experience painful movements or relief after passing their bowels. Depending on where the TrPs are located in the sphincter ani muscle, patients may report specific pain on the side of the TrP. Patients often report that increased physical activity and stress has a direct effect on their symptoms.

In women, TrPs in the bulbospongiosus muscle cause dyspareunia, particularly during entry, and aching pain in the perineal region. In men, these TrPs cause pain in the

retroscrotal region, discomfort when sitting erect and forward, and occasionally a degree of impotence, and such people may also report pre- or post-ejaculation penis pain.¹⁷ Ischiocavernosus TrPs likewise cause perineal pain but are less likely to interfere with intercourse. Involvement of the obturator internus muscle can cause pain and a feeling of fullness in the rectum, with occasional referral of pain down the back of the thigh.³⁷ This muscle may also refer pain into the vagina.^{21,22} In women, the piriformis muscle is a common cause of painful intercourse during deep penetration.

The levator ani muscle is the most widely recognized source of referred pain in the perineal region. Patients may report pain in the sacrum,³⁴ coccyx,^{32-34,38} rectum,^{34,39,40} pelvic floor or perirectal area,^{34,39} vagina,³³ urogenital structures,¹⁷ and low back.³⁸ Patients will report increased symptoms with sitting and difficulty being comfortable while sitting.³⁷⁻⁴⁰ They may also report increased symptoms while lying supine³² and with defecation.⁴⁰ Patients with TrPs in the posterior region of the pelvic floor, including posterior sphincter ani, iliococcygeus, posterior part of pubococcygeus, and coccygeus muscles, may report a feeling of fullness in the rectum as well as pre- and post-bowel movement pain.¹⁷ Patients with TrPs in the anterior portion of the levator ani (puborectalis and pubococcygeus) and bulbospongiosus muscles often report increased frequency, urgency, bladder discomfort, suprapubic pain, postejaculatory pain, and pain in the tip of the penis.^{17,41}

Trigger points in the coccygeus muscle were identified as the cause of pain similar to that ascribed to TrPs in the levator ani muscle and referred to the coccyx, hip, or back. Trigger points in this muscle are likely to cause low back pain late in pregnancy and early in labor. Tenderness and “spasm” (tension) of the coccygeus muscle were usually the key factors responsible for low back pain suffered by 1350 women seen for infertility.²² The issue of sitting pain has often been described as posterior tail bone discomfort and can also be described as pain in the ischial tuberosities, pain isolated to the soft tissue of the perineum and the rectum (a golf ball in the pelvis), and anterior pain in the perineum and base of the penis in men, and the vulva in women.

3.3. Patient Examination

After a thorough subjective examination and establishing the event(s) associated with the onset of reported symptoms, the clinician should make a detailed drawing representing the pain pattern that the patient has described. This activity will assist in planning the physical examination and can be useful in monitoring the progression of the patient as symptoms improve or change. Any patient with primary reports of abdominal or pelvic pain should alert the clinician to perform a thorough review of systems. Any concerns regarding the involvement of the cardiovascular or respiratory systems, gastrointestinal, or urogenital system as a source of symptoms should result in an immediate referral to a physician. All potential perpetuating factors should be noted and mechanical factors considered.

Figure 52-3. Referred pain patterns generated by TrPs in the pelvic floor muscles (A). Referred pain patterns from the right bulbospongiosus, ischiocavernosus, and anterior levator ani muscles (B); in the right sphincter ani, levator ani, and coccygeus muscles (C);

in the right obturator internus muscle. Pain referred from this muscle sometimes spills over to include the posterior proximal region of the thigh.

The clinician should observe the patient's posture in sitting, standing, walking, and reaching. Articular dysfunctions associated with pelvic floor muscle TrPs include sacral, coccyx, pubic, and innominate dysfunctions, hip dysfunctions, and lower extremity biomechanical malalignment. Muscle spasm and tenderness secondary to articular dysfunction at the sacroiliac joint are likely to be associated with coccygeal and low back pain. Conversely, tension of the muscles attached to the coccyx can destabilize the sacroiliac joint.²² Ventral coccygeal tenderness is often associated with a hypomobile sacroiliac joint.⁴² Lewit found that only one-fifth of the patients who had tenderness on palpation of the ventral surface of the coccyx reported coccygeal pain.⁴² The majority suffered primarily from low back pain.

Upslip, or innominate shear dysfunction (upward displacement of an innominate bone in relation to the sacrum), is an important source of low back and groin pain.⁴³ A total of 63 patients in a private orthopedic practice who were examined because of pain were found to have an innominate upslip dysfunction, the most common site of the chief pain report was the low back and groin (50%).⁴⁴

The muscle examination should begin with the external muscles. In the supine position, the clinician must test the abdominals, diaphragm, iliopsoas, iliacus, adductors, pectineus, and perineal muscles; in the side-lying and/or prone position, the clinician must test the quadratus lumborum, tensor fascia latae (TFL), gluteus minimus, gluteus medius, gluteus maximus, piriformis, other hip rotators, and the hamstring muscles, as well as the obturator internus tendon of insertion. All of these muscles can contribute to the activation and perpetuation of TrPs in the pelvic floor muscles.¹⁷ Figure 52-3 shows the relationship between some of these TrPs and their associated pelvic pain referral patterns.¹⁷ Box 52-1 shows common areas of referred pain from TrPs in men.

The internal muscles of the pelvis can be examined in several positions depending on the location of specific suspected TrPs and patient gender. Although women can be examined vaginally, a rectal exam should always be done as well. When the obturator internus muscle has active TrPs, the range of motion of hip internal rotation will have a painful restriction. The clinician tests this in the prone position by looking for restricted internal rotation of the hip in the anatomic zero position. A considerably greater stretch of the obturator internus muscle is obtained by flexing the thigh 90° and then adducting it. This maneuver, however, also exerts tension on the gluteus medius, piriformis, gemelli, and obturator externus muscles.

Typically, the sacrococcygeal joint is quite mobile. The coccyx normally extends through an arc of about 30° and bends laterally to bring the tip about 1 cm from the midline. Mobility is greater in women than in men.³³ Bilateral tension of the coccygeus muscles tends to flex the sacrococcygeal joint. Unilateral coccygeus muscle tension pulls the coccyx toward one side.³³

Lewit⁴¹ emphasizes how frequently patients who report low back pain have marked

tenderness inside the tip of the coccyx. In such cases, the coccyx is kyphotic (pulled in toward the pelvis) but is not tender to pressure on its dorsal surface, and movement at the sacrococcygeal joint is not painful. Because of this kyphotic curvature and the hypertonus of the adjacent gluteus maximus muscles, it is difficult for the clinician to reach beneath the tip of the coccyx to where the ventral surface is so tender⁴¹; therefore, this tenderness is easily overlooked. However, when present, it is a strong indication for the need to determine the cause by doing an intrapelvic examination, as described in the next section.

3.4. Trigger Point Examination

In 2009, the European Association of Urology published guidelines suggesting that TrPs should be considered in the diagnosis of CPPS, and there are several studies demonstrating the relationship between CPPS and TrPs.^{45–48}

Manual examination of TrPs requires adequate manual skills, training, and clinical practice to develop a high degree of reliability in the examination. For the purpose of locating TrPs within the pelvis, the pelvic muscles can be considered in three categories: perineal muscles, pelvic floor muscles, and pelvic wall muscles. Trigger points of the pelvic floor muscles may be identified in as many as 85% of patients suffering from urologic, colorectal, and gynecologic pelvic pain syndromes and can be responsible for some, if not all, symptoms related to these syndromes.⁴⁹ Trigger points in the pelvic floor musculature may often coexist with TrPs in the abdominal wall muscles, which can help differentiate pelvic and abdominal pain of visceral versus somatic origin.^{50, 51}

The external perineal muscles can be examined with both cross-fiber flat palpation and cross-fiber pincer palpation. The intrapelvic muscles are examined through the rectum and the vagina. For the rectal examination, the patient can be placed in a semilateral prone position with pillows under the abdomen. Using a gloved finger, the sphincter ani muscle is examined first. The left internal muscles of the pelvis are then examined with the right hand, and the right pelvis is examined with the left hand, shifting the patient as necessary. The clinician applies a consistent pressure level for tissue palpation. As recommended, when examining patients with fibromyalgia, use an approximate palpation force of 4 kg/cm² to assess pain. For each area examined, patients are asked to report the level of pain experienced during palpation from 0 to 3+ (*severe*).^{17, 52} The patient may also lie supine in the lithotomy position, or if footrests are not available, semi prone in Sims position. It is best to begin the examination with the hand that supinates toward the symptomatic side. If TrPs are found on that side, it is wise to examine the opposite side of the pelvis for comparison, which is most effectively done with the other hand. It is difficult and awkward to perform an adequate rectal examination of the muscles on both sides of the pelvis with one hand.

Pelvic Floor Muscles

The pelvic floor muscles that commonly have TrPs are the sphincter ani, levator ani, coccygeus, and obturator internus muscles. Although the levator ani and coccygeus muscles

are over most of the pelvic floor muscles, the intrapelvic rectal digital examination begins with the sphincter ani muscle.

Sphincter Ani

If the patient has TrPs in the anal sphincter muscle, insertion of the finger can be distressing even when done very carefully. First, the clinician should examine the anal orifice for internal hemorrhoids, which can perpetuate TrPs of the anal sphincter muscle. Lubricant is liberally applied to the examining gloved finger and the anal orifice. Ordinarily, as the clinician inserts the finger, he or she would gently apply pressure toward one side of the anus to help relax the sphincter muscle. However, if one inadvertently presses on TrPs in the muscle, it may increase the patient's pain. In the presence of excessive sphincter tension or tenderness, the patient, instead of the clinician applying side pressure, may bear down on the rectum to enhance relaxation of the sphincter ani muscle as the clinician slowly inserts the examining finger directly into the anal orifice. Golfam et al⁵³ studied the effect of topical nifedipine (a calcium channel blocker) on anal fissures, and it was shown to have a significant effect on pain reduction and improved recovery time in patients with anal fissures and hemorrhoids. Patients in the nifedipine group showed significant healing and relief from pain compared with patients in the control group.⁵³ This study may lead to an appropriate treatment to reduce sphincter tension and ease the pain of rectal examination of patients with pelvic pain in the future.

By gently flexing the tip of the finger, the clinician can feel when it has passed the sphincter muscles. The finger first encounters the external and then the internal sphincter ani muscle. The finger should be withdrawn to halfway along the sphincter muscles and pressure gently applied to the muscle at every one-eighth of a circle (positions at 12:00, 1:30, 3:00, etc.) to identify tenderness caused from TrPs. When the finger locates tenderness in one direction, the muscle is explored to determine where the spot of maximum tenderness exists. An associated taut band may be identified if the TrP is not too tender and the patient can tolerate the additional pressure. If the muscle is strongly contracted, the patient can relax it by bearing down, making the contrast between the taut band and relaxed fibers more evident. A taut band, when present, usually extends from one-quarter to halfway around the anus. Multiple taut bands are typically identified when TrPs are present.

When an anal sphincter muscle has very active TrPs, their tenderness may preclude further rectal examination of the intrapelvic muscles. The movement and additional pressure of the finger may be intolerable. In women, the vaginal examination may then be substituted. Otherwise, the anal sphincter TrPs must be inactivated before the patient can be examined for intrapelvic TrPs.

Orientation Inside the Pelvis

Establishing relevant bony and ligamentous landmarks for reference, and the prostate gland in men, helps greatly in identifying the intrapelvic muscles by palpation. For orientation

purposes, it is helpful in identifying the structures that border the levator ani muscle (Figures 52-1, 52-2, and 52-4).

Usually, there are no muscles found in the midline on the ventral surface of the coccyx and the sacrum. When the patient is examined rectally, only the rectal wall lies between the examining finger and these bones. In the midline below (distal to) the tip of the coccyx, the anococcygeal body (which usually is not distinguishable by palpation) extends to the sphincter ani muscle and serves as the attachment for much of the pubococcygeus portions of the levator ani muscle. Just anterior to the rectum is an analogous structure, the perineal body, to which the bulbospongiosus, transverse perinei, and sphincter ani muscles attach.

It is relatively easy to examine the range of motion of the coccyx. One grasps the coccyx between the finger inside the rectum and the thumb outside to flex, extend, and bend it laterally, testing for tenderness at its articulations. All of the coccygeal joints may be mobile. The most proximal joint that exhibits mobility is usually the sacrococcygeal joint.

A firm, tendinous edge crossing the pelvis at about the level of the sacrococcygeal joint (Figure 52-2) identifies the lower border of the sacrospinous ligament. This border is nearly always sharply delineated. It lies close to the sometimes overlapping borders of the iliococcygeal portion of the levator ani muscle, below, and the coccygeus muscle, above. Laterally, the ligament ends at a palpable, hard, bony prominence, the spine of the ischium, to which the tendinous arch of the levator ani muscle also attaches.⁴ The posterior half of this tendinous arch is palpable as it swings around the pelvis to attach anteriorly to the body of the pubis. The arch may become indistinguishable near the anterior margin of the obturator membrane. This arch serves as the lateral attachment of the iliococcygeus portion of the levator ani muscle. Therefore, this portion of the levator ani muscle lies below it. The obturator internus muscle extends above and below the arch of the levator ani muscle. The obturator internus muscle can be palpated directly anywhere above the arch, but below the arch, it can only be palpated through the levator ani (iliococcygeus) muscle. Just caudal to the tip of the ischial spine, a soft spot felt through the levator ani muscle locates the opening of the lesser sciatic foramen.

Levator Ani

Palpation of the most anterior fibers of the levator ani muscle is an important area to check for TrPs that lie alongside the prostate in men, and inserting onto the dorsal surface of the pubis. The pubococcygeus portion of the levator ani muscle is often subdivided into separate parts according to the pelvic viscera to which they relate (puboperinealis, puboprostaticus, pubovaginalis, puboanalisis, and puborectalis).² These TrPs are associated with the urogenital symptoms mentioned previously. In men, once the finger passes through the anal canal, the clinician first locates the prostate gland central and anterior. With the index finger inserted deep, the knuckles of the hand will come to rest on the ischial tuberosity. This will allow the clinician to examine the deepest fibers of the anterior levator ani muscle (Figure 52-5A and B).

(Note: In women, these deep anterior fibers of the levator ani muscle are much easier

palpated vaginally.) Next, the clinician gently slides the finger inferiorly alongside the prostate examining shallower fibers of the muscle until reaching the perineal body. At this location, the clinician can use pincer palpation with the index finger inside and the thumb outside to further examine TrPs in the perineal body and transverse perinei muscle. From this location, the clinician sweeps laterally along the levator ani muscle checking both deep and shallow fibers for TrPs until reaching the middle of the sacrospinous ligament and then the coccyx. Thiele recommended sweeping the finger slowly from side to side through an arc of 180° at successively higher levels, allowing the clinician to palpate all of the fibers of the levator ani, the coccygeus, as well as the obturator internus muscles.³³ He commented on how frequently individual fascicles stood out like tight cords with areas of relaxed muscle between them and reported that sometimes the entire levator ani muscle was tense and felt like a firm sheet of muscle stretched from its tendinous arch to the sacrum, coccyx, and anococcygeal body.³³ A similar examination of the piriformis muscle is illustrated in Figure 52-4 with useful anatomic landmarks. Pressure on levator ani TrPs nearly always reproduces the patient's reported pain, either anteriorly in the urogenital region or posteriorly in the region of the coccyx.¹⁷

When the clinician finds TrPs that seem to be in the lateral portions of the levator ani muscle below this muscle's tendinous arch, care must be exercised to be sure that the tenderness is not due to TrPs in the underlying obturator internus muscle. The two muscles can be distinguished by palpating while asking the patient to squeeze the finger in the rectum (levator ani muscle activation), relax, and then abduct the flexed thigh or externally rotate the extended thigh on that side against resistance (obturator internus muscle activation). The increase in muscle tension identifies the contracting muscle.

Coccygeus

The coccygeus muscle is palpable usually at the level of the sacrococcygeal joint (Figure 52-2).⁴ Much of the muscle lies between the examining finger and the underlying sacrospinous ligament. In some individuals, the muscle is intertwined with the ligament, the caudal border that is usually palpable. Against this firm ligamentous foundation, taut bands and their TrPs are usually readily identified by cross-fiber flat palpation across the coccygeus muscle.

Occasionally, a thick band of coccygeus muscle fibers crosses the midline. Here it is readily palpable against the lowest part of the sacrum or the uppermost region of the coccyx. The gluteus maximus muscle attachment to the outer margins of the sacrum and the coccyx corresponds closely to the coccygeus muscle's attachment on the inner margins of these bones.²⁹

Pelvic Wall Muscles

One pelvic wall muscle, the obturator internus muscle, covers the anterolateral wall of the lesser pelvis. Looking into the pelvis from above, one sees that much of this muscle is covered by the levator ani muscle (Figure 52-4). The obturator internus muscle exits the

pelvis through the lesser sciatic foramen, which is bounded on two sides by the sacrospinous and sacrotuberous ligaments. The sacrotuberous ligament attaches to the externally identifiable ischial tuberosity. The other major intrapelvic muscle, the piriformis muscle, is found cephalad to the sacrospinous ligament, and this is considered in Chapter 57. The sacrococcygeus ventralis muscle, when present, is palpable as longitudinal fibers along the margins of the lower sacrum and the coccyx.

Figure 52-4. Internal palpation of the left piriformis muscle (dark red within the pelvis and light red outside the pelvis) via the rectum, viewed from in front and above. The levator ani muscle is medium red; the coccygeus and obturator internus muscles are light red. The sacrospinous ligament (covered by the coccygeus muscle) is the last major transverse landmark identified by the palpating finger before it reaches the piriformis muscle. The sacrospinous ligament attaches cephalad mainly to the coccyx, which is usually easily palpated and mobile. The posterior wall of the rectum and the S3 and S4 nerve roots lie between the palpating finger and the piriformis muscle.

Figure 52-5. A, Anterior view; internal examination of the pelvis, with the index finger palpating internally. B, Posterior view; externally, knuckles rest on the ischial tuberosity. In women, these deep anterior fibers of the levator ani muscle are much easier palpated vaginally.

Obturator Internus

A view of the pelvis from above shows that the posterior portion of the obturator internus muscle must be palpated through the levator ani muscle (Figure 52-4).⁴ A frontal section² likewise illustrates this and shows the relation of these muscles to the tendinous arch. A frontal section and a cross section⁵⁴ through the prostate depict how one must palpate the thick posterior part of the obturator internus muscle through a thin layer of the levator ani muscle on either side of the prostate (or vagina).

When running the finger around the lateral wall of the pelvis above the tendinous arch of the levator ani muscle from the ischial spine to the pubis, any observed tender points or taut bands are in the obturator internus muscle. The obturator internus muscle exits the pelvis through the lesser sciatic foramen. This point of exit lies below (caudal to) the tip of the ischial spine beneath the tendinous arch. Because this is an area of musculotendinous junction where most of the obturator internus muscle fibers are represented, it is a critical point to examine for tenderness to determine if TrPs are present anywhere in the muscle. Tenderness at this location is comparable to that in the region of the musculotendinous junction of the psoas major muscle just above its attachment to the lesser trochanter of the femur (see Chapter 51).

Piriformis

See Chapter 57 for a detailed description of the intrapelvic examination of the piriformis muscle. The rectal examination is illustrated in Figure 52-4.

Sacrococcygeus Ventralis

If the sacrococcygeus ventralis muscle (when present) has TrPs, the clinician will find spot tenderness along the lower sacrum or the coccyx in a taut band running parallel to the axis of the spine. The fibers of the levator ani and coccygeus muscles can also cause tenderness at the edge of the coccyx. Pressure on an active sacrococcygeus TrP is likely to reproduce pain in the coccyx.

Vaginal Examination

In women, the bulbospongiosus muscle can be satisfactorily examined for TrPs only by vaginal examination. The patient should be placed in the lithotomy position for this approach. The bulbospongiosus and levator vaginae portions of the levator ani muscle enclose the introitus. They can be located and their strength assessed by having the patient squeeze the clinician's examining finger. Trigger points inhibit these muscles. These muscles are examined for TrPs by gentle cross-fiber pincer palpation at about the middle of each lateral wall of the introitus. When present, the taut bands are clearly delineated, tender, and contain TrPs that, when compressed, usually refer an ache to the vaginal and perineal regions, reproducing the patient's reported pain.

The clinician examines the ischiocavernosus muscle by pressing directly laterally from within the distal vagina against the edge of the pubic arch. This muscle and the crus clitoridis that it covers are normally not tender. When compressed, active TrPs in this muscle refer pain to the perineal region. If the clinician places two fingers against the lateral wall of the pelvis just beyond the inside margin of the pubic arch over the obturator membrane, the upper finger overlies the anterior portion of the obturator internus muscle, whereas the lower finger palpates the levator ani muscle. These muscles can be identified as described previously in the discussion of the levator ani muscle. Furthermore, one can distinguish the backward angulation of the anterior obturator internus muscle fibers from the transverse orientation of the levator ani muscle fibers; this is more difficult to do by rectal examination. Higher in the pelvis, the clinician palpates the bulky posterior portion of the obturator internus muscle anterior to the ischial spine.

The coccygeal region and the coccygeus muscle are more difficult to palpate from the vagina than from the rectum because one must palpate through two layers of rectal mucosa and one of vaginal mucosa. An optimum localization of all the intrapelvic musculoskeletal structures requires both rectal and vaginal examinations.

Perineal Muscles

The perineal muscles (the transverse perinei, bulbospongiosus, and ischiocavernosus) are the most superficial and contribute some support to the pelvic floor muscles. None of these muscles are likely to be identifiable unless they have taut bands that lie parallel to the direction of the muscle fibers. In both sexes, the bilateral ischiocavernosus muscle frames the pubic arch that borders the perineum beneath the symphysis pubis.

External Pelvic Examination: Men

Ideally, the patient should be placed in the lithotomy position with the feet in stirrups. If this is not practical, then he can lie supine, pulling his knees up toward the armpits. The testicles are lifted out of the way with a towel used as a sling.^{1, 4}

The bulb of the penis is palpable in the midline, between the anus and the base of the shaft of the penis, through the skin of the scrotum between the testicles. The bulbospongiosus muscle fibers angle around the bulb in a pennate fashion, more circumferential than longitudinal. Taut bands and TrP tenderness are most readily detectable if the bulb is at least partially tumescent, so that there is a firmer base against which to perform flat palpation. The ischiocavernosus muscles angle in and upward on either side of the bulb.

The transversus perinei superficialis muscle is not usually distinguishable by palpation unless it contains taut bands. The muscle fibers extend from the ischial tuberosity on each side to the fibrous perineal body that lies between the anus and the bulb of the penis. To feel these taut bands and localize the TrP spot tenderness, it sometimes helps to provide counter pressure against the external palpating finger by one finger in the rectum.

External Pelvic Examination: Women

In woman, the lithotomy position with the feet in stirrups is likewise most satisfactory for examining the superficial pelvic floor muscles. Usually, only the ischiocavernosus and transversus perinei muscles are identifiable by external palpation, and then only if they have taut bands and tender TrPs. The relationships of these muscles are clearly drawn and realistically depicted.^{1, 2, 4}

The ischiocavernosus muscle and its TrPs are more readily located by vaginal examination. The ischiocavernosus muscle lies close to, and along most of the length of, the perineal margin of the pubic bone below the pubic symphysis. On vaginal examination, taut bands become evident when compressed by cross-fiber flat palpation against the margin of the pubic bone at the mid-vaginal level and at right angles to the direction of the muscle fibers.

As in men, the transversus perinei muscle on each side spans the distance between the perineal body centrally and the ischial tuberosity laterally. Palpation must be at right angles to the direction of the fibers, and the muscle must be under slight tension to identify taut bands most effectively.

No nerve entrapments by these pelvic muscles have been demonstrated. However, the situation at the lesser sciatic foramen with regard to potential entrapment of a nerve appears analogous to sciatic nerve compression at the greater sciatic foramen, as discussed in Chapter 57. The lesser sciatic foramen has firm, unyielding boundaries: the bony ischium on one side and heavy ligaments, the sacrotuberous and the sacrospinous, on the other side. As these two ligaments fuse as they pass each other, there is no space available for pressure relief if the foramen becomes completely filled. The pudendal nerve, the internal pudendal vessels, and the obturator internus muscle with its tendon pass through the foramen. At this

point, the obturator internus muscle usually has become mainly tendinous, but there may be a sufficient number of muscle fibers passing through the foramen to compress the pudendal nerve and vessels if the muscle develops TrPs, shortens, and bulges. This is a possibility that deserves investigation when perineal pain or dysesthesia is unexplained.

4. DIFFERENTIAL DIAGNOSIS

4.1. Activation and Perpetuation of Trigger Points

In any part of the pelvic floor muscle complex, TrPs may be activated by unaccustomed eccentric loading, eccentric exercise in the unconditioned muscle, or maximal or submaximal concentric loading.⁵⁵ Trigger points in the pelvic floor muscles are sometimes activated by a severe fall, long periods of prolonged sitting, driving, bicycling, an automobile accident, or surgery in the pelvic or abdominal region. Often, the patients cannot identify a specific initiating event. However, chronic tension of the pelvic muscles coupled with psychosocial stress and dysfunction can likely contribute to the onset of CPPS and the perpetuation of TrPs in the pelvic floor muscles.⁵² Levator ani TrPs are certainly perpetuated, and perhaps activated, by sitting in a slumped posture for prolonged periods of time. Thiele radiographically demonstrated that the acute angulation of the coccygeal joints was caused by sitting on a hard surface in a slumped posture.³³ The compressed gluteus maximus muscle transmits pressure to the coccyx. Thiele attributed coccygodynia to this posture in 32% of 324 patients.³³ Cooper considered prolonged sitting in a slouched position while watching television as the factor responsible for coccygodynia in 14% of 100 patients.³¹ Lilius and Valtonen regarded this posture as an important cause of levator ani muscle spasm syndrome.³⁴ In those patients with no known initiating event, possible causes for the muscle hyperirritability and TrPs are nutritional inadequacies and/or other systemic perpetuating factors.^{56,57} Articular dysfunctions of the sacroiliac joints,⁴¹ sacrococcygeal articulation, and the lumbosacral junction may be potent aggravating sources of TrPs in these pelvic floor muscles.

4.2. Associated Trigger Points

Associated TrPs can develop in the musculature within the referred pain areas resultant from an active TrP.⁵⁷ Therefore, muscles in the referred pain areas for each muscle should also be considered for examination. Trigger points in the perineal muscles (namely, the bulbospongiosus, ischiocavernosus, and transverse perinei) are likely to present as a single muscle syndrome. On the contrary, pelvic floor muscles (for instance, the sphincter ani, levator ani, and coccygeus) are much more likely to exhibit multiple muscle involvement. Increased tension of the levator ani muscle often occurs in conjunction with increased tension of the gluteus maximus muscle as well as gluteus medius and minimus muscles.^{41,58}

The obturator internus and piriformis muscles are lower extremity muscles and, as

such, are prone to develop TrPs together, and in association with, other external rotators of the hip (gemelli, obturator externus, and quadratus femoris muscles). Trigger points in the rectus abdominis, external obliques, adductor magnus, gluteus maximus, gluteus minimus, and quadratus lumborum muscles can refer pain to specific pelvic floor areas (Box 52-1).¹⁷ The rectus abdominis muscle can refer pain to the urogenital structures as well as the rectum and the perineum. The abdominal oblique muscles can refer to the groin, testicles, suprapubic region, and bladder. The quadratus lumborum, psoas, and iliacus muscles can refer to the groin and the adductor magnus muscle to the rectum and the deep pelvic floor muscles.

Box 52-1 Common areas of referred pain from trigger points in men

Palpated Muscles	% Penis	% Perineum	% Rectum	% Suprapubic	% Testes	% Groin

Adapted from Anderson RU, Sawyer T, Wise D, Morey A, Nathanson BH. Painful myofascial trigger points and pain sites in men with chronic prostatitis/chronic pelvic pain syndrome. *J Urol*. 2009;182(6):2753-2758.

Numerous authors have used a variety of names to describe what would appear, on thoughtful consideration, to be largely myofascial pain syndromes of the pelvic musculature: tender coccyx,⁴¹ coccygodynia,^{31-33,37,59,60} coccygeal spasm,²² levator

syndrome,^{39, 61–64} levator ani syndrome,³⁸ levator spasm syndrome,⁶⁵ levator ani spasm syndrome,^{34, 66} tension myalgia of the pelvic floor,⁶⁷ pelvic floor syndromes,⁶⁸ pelvic pain syndrome,⁴⁴ proctalgia fugax,^{69–74} and obturator internus spasm.³⁶

Coccygodynia

Although the dictionary definition of coccygodynia is “pain in the coccygeal region,”⁷⁵ several authors^{37, 41} draw a sharp distinction between what they consider “true” coccygodynia resulting from traumatic injury to the coccyx and conditions elsewhere that refer pain or tenderness to the coccygeal region. One such condition is a myofascial pain syndrome.

Authors have associated pain in the region of a nontender coccyx (dorsal surface) with abnormal tension and marked tenderness of the levator ani muscle,^{32, 37, 39, 41} coccygeus muscle,^{22, –32, 37} and gluteus maximus muscle.⁴¹ Pace and Long explicitly recognized that coccygeal pain is referred from TrPs in the pelvic muscles.^{37, 68}

Levator Ani Syndromes

The levator ani muscle is associated with several conditions that cause pelvic pain: levator spasm syndrome,⁶⁵ levator ani spasm syndrome,^{34, 66} levator syndrome,^{39, 61} and pelvic floor syndromes.⁶⁸ For example, the levator ani spasm syndrome³⁴ causes pain in the sacrum, coccyx, rectum, and pelvic diaphragm. It is diagnosed by finding on rectal examination “spastic,” tender muscles in the pelvic floor (puborectalis, iliococcygeus, and coccygeus). The piriformis muscle is not included in this group as it refers pain in the buttock and down the thigh.^{31, 33, 34, 65, 68}

This levator ani syndrome was identified in 31 patients on a physical medicine service. As in other studies, most of the patients with this syndrome were women (90%). The pain was located in the sacrum (100% of patients), pelvic diaphragm (90%), anal region (68%), and in the gluteal region (only 13%). The levator ani muscle was tender and “spastic,” and 55% of these signs were bilateral. All patients experienced sharp pain in the sacral area lasting 5 to 10 minutes after digital examination. Of the women who attempted intercourse during the illness, 43% suffered dyspareunia. Forty percent of all patients reported disturbed bowel function (constipation or frequency), but none experienced painful bowel movements. Twenty percent reported pain when sitting. Only 10% of the patients failed to respond to massage therapy of the levator ani muscle, and 74% became symptom-free or had only very slight residual symptoms.³⁴

Figure 52-6. Therapeutic wand and instrument for TrP self-pressure release.

Patients with pelvic floor syndromes experience pain referred in various combinations to the buttock, underneath the sacrum, in the hip laterally, the thigh posteriorly, and from the piriformis, coccygeus, or levator ani muscles.⁶⁸ Patients reported pain when seated on hard surfaces and when sitting down or standing up from a chair. Digital examination of an involved muscle revealed trigger areas with local soreness and a tight, fibrous, nodular feel of the involved muscle.

Proctalgia Fugax

Proctalgia fugax is defined as “painful spasm of the muscle about the anus without known cause.”⁷⁵ It is characterized by paroxysms of anorectal pain in the absence of identifiable local lesions. It is not a rare condition, and 13% to 19% of apparently healthy persons surveyed have symptoms of proctalgia fugax, although most experience fewer than seven episodes per year.⁷¹ The pain usually occurs irregularly in bouts that generally show no correlation to activity or to the condition of the patient.⁷¹ Proctalgia can begin as early as

13 years of age.⁷⁴ A physician with this condition wrote an eloquent description of it.⁷²

As we have learned more about most “idiopathic” diseases, they have turned out to represent a number of conditions lumped together under one rubric. Proctalgia fugax appears to be no exception. The levator ani syndrome, noted previously, and coccygodynia, as described by Thiele,^{32,33} bear a remarkable resemblance to proctalgia fugax.

Two studies found evidence of specific causes for proctalgia fugax. One study reported pressures in the rectum and the sigmoid colon measured by inserting instrumented balloons, whereas two patients were experiencing recurrent pain.⁷⁰ The small changes in pressure observed in the rectum did not correlate with the episodes of pain, but the intermittent peaks of pressure observed in the sigmoid colon did. The greater the pressure peaks, the more likely the subject was to identify pain, which began a short time before a peak. This study suggested that the pain resulted from muscular contraction of the wall of the sigmoid colon, not from pressure within the lumen.

Trigger points stimulated by tension may exist in smooth muscle, interstitial connective tissue, or the lining of the bowel wall. In the other study, Douthwaite reported 10 physicians who examined themselves during attacks of proctalgia fugax.⁶⁹ None detected spasm of the anal sphincter muscle. They did palpate a tense, tender band on one or the other side of the rectum, which they located in the levator ani muscle. These findings are consistent with TrPs in the levator ani muscle. A few patients experience attacks of proctalgia following coitus. Peery postulates that the pain derives from exaggerated or prolonged contraction of the rectal sphincter muscle after orgasm.⁷¹ This pain might also derive from TrPs in the sphincter ani, bulbospongiosus, or ischiocavernosus muscles.

Tension Myalgia of the Pelvic Floor

Sinaki and associates⁶⁷ consolidated the various syndromes of the pelvic musculature (piriformis syndrome, coccygodynia, levator ani spasm syndrome, and proctalgia fugax) under one umbrella term: tension myalgia of the pelvic floor muscles.⁶⁷ They saw the patients in the Department of Physical Medicine and Rehabilitation at the Mayo Clinic. Nearly all of the 94 patients were between 30 and 70 years of age; most were between 40 and 50 years. Women constituted 83% of the group, which is about the usual percentage of women patients with a levator ani syndrome.⁶⁵ Pain in the coccygeal area and a heavy feeling in the rectal or vaginal region were the most prominent symptoms occurring in 82% and 62%, respectively. Defecation caused pain in 33% of the patients. All patients had tenderness of the pelvic floor muscles on rectal examination. This examination elicited localized tenderness of the piriformis, coccygeus, levator ani muscles, sacrococcygeal ligaments, and muscular attachments to the sacrum and coccyx, or some combination of the above. It is likely that many of these patients had TrPs in the tender muscles, but no mention was made of the presence or absence of taut bands or referral of pain when pressure was applied to a tender spot.

Chronic Prostatitis and Chronic Pelvic Pain Syndrome

A recent National Ambulatory Care Survey stated that there may be 20 office visits per 1000 men annually with symptoms consistent with prostatitis, with a high prevalence of 5% to 16%.^{76,77} In most instances, the malady is designated chronic prostatitis (CP), and empirical use of antibiotics represents the mainstay of therapy. However, 95% of CP syndromes in men are nonbacterial and idiopathic. They represent a nonspecific pain disorder.⁷⁸ The occurrence and persistence of pain described as perineal, testicular, penile, and lower abdominal discomfort with or without voiding symptoms is the primary presenting dilemma. A neurobehavioral perspective to this chronic pain syndrome is now emerging.⁷⁹ Pelvic pain manifests as a myofascial pain syndrome, in which abnormal muscular tension could explain much of the discomfort and abnormal urinary dysfunction seen in this disorder.^{80,81} Some investigators have evaluated and attempted to treat associated muscular tenderness of chronic pelvic pain, particularly painful TrPs.^{17,35,40,82–85} Palpation of specific, painful pelvic TrPs elicits strong association with reported patient description of painful anatomic locations.¹⁷

4.3. Associated Pathology

Many patients with urogenital dysfunction will present with TrPs in the abdominal and pelvic floor musculature. As mentioned in Chapter 49, visceral diseases can be associated with abdominal wall TrPs. Abdominal wall TrPs are especially likely to develop with any inflammatory visceral disease as a result of the viscerosomatic reflex. In fact, abdominal TrPs had a 93% predictive value for discriminating visceral from somatic pain.⁵⁰ The relationship between TrPs and visceral problems is bidirectional because modification of the sensory input to the central nervous system in the somatic areas of pain referral from visceral nociceptive input can modify the perception of pain.

Weiss reported the successful amelioration of symptoms in patients with Bladder Pain syndrome/Interstitial Cystitis (BPS/IC) using TrP release.⁸⁶ In 2002, Doggweiler-Wiygul and Wiygul found that inactivation of TrPs in the pelvic floor muscles resolved pain in patients with severe CPPS, BPS/IC, and irritative voiding symptoms.⁸⁷ In 2005, Anderson et al demonstrated that the incorporation of TrP inactivation into a multimodal approach for CPPS in men resulted in an effective therapeutic approach, by providing a reduction in pain and urinary symptoms.³⁵ Later, Anderson et al also found that TrP inactivation was associated with significant improvement in urinary symptoms, libido, and ejaculatory and erectile pain in men with CPPS.^{17,35,88} Langford et al demonstrated the effectiveness of TrP inactivation of the levator ani muscles for the management of some patients with CPPS.⁸⁹ Fitzgerald et al demonstrated a better response rate of 57% in patients diagnosed with CPPS and who were treated with TrP therapy when compared with the response rate of 21% in those patients receiving global therapeutic massage.⁸³ In some refractory cases, more aggressive therapy with varied TrP needling techniques, including dry needling, anesthetic injections, or botulinum toxin A injections, can be used, in combination with conservative therapies.⁴⁸ Recently, the works of Fitzgerald et al in 2009 and 2012,^{83,90} Konkle and Clemens in 2011,⁹¹ and Anderson et al in 2016⁹² confirm increasing evidence

that internal physical therapy and self-treatment is safe and effective regardless of gender. A neurobehavioral perspective to this chronic pain syndrome is now emerging.⁷⁹ Pelvic pain manifests as a myofascial pain syndrome, in which abnormal muscular tension could explain much of the discomfort reported by these individuals.^{80, 81}

Chronic hemorrhoids and fissures can aggravate symptoms in the related pelvic floor muscles.³⁴ Chronic inflammatory conditions within the pelvis such as endometritis, adenomyosis, chronic salpingo-oophoritis, chronic prostatovesiculitis,³⁴ Crohn disease, ulcerative colitis, irritable bowel syndrome, and BPS/IC may evoke referred pain and tenderness of the pelvic floor muscles and have been associated with the levator ani spasm syndrome.^{34, 93} However, other coexistent pelvic diseases, including ovarian cysts, pelvic adhesions, and fibroids, may have a successful response to local injection of TrPs in the levator ani and coccygeus muscles and in posthysterectomy vaginal cuff scars.⁴⁴

5. CORRECTIVE ACTIONS

When seated, the patient should use a small pillow for lumbar support and should lean against the backrest of the chair. This position maintains the natural lumbar lordosis and raises the thoracic cage anteriorly, which places the lumbopelvic spine in the optimum position. Neutral lumbar spine should be the goal in the seated, supine, prone, and standing positions. In the seated position, the weight should be placed through the “sit” bones and not through the gluteal muscles. Thiele strongly emphasized the therapeutic importance of sitting posture in patients with coccygodynia.³³ He recommended a slow shift of weight from one buttock to another and to avoid placing weight in the middle buttocks, sacrum, or tailbone. He was able to demonstrate acute angulation of the coccyx radiographically when the patient was seated in the slumped posture placing weight through the central buttocks and sacrum. He reports that his patients responded well this postural correction, and he determined this was the cause of the patients’ symptoms in 31% of 324 cases.³³ Cooper³¹ found that slumped seated posture was responsible for the pain in 14% of 100 cases with a diagnosis of coccygodynia. Other authors have made a point of teaching their patients with coccygodynia who slump while sitting to obtain a more erect seated position.³⁴ When sleeping on the side, a pillow should be used between the legs to keep the hips and the spine aligned. Proper sleep posture is addressed in Chapter 76.

When patients with TrPs fail to respond to specific local treatment, or when the beneficial results are only transient, the clinician should aggressively investigate the possibility of nutritional inadequacies or other systemic perpetuating factors for the perpetuation of TrPs. For the patient with TrPs in the coccygeus and levator ani muscles, the clinician should identify and, if possible, correct any articular dysfunctions of the sacroiliac joints and sacrococcygeal or lumbosacral articulations. Also in such cases, resolution of any chronic inflammatory condition within the pelvis, such as endometritis, chronic salpingo-oophoritis, chronic prostatovesiculitis, BPS/IC, and urinary tract infections may be critical to pain relief. Recently, a new multimodal approach to treating pelvic TrPs has been documented. Anderson et al have reported successful use of a 6-day

intensive treatment protocol for refractory CP and CPPS using TrP release and paradoxical relaxation.^{35,51,92}

If an individual experiences pain in the pelvic or coccygeal region, he or she should seek a professional consultation from a clinician who is trained in specific pelvic floor examination and management skills before performing any of the self-treatment techniques described in the following paragraphs.

Patients with TrPs inside the pelvic floor muscles can perform TrP self-pressure release techniques and deactivate their TrPs using their finger or a therapeutic wand.^{92,94} Trigger point self-pressure release combined with a self-stretch of external pelvic muscles can also reduce the influence of associated TrPs in the pelvic floor muscles. Anderson et al demonstrated the effectiveness of palpating individual muscle groups, identifying TrPs, and holding pressure for about 60 seconds.⁹² Specific physiotherapy techniques that can be used in conjunction with TrP release include voluntary contraction and release, hold-relax, contract-relax, reciprocal inhibition, and deep tissue mobilization, including stripping, strumming, skin rolling, and effleurage. This self-treatment is prescribed weekly for 4 weeks and biweekly for 8 weeks thereafter. Two authors referred to stretching treatment of the levator ani muscle in terms of “stretching the spastic muscles,”³⁴ and “retropulsion of the coccyx.”²² Dorsal mobilization of the coccyx to stretch the levator ani muscle can be included as part of the self-release procedure.

In conjunction with physiotherapy, a fundamental aspect of the protocol by Anderson is paradoxical relaxation training, which is a method of autonomic self-regulation to reduce pelvic muscle tension.³⁵ Patients received 1 hour of individual verbal instructions and a supervised practice session at weekly intervals for 8 weeks in paradoxical relaxation exercises devised by Anderson and Wise to achieve specific profound relaxation of the pelvic floor muscles.⁸⁸ The word *paradoxical* is used because patients are directed to accept their tension as a way of relaxing/releasing it. Components of the training included a specific breathing technique to quiet anxiety as well as relaxation training sessions directing patients to focus attention on the effortless acceptance of tension in specific areas of the body. Daily home practice relaxation sessions of 1 hour were recommended for a minimum of 6 months using a series of 36 instructional lessons (7-42 minutes each) to accomplish the incremental relaxation of residual tension in specific body areas, aimed at simultaneous relaxation of the pelvic floor muscles. This case study analysis indicates that this protocol was successful in producing a 72% moderate/marked improvement in subject symptoms and it may be an effective treatment approach in patients with CP/CPPS, providing pain and urinary symptom relief with the least downside risk. The treatment that was described is based on the new understanding that certain chronic pelvic pain reflects a self-feeding state of tension in the pelvic floor muscles, perpetuated by cycles of tension, anxiety, and pain. This treatment protocol aims to rehabilitate the pelvic floor muscles, while simultaneously modifying the habit of focusing tension under stress.^{35,51,92} Hubbard et al reported that TrPs show a significant increase in EMG activity during psychological stress. Therefore, a major goal in treatment is helping these patients modify their sympathetic response to stress

with therapeutic techniques such as paradoxical muscle relaxation, autogenics, imagery, and biofeedback.⁹⁵

Anderson et al studied the effectiveness of an internal pelvic therapeutic wand for self-pressure release and in 2015 conducted a study utilizing the therapeutic wand including both men and women with urologic pelvic pain syndrome.^{92,94} The patients were taught the anatomic location of their TrPs that reproduced the patient's reported pain. Brief gentle pressure was applied initially to help the patient make the distinction between the prostate (in men) and the tissue surrounding it in which TrPs typically are found. Patients were assisted in localizing their own TrPs by using the pelvic map specifically generated for them. Figure 52-6 illustrates the therapeutic wand that is made with solid ultem plastic with a distal shepherd's crook curve, a diameter of 3.2 cm, and a nitrile rubber tip that measures 1.9 cm, which allows the patient to insert a predetermined but limited length into the rectum or vagina. A movable guard prevents further advancement. The wand serves as an extended finger that is easily navigated inside the pelvis. It is used to locate and release painful internal TrPs. The algometer sensor is easily visible and allows same-time monitoring of point pressure to prevent excessive or dangerous force. The surface area of the terminal ball that is applied to the tissue surface is 1.91 cm² (0.75 in²), and the pressure gauge integrated with the wand tip provides numerical readings that correspond to applied torque pressure in the range of 0 to 2 kg/cm². If a maximum pressure were to be applied, it would equal to 8.7 psi or 0.62 kg/cm². Patients were instructed not to exceed read-out values greater than 0.34 kg/cm² and were trained to massage their own pelvic musculature without causing rectal or vaginal tissue trauma. They were also instructed to never apply pressure that elicited neurologic stimulation such as tingling, pulsation, or radiated pain such as sciatica. Per protocol, the therapeutic wand manipulations were to be performed on a regular basis, typically 3 to 4 times per week, approximately 5 to 10 minutes during each session to release the pelvic floor TrPs and areas of myofascial tenderness and restriction (Figure 52-6). Patient education included a description of the internal muscles, bladder, cervix, uterus, and prostate anatomy. The physical therapist created individualized drawings to map specific tender TrPs for each patient, the patient insertion, and safe pressure application. Patients used a water-based lubricated, vinyl or nitrile glove over the wand tip. The anus or vaginal introitus were also lubricated with a water-based gel. Care was taken to avoid any tissue dryness or resistance during insertion of the wand.

To palpate anterior TrPs, Figure 52-7A illustrates the recommended patient position, supine, with back and head elevated 45°. To palpate posterior and lateral TrPs, the patient is instructed to obtain a side-lying position (Figure 52-7B). Men were taught the anatomic location of the prostate. Brief gentle pressure is applied initially to help the patient make the distinction between the prostate and the tissue surrounding it where TrPs are typically found. Patients were assisted in localizing their own TrPs by using the pelvic map specifically generated for them, beginning at an anterior region and working toward the posterior region. After the identification of deep TrPs, patients were instructed to slowly withdraw the wand in increments of 1 to 2 in in order to recheck at a shallower depth. This was repeated until removal of the wand.

Figure 52-7. Position for TrP self-pressure release with TrP wand. A, Anterior approach. B, Posterior approach.

Women were instructed to use both vaginal and rectal wand insertion to determine optimal effectiveness. The glove covering on the tip of the wand was replaced when changing from vaginal to rectal self-pressure release or vice versa. Gradual increased pressure on each TrP started with a 10- to 12-second gentle motion technique to identify the precise TrP and then 15- to 90-second static holding pressure until tenderness around the TrP abated. Acute flare-ups of pain were expected during the initial therapeutic maneuvers as it occurs frequently in manual treatment performed by a physical therapist or physician. However, patients were discouraged from inducing further discomfort or pain beyond a 5 to 7 score on a pain visual analog scale (VAS; 0-10). For continued therapy, patients were instructed to lubricate a gloved finger and gently stretch the rectal or vaginal opening before insertion of the wand. Instruction for home usage of the wand was provided, and patients were checked up to three times for clarifications by the physical therapist or MD before discharge from the clinic. Any trace bleeding was to be promptly reported and the manual therapy discontinued for several days. In the event of continued bleeding, patients were required to have a physician evaluation and follow-up. This study demonstrated that a protocol of proper training, education, and professional supervision provides safety and efficacy for patients with Urological Chronic Pelvic Pain Syndrome (UCPPS) to perform their own internal TrP release using an internal therapeutic wand once the patient has been educated by the clinician. This study also demonstrates that the therapeutic wand is associated with a significant reduction in pelvic muscle sensitivity. The patient's ability to self-administer internal TrP self-pressure release has an obvious benefit by eliminating the need for frequent conventional physical therapy (PT) office visits. In addition, this wand makes internal TrP self-pressure release available for the many individuals suffering from pelvic pain and who do not have access to knowledgeable health care practitioners.^{92, 94}

Thiele Massage

Thiele presented the classic illustrated description for the examination and treatment by massage of the levator ani and coccygeus muscles via the rectum. He recommended rubbing the muscle fibers along their length, from origin to insertion, with a stripping motion (as when sharpening a straight razor), applying as much pressure as the patient could tolerate with moderate pain. The patient was instructed to “bear down” during massage to relax these muscles. The patient provided the massage motion for 10 to 15 repetitions on each side of the pelvis, and this treatment was repeated daily for 5 or 6 days and then every other day for 7 to 10 days. Massage only once or twice a week was found to be ineffective. Of the 223 patients with coccygodynia who were treated in this way, 64% were “cured” and 27% improved.³³

Malbohan and associates also reported the successful use of massage of these two muscles in the treatment of nearly 1500 patients with low back pain attributed to coccygeal spasm.²² Cooper³¹ reported that 81% of 62 patients with coccygodynia were relieved of pain by the Thiele type of massage, but careful instruction about proper sitting posture relieved an even higher percentage of 28 other patients.³¹ Grant and associates found that two or three levator ani massages spaced 2 to 3 weeks apart, in conjunction with heat and diazepam, provided good results in 63% of patients with the levator syndrome.⁶¹

Stripping massage is a powerful tool for the inactivation of these accessible TrPs. Massage is painful, but it can be effective when other modalities have failed. One is able to identify the taut bands and TrPs requiring attention and literally place one’s finger on the source of the pain, treating its source until the problem is resolved.

Postisometric relaxation is another technique that a patient can utilize to self-treat pain in the coccygeal region. The patient lies on the stomach with the heels rotated outward, which places the gluteus maximus muscle on partial stretch. The patient then squeezes (contract) the buttocks together gently with very little force, and maintains this for 10 seconds, and then relaxes. This is repeated four to five times. The portion of the gluteus maximus muscle that attaches to the coccyx is embryologically separate from the rest of the gluteus maximus muscle; this fact may relate to the effectiveness of the postisometric therapy for this part of the muscle.³

Clinical Considerations of Trunk and Pelvic Pain

César Fernández de Las Peñas, Joseph M. Donnelly, and Timothy Douglas Sawyer

1. LOW BACK PAIN

1.1. Overview

Back pain is second only to the common cold as a cause of lost time from work and results in more lost productivity than any other medical conditions.¹ It has been estimated to result in 175.8 million days of restricted activity annually in the United States, and at any given time, 2.4 million Americans are disabled secondary to low back pain (LBP). Of these, half are disabled. Data from the National Ambulatory Medical Care Survey from 1989 to 1990 revealed that there were almost 15 million office visits for LBP, ranking this as the fifth reason for all physician visits. The cost of treatment for patients with LBP has a major economic impact worldwide. In the United States, patients with musculoskeletal conditions account for a total annual medical care costs of approximately \$240 billion, of which \$77 billion is related to musculoskeletal conditions. In 2006, the total costs associated with LBP in the United States exceeded \$100 billion per year, with a majority of the costs associated with lost wages and reduced productivity.² This figure exceeds the costs for all other musculoskeletal conditions, which total about \$77 billion per year.³ Hoy et al⁴ showed that the burden of LBP has increased in the decades since the disability-adjusted life years related to LBP increased from 58.2 million in 1990 to 83.0 million in 2010.

The reported prevalence of LBP ranges from 25% to 75% and depends on the definition used in the epidemiologic study. In a systematic review, Jackson et al⁵ found that the prevalence of LBP was 18% for the general adult population, 31% for the elderly general population, and 44% for workers in low-income and middle-income countries. In fact, a recent meta-analysis observed that the prevalence of LBP in standard emergency settings was 4.39%, supporting the high relevance of this condition.⁶ Freburger et al⁷ examined the trends in the prevalence of chronic LBP in North Carolina comparing a representative sample in 1992 with a sample in 2006. They found the prevalence of chronic LBP for the total population more than doubled over the period, from about 4% to more

than 10%. For women of all ages and men aged 45 to 54, the prevalence and incidence nearly tripled. In addition, the number of these individuals seeking health care for treatment also increased from 71% in 1992 to 84% in 2006.⁷ Palacios-CeÁ±a et al⁸ also found that the prevalence of LBP has slightly increased in recent years in Spain.

These data demonstrate the rising prevalence of chronic LBP in society and the challenge it continues to pose for health care practitioners to find effective treatment and intervention strategies for this condition. Within the population of patients with persistent chronic pain, LBP is one of the most prevalent musculoskeletal disorders, affecting 70% to 85% of the adult population at some point in their life. Twelve months following the onset of an episode of LBP, as many as 45% to 75% of the patients still experience pain, accounting for major expenses in health care and disability systems. Despite extensive global research efforts, persistent chronic pain remains a challenging issue for clinicians and is a huge socioeconomic burden.⁹

LBP is a heterogeneous disorder that includes patients with dominant peripheral nociceptive, neuropathic, and centralized mechanisms of symptoms and may also include autonomic influences. For effective and efficient treatment for patients with LBP, classification systems, clinical practice guidelines, diagnostic procedures, and a proper understanding (subclassification) of pain mechanisms utilized in tandem with a sound clinical reasoning process are showing great promise. Recent research supports the inclusion of the patient's perspectives and biopsychosocial considerations into any classification system or clinical practice guideline related to LBP.^{10, 11} The neurophysiologic mechanism of the patient's pain report should be classified as predominantly nociceptive, neuropathic, central, or a combination thereof.^{10, 12} From the authors' perspective, the main observed deficiency in most clinical practice guidelines of LBP is the lack of inclusion of trigger points (TrPs) as a possible source of the patient's symptoms or as a contributing factor to movement impairment and nociceptive pain mechanisms, psychosocial aspects, and the contextual meaning for the patient.

The pathoanatomic approach and the structural lesion model for the treatment of LBP have failed to yield favorable results in regard to effective treatment for LBP. However, they continue to be the preferred and most used medical approaches despite their resulting in clinician and patient frustration. Classification systems have emerged in the past 20 years and are gaining in popularity as they attempt to more effectively manage patients with LBP. Guidelines for LBP developed in 1994 by the Agency for Health Care Policy and Research (AHCPR) are still being utilized by some medical professionals to manage patients with acute LBP.¹³ Recent clinical guidelines on the management of LBP in the United Kingdom and the United States have been published by the National Institute for Health and Care Excellence¹⁴ and the American College of Physicians,¹⁵ respectively. These guidelines recommend a combination of pharmacologic drugs, manual therapies, exercise, and education for the management of patients with LBP; no specific reference to TrP therapy is included in any guideline.^{14, 15} Further and specific to LBP, physicians and physical therapists usually exhibit deficiencies in adhering to the clinical practice guidelines, providing several opportunities for variation in clinical practice. This variation can be

related to those findings reported by a recent systematic review where, from more than 20 clinical guidelines on LBP, only 4 can be strongly recommended based on their quality assessed by Appraisal of Guidelines Research and Evaluation score.¹⁶

There are four primary LBP classification systems that attempt to match a treatment approach to a homogenous population of patients. These four classification systems include the McKenzie mechanical diagnosis and therapy classification,¹⁷ treatment-based classification,¹¹ movement-systems impairment model,¹⁸ and the mechanism-based classification.¹⁰ However, these four systems each have their own limitations. None is comprehensive in its approach, and they do not fully account for the variability in clinical presentations, the degree to which psychosocial factors are considered, the clinical complexity of utilizing the systems, and the possibility that a patient may be able to independently manage his or her episode of LBP without a formal treatment process. A detailed review of these classification systems is beyond the scope of this book, and readers are referred to other texts for further information. As classification systems are tested for their reliability and treatment efficacy, it is expected that there will be more “convergence of than divergence among the four systems.”¹¹

Fritz et al¹⁹ compared the effectiveness of treatment-based classification physical therapy with therapy based on AHCPR guidelines for patients with acute work-related LBP. The study included 78 subjects with acute work-related LBP of less than 3 weeks' duration and who were randomly selected to receive therapy based on classification with matched interventions or therapy based on AHCPR guidelines. The use of treatment-based classification therapy approach resulted in improved disability and quality of life as well as return to work status following 4 weeks when compared with those in the AHCPR guideline therapy group. Brennan et al²⁰ investigated treatment-matched interventions versus nonmatched interventions in 123 individuals presenting with LBP. They found that patients who received matched treatment interventions experienced better short- and long-term reductions in disability than those receiving unmatched interventions. Following a 1-year follow-up, those who received matched treatment interventions continued to have better long-term outcomes. This study supports the use of a treatment-based classification system to treat nonspecific LBP.²⁰ It is possible that the inclusion of TrP therapy into this treatment-based classification system can lead to the identification of a subgroup of patients with LBP potentially responders to its treatment.

Discogenic Pain

Disc degeneration in humans can begin as early as the third decade of life. Aging, obesity, smoking, awkward or sustained postures, vibration from transportation, excessive axial loads, and other factors accelerate the degeneration of intervertebral discs. At present, most data indicate that chronic LBP is most closely related to the anatomic structure of the intervertebral disc, particularly in patients with no obvious herniation of the nucleus pulposus, representing the clinical pathology of the disease process known as discogenic lower back pain (DLBP). DLBP is believed to be the most common disease of chronic

LBP, accounting for 39% of its incidence. Lower disc herniation represents less than 30% of cases, and other causes, such as zygapophysial joint pain, are responsible for an even lower proportion of LBP cases.

The four common classes of disc herniations are as follows: (1) *Disc protrusion* occurs when the nucleus pulposus bulges outward into the annulus fibrosis, but no damage is done to the annulus; (2) *Disc prolapse* occurs when the nucleus pulposus bulges outward into the annulus, and the annular lamina are damaged; (3) *Disc extrusion* occurs when the nucleus pulposus breaks past the outer lamina of the annulus fibrosis and into the space beyond; and (4) *Disc sequestration* occurs when the nucleus pulposus breaks free of the annulus. The mechanism of injury may occur with forward bending with or without rotation, falling onto the buttock with spine flexed, coughing or sneezing, or bearing down for a bowel movement. The disc will commonly refer pain locally into the low back, but in addition to this, the symptoms will commonly extend down posteriorly into the gluteal region. Pain that extends beyond the gluteal region and into the leg is most likely a result of nerve irritation. Symptoms can include referral to the lower thoracic or upper lumbar region, abdomen, flanks, groin, genitals, thighs, knees, calves, ankles, feet, and toes.^{21, 22}

DLBP results in a loss of lower back function secondary to pain. Although the outer annulus fibrosis of the disc may remain intact, multiple processes (degeneration, end plate injury, inflammation, etc.) can internally stimulate nociception inside the disc without nerve root symptoms. This is mainly due to the outer one-third of the annulus fibrosis having innervation from the recurring meningeal (sinuvertebral) nerve and its vascularization. Additionally, there is no root symptom and no evidence of segmental activities of the radiology. Disc disorders were first documented by Crock in 1970, and the term DLBP was coined in 1979. Since then, many scholars have conducted in-depth studies on this condition. According to epidemiologic data, DLBP is a complex disease with genetic, community, and health care implications. A systematic review looking at magnetic resonance imaging and findings of disc degeneration in adults with LBP found that disc bulge, disc degeneration, disc extrusion, disc protrusion, and spondylolysis were more prevalent in adults presenting with LBP especially at age 50 and over, when compared with asymptomatic adults.²³ Patients with a genetic susceptibility to DLBP are considered high risk and experience changes in the chemical and biologic composition of their intervertebral discs, as well as metabolic changes in their bodies. Abnormal stresses reduce the amount of water in the nucleus pulposus, inducing degeneration of the disc. The disc is then unable to bear stress evenly, and a localized increase in stress can cause structural injuries that lead to a tear or rupture in the annular fibrosis and end plate. Damage to the end plate accelerates the pathologic process of disc degeneration. During this degenerative process, cells of the nucleus generate an inflammatory response, releasing a large number of inflammatory factors or cytokines. Large epidemiologic studies have demonstrated that LBP is commonly associated with lumbar disc degeneration.²⁴ Studies have also suggested that patients with DLBP have significantly higher levels of released interleukin-1 (IL-1), IL-6, and IL-8 compared with patients with disc herniation. These proinflammatory cytokines travel into the fissure of the end plate or the outer third of the annular fibrosis, stimulate nociception

(through free nerve endings), and may produce a pain response. Therefore, DLBP requires two factors to induce pain: the existence of free nerve endings and proinflammatory cytokines. There is a high density of nerves and blood vessels in the outer third of the annulus and end plate area, which is likely the site where nociception is produced. Thus, the inflammatory response is the main pathophysiologic cause of DLBP.²⁵ Only a small proportion (approximately 20%) of LBP cases can be attributed with reasonable certainty to a pathologic or anatomic entity. Therefore, diagnosing the cause of LBP represents the biggest challenge for medical practitioners. Spinal abnormalities are more common in athletes than in nonathletes in the general population. Spinal injury patterns can be observed in athletes who are subjected to trauma. Athletes are susceptible to degenerative disc changes at an early age due to the repetitive loading activities involved in sports.²⁵

Another possible discogenic source of back pain is enthesopathy at the junction of the disc and the vertebral endplate.²⁶ Sixty-one percent of 67 patients tested experienced back pain when this area was stimulated.²⁷ Horn et al²⁸ found that insertion regions that had been exposed to overload tensile forces showed the same changes as those observed in epicondylitis in the elbow. There is a strong possibility that pain from disc tears or disc enthesopathy can cause referred pain and quite likely reflex muscle spasm of the functionally related muscles.

Medical practitioners need to be cautious in determining a cause and effect relationship between degenerative disc disease, disc bulge, and disc prolapse in patients presenting with LBP with or without lower extremity pain. In a systematic review, Brinjikji et al²⁹ reported that the prevalence of degenerative disc disease, disc bulge, and disc protrusions in asymptomatic individuals increased from 37% at age 20 to 96% at age 80, from 30% at age 20 to 84% at age 80, and from 29% at age 20 to 43% at age 80, respectively. The investigators conclude that many degenerative features identified on diagnostic imaging are more likely not associated with pain but are rather part of the normal aging process, and the results of imaging need to be interpreted in the context of the clinical presentation.²⁹

The pain referral from disc dysfunction can be similar to the referred pain from TrPs, and the muscle spasm may be a major activator of TrPs in those same muscles. This connection, however, does not assume that the pain is a result of the muscle spasm itself. It is very likely that most muscle spasms are of somatic–somatic reflex origin outside of the muscle in spasm. For nearly a century, it has been widely accepted that muscle spasms cause pain and that the pain, in turn, perpetuates muscle spasm. Mense et al³⁰ completed an extensive review of the error of this theory and concluded that clinical research and neuromuscular physiology make that assumption untenable. Nevertheless, a disc dysfunction can be associated with active TrPs. One study found an association between the presence of TrPs in the muscles innervated by the corresponding segmental level (eg, L4-L5 lesion and tibialis anterior muscle TrPs or L5-S1 lesion with gluteus medius and gastrocnemius TrPs) in individuals with lumbar disc prolapse,³¹ supporting this theory. Further, Adelmanesh et al³² found gluteal TrPs in 75% of patients with lumbar radiculopathy, supporting an association between nerve and muscle pain.

1.2. Initial Evaluation of a Patient With Low Back Pain

The first step when screening a patient with LBP is to determine if he or she is appropriate for conservative care and, in this case, for manual therapy. The clinician must perform a careful historical examination and a motor and sensory examination to establish if the patient has any red flag indicators for referral. Further, clinicians should also be conscious of potential psychosocial factors associated with LBP that the patient can exhibit that may contribute to the patient's persistent pain and related disability. For instance, fear-avoidance beliefs have been associated with poor treatment outcome in patients with LBP of less than 6 months³³; so, earlier identification is relevant.

Emphasis has been placed on matching the patient to optimal interventions based on the identification of signs and symptoms collected during the interview and physical examination. It is, therefore, important to identify the main pain complaint (eg, numbness, weakness, location of symptoms) of the patient to orientate the examination. A body pain drawing is beneficial to establish a pattern and location of the pain. It helps determine if the pain is mainly located in the lumbar spine or radiates and, if it radiates, the distribution of the symptoms. In addition, the quality of the pain can help identify the main tissue responsible for the symptoms or pain referral. Palpation of those muscles that refer pain to the region, for example, the psoas, iliocostalis lumborum, quadratus lumborum, gluteus medius, piriformis, and other muscles, is extremely important.

The physical examination can include elements of observation (lumbar spine posture), active spinal motion testing, palpation, muscle length, muscle strength, passive physiologic and accessory motion testing, as well as special tests for identifying radiating symptoms. All planes of motion of the lumbar spine should be assessed with active and passive movements. Responses during active movements associated with symptoms or pain noted during the clinical history and presence of aberrant movements should be considered highly relevant. For instance, directional preference (movement reducing the symptomatology—*Centralization*) during lumbar spine range of motion can determine a potential therapeutic line of attack. Specific tests of joint mobility or lumbar spine instability (eg, prone instability test), or other additional tests, such as the straight leg raise test, should also be considered. Motor control examination of abdominal wall musculature, particularly the transversus abdominis and lumbar multifidi muscles, should be included. Finally, clinical examination of the hip, sacroiliac joint, and sometimes thoracic spine may also be warranted to determine their contribution to LBP. For instance, the patient can be examined supine for TrPs in the iliopsoas or abdominal wall muscles. In side-lying, quadratus lumborum, tensor fascia latae, gluteus medius, gluteus maximus, gluteus minimus, and latissimus dorsi muscles can be examined. Once prone, the examination continues with the lumbar and thoracic paraspinal, multifidi, and piriformis muscles.

1.3. Trigger Points and Low Back Pain

Several authors suggest a potential role in and importance of TrPs as a contributing factor to LBP.^{34–36} Bonica and Sola³⁷ illustrated 11 specific muscles with TrPs that cause LBP.

Rosomoff et al³⁸ found that 96.7% of 283 patients diagnosed of nonspecific LBP because they had “no objective findings” on routine physical examination exhibited active TrPs. Among 18 patients with lumbago, Dejung³⁶ found that 14 had TrPs in the gluteal muscles, 13 had TrPs in the abdominal muscles, and 8 had TrPs in the paraspinal muscles; additionally 5 other muscles had also TrPs. Most of the patients had multiple muscles with TrPs. One day following TrP injection therapy, patients experienced a 75% reduction in symptoms, suggesting that TrPs were a potential source of symptoms and a contributing factor. However, a cause and effect relationship could not be proven. Teixeira et al³⁹ identified the presence of active TrPs in the quadratus lumborum and gluteus medius muscles in 85.7% of patients suffering from LBP associated to a postlaminectomy pain syndrome. Chen and Nizar⁴⁰ reported that 63.5% of patients with chronic LBP exhibited TrPs in the piriformis and lumbar paravertebral muscles. Patients with nonspecific LBP have increased numbers of latent TrPs compared with their healthy counterparts, and those with a greater number of active TrPs have a higher pain intensity. A more recent study found that the most prevalent muscles involved in nonspecific LBP include the iliocostalis lumborum, quadratus lumborum, and gluteus medius muscles.⁴¹ Controlled research studies critically examining the role of TrPs in LBP are conspicuous by their absence and are urgently needed.

Occasionally, one muscle will be responsible for the symptoms as presented, but it is much more common for several muscles to contribute to overlapping pain patterns and related symptoms. The composite pattern resulting depends upon the extent of muscle involvement. No two patients present exactly the same picture.⁴² Therefore, it would be reasonable to suggest that inactivation of active TrPs in patients with LBP could often at least help relieve pain symptoms. There is preliminary evidence of this.⁴³

Figure 53-1 illustrates an example of a composite pattern produced by TrPs in four muscles that commonly refer pain to the lumbosacral region. Figure 53-2 illustrates a comparable composite pattern produced by TrPs in four muscles that refer pain to the pelvic region. Thus, it is safe to say that the presence of TrPs is very common in LBP, and that a proper examination and treatment of them will help resolve pain and improve motor control to enable return to functional activities. A significant number of patients with this condition have had multiple treatments of either medical intervention, including steroid injections, nerve blocks, gabapentin, opiates and nonopiate pain relievers, as well as traditional physical therapy, osteopathic or chiropractic manipulation and multiple modalities, including electrical stimulation, ultrasound, or laser therapy with varying outcomes.

Figure 53-1. Individual referred symptoms of some TrPs that refer pain to the lumbosacral region. The composite pain pattern in the center figure represents the summated referred symptoms a patient may experience.

Figure 53-2. Individual pain patterns of some TrPs that refer pain to the pelvic region. The composite pain pattern in the center figure represents the summated referred symptoms a patient may experience.

2. SACROILIAC JOINT DYSFUNCTION

2.1. Overview

Sacroiliac (SI) joint pathology refers to dysfunction of the innominate articulations that creates pelvic pain. Visser et al⁴⁴ found that 41% of patients with LBP and leg pain had mechanical pain of the SI joint. Further, Madani et al⁴⁵ observed that 72.3% of subjects who had imaging with confirmed herniated disc pathology also displayed clinical signs and

symptoms consistent with SI joint pathology. Nevertheless, the SI joint as a source of LBP is a topic of debate. The gold standard for verifying the SI joint as the source of pain is the use of intra-articular anesthetic injections. The prevalence of intra-articular pain arising from the SI joint has been estimated to be as low as 13% and as high as 30%.^{46–48} Maigne et al⁴⁹ found the prevalence to be 18.5% when utilizing double diagnostic anesthetic blocks.

Dreyfuss et al⁵⁰ stated that known causes of pain in this region are spondyloarthropathy, crystal and pyogenic arthropathy, fracture of the sacrum and pelvis, and diastasis resulting from pregnancy or childbirth. Other traditionally accepted mechanisms of injury typically include activities that require opposing innominate motion in which one innominate is posteriorly rotated and the other is relatively anteriorly rotated. Falling on to the buttock or heavy lifting may be reported as well. It is important to consider that the SI joint has minimal movement;^{48, 51} these potential etiologic mechanisms mostly represent changes in compressive forces on the SI joint.

Common signs and symptoms include pain in the region of the sacral sulcus, just medial to the posterior superior iliac spine, and pain that may travel distally into the buttock and posterior thigh. The symptoms generally do not extend beyond the knee or up to the lumbar spine, but Slipman et al⁴⁶ noted that occasionally symptoms can travel as far distal as the foot and may also wrap around anteriorly to the groin and sometimes to the abdomen.⁴⁶ The symptoms may be aggravated by walking, running, or cycling, movements of sit to stand, twisting activities, rolling over in bed, heavy lifting, and prolonged sitting or standing.

2.2. Initial Evaluation of a Patient With Sacroiliac Joint Dysfunction

Clinical examination of the SI joint is controversial. Pain patterns induced by this joint are debatable, and the ability to detect mobility impairments remains questionable.⁴⁸ Pain patterns can help for a first suspicion of associated SI joint pathology. A rectangular pain area just distal to the posterior superior iliac spine has been proposed to be the most often symptomatic pain area for SI joint.^{46, 52} However, there is high variability in pain referral from SI joint with significant overlap in lumbar pathology, probably due to the complex and variable innervation noted with a proposed contribution of lumbar and sacral roots.⁵³

Examination may reveal an apparent leg length discrepancy, thereby affecting both lumbar and thoracic frontal plane curvature. When observed dorsally, there may be the presence of a scoliotic curve. Tests that identify SI joint pathology are classified into the following three categories: motion palpation test, pain provocation tests, and static palpation test for symmetry. The literature shows that pain provocation tests were the most reliable, with palpation being inherently unreliable.⁵⁴ Similarly, validity of palpatory and motion symmetry tests for the SI joint has consistently been found to be limited. Therefore, the use of a cluster of five tests (ie, the thigh thrust test, the compression test, the distraction test, torsional stress test [Gaenslen test], and sacral stress test) emphasizing sacroiliac provocation along with active straight leg raise test and the stork test is an

effective evaluation of the SI joint, especially when repeated motions of the lumbopelvic spine have no influence on the symptoms.^{55–57} Laslett et al⁵⁸ found that the presence of three of these five tests provides a positive likelihood ratio (+LR) of 4.16. Any of these tests is considered positive if they reproduce the patient's comparable sign, that is, familiar symptoms or pain recognition.

2.3. Trigger Points and Sacroiliac Joint Dysfunction

Local pain from SI joint dysfunction could be also mimicked by pain referral from TrPs in some trunk muscles, such as the quadratus lumborum or gluteus medius muscles. When an apparent iliac upslip or innominate shear dysfunction is present, the associated disorder and movement dysfunction at the SI joint may be sustained by inhibition and persistent asymmetrical muscle tension on the pelvis cause by gluteus minimus and medius TrPs. Sacroiliac joint dysfunction can co-exist with piriformis TrPs, and ventral coccygeal tenderness is often associated with a SI joint articular dysfunction.⁵⁹ The other muscles likely to be implicated in SI joint dysfunction are the thoracolumbar paraspinals, multifidi, and gluteus maximus muscles. Treatment of SI joint dysfunction requires an effective treatment of associated TrPs, in particular the quadratus lumborum muscle, followed by correction of the articular dysfunction if present or vice versa. In the case of hypermobility, treatment utilizing a stretching technique would be contraindicated. When there are TrPs in muscles that cross hypermobile joints, these TrPs should be inactivated using techniques that do not extend the muscle to its maximum length.

3. LUMBAR STENOSIS

3.1. Overview

Lumbar stenosis may be either central stenosis or lateral stenosis. Central stenosis is a narrowing of the central vertebral canal, and lateral stenosis is a narrowing of the intervertebral foramen. Central stenosis may compromise the cauda equina, whereas lateral stenosis may compromise the spinal nerve roots. Either central or lateral recess stenosis is a degenerative process without a specific history of macro-trauma. It is more common in people with a long history of manual heavy labor jobs and repeat movements of bending or heavy lifting, making the case that stenosis results from micro-trauma. People with lumbar stenosis usually report an insidious onset of LBP.⁶⁰ Central stenosis can crowd the lumbar spinal cord or the cauda equine, causing upper motor neuron signs including hyperreflexia, hypertonia, and decreased strength and sensation below the level of pathology. Impingement of the cauda equina can cause lower motor neuron signs, including hyporeflexia, hypotonia, and decreased strength and sensation (saddle anesthesia). Patients with either central or lateral stenosis have low tolerance for trunk extension postures or activities. Patients with lateral stenosis may report pain or sensory changes in one or both lower extremities. Pain may be located below the buttocks or the knees.⁶¹

3.2. Initial Evaluation of a Patient With Lumbar Stenosis

Physical examination findings include decreased lumbar extension with pain reproduction. Lower extremity pain is reproduced with trunk extension or active hip extension. A positive two-staged treadmill test will show increased time needed to develop symptoms when walking uphill and less recovery time needed when compared with walking on a level surface.⁶² Neurologic findings may include an abnormal Romberg test, sensory vibration deficit, lower extremity weakness, and decreased peripheral deep tendon reflexes.⁶¹

3.3. Trigger Points and Lumbar Stenosis

Because of the degenerative nature of spinal stenosis, symptoms are most likely managed with therapeutic strategies for keeping the intervertebral foramina relatively open by biasing the lumbar spine into a flexion posture combined with mobility exercises to maximize hip and thoracic extension range of motion. Treatment should include abdominal muscle neuromuscular reeducation along with manual therapy to restore lumbar accessory motion, stretching of the one and two joint hip flexors, and progressive body-weight-supported treadmill walking program.⁶³ If back pain and lower extremity pain are present, TrPs that typically refer to these areas should be specifically assessed. If present, the patient should be taught TrP self-pressure release, instructed in proper resting and active postures, and prescribed a home exercise program. It is highly unlikely that TrP therapy alone will have any long-lasting effect; however, it should be a part of the comprehensive rehabilitation program that may reduce the pain and discomfort associated with the myofascial contributions to the pain presentation.

4. LUMBAR INSTABILITY

4.1. Overview

Identification and management of lumbar spine instability is a challenge for clinicians and their patients. Chronic lumbar instability is presented as a term that can encompass two types of lumbar instability: mechanical (radiographic) and functional (clinical) instability. The components of mechanical and functional instability are presented relative to the development of diagnosis and management. Lumbar segmental instability can be caused by several factors. The excessive intervertebral motion may be due to degenerative changes in the intervertebral disc, spondylolisthesis, fracture, trauma, or a previous surgical procedure. This excessive motion can put pressure on the spinal cord, cauda equina, or nerve roots. Excessive intersegmental motion can also put undue stress on the facet joint capsule or ligaments. The primary age group to experience lumbar instability is 20- to 30-year-olds. Epidemiologic studies using a diagnosis of functional instability are lacking. Puntumetakul et al⁶⁴ found the prevalence of clinical lumbar instability in Thai rice farmers to be 13%.

Patients with lumbar segmental instability have been proposed as a unique subgroup of patients with LBP; there have been conflicting studies regarding criteria to define this

condition. Hicks et al⁶⁵ described a clinical prediction rule for patients with LBP who would be successful with a stabilization classification for treatment (clinical lumbar instability). These authors found that patients who achieve positive outcomes are more than 40 years of age, have a positive prone instability test, the presence of aberrant movements, and a passive straight leg raise test $>90^{\circ}$.⁶⁵

4.2. Initial Evaluation of a Patient With Clinical Lumbar Instability

A postural examination can reveal posterior skin creases in the trunk and a limited trunk range of motion in a specific direction, with a possible painful arc of motion. The patient may demonstrate excessive range of motion and abnormal (aberrant) quality of movement with hinging or catching. For instance, an instability catch or hinge in returning from spinal flexion, as well as functional asterisk signs that reproduce the patient's symptoms during such activities as going from sit to stand or any other transitional positions, can appear during the active range of motion assessment. In fact, the most common objective factors related to clinical lumbar instability include poor lumbopelvic control such as segmental hinging or pivoting with movement, poor proprioceptive function, poor coordination and neuromuscular control such as juddering or shaking during movement, and decreased strength and endurance of local muscles at a level of segmental instability. Abnormal accessory movement testing, indicating loss of stiffness or increased neutral zone at one segment, is usually present. Passive tests commonly used for clinical lumbar instability include passive accessory intervertebral motion, passive physiologic intervertebral motion, prone instability test, and the prone lumbar extension test.⁶⁶ Ferrari et al⁶⁷ reported that the prone instability test and the passive lumbar extension test exhibited the highest clinical utility to detect lumbar instability in specific LBP. However, the reliability of these tests has been questioned by others.⁶⁸

4.3. Trigger Points and Lumbar Instability

There may be palpable taut bands indicative of TrPs and facilitation of postural muscles. Therefore, if pain is present, a TrP evaluation should be performed in patients with a suspicion of clinical lumbar instability. However, with this diagnosis, rehabilitation should include proprioceptive training along with specific exercises to facilitate recruitment of the stabilizing muscles, including the deep fibers of the multifidi, transverse abdominus, diaphragm, and pelvic floor muscles as well as TrP therapy. All these muscles should be carefully examined for TrPs, either active or latent, as they could cause dysfunctional muscle activation patterns, early fatigue, and prolonged recovery period. It is possible that TrPs in the local stabilizer muscles can perpetuate muscle imbalance, hence promoting pronounced clinical lumbar instability.

5. LUMBAR LIGAMENT SPRAIN AND STRAIN

5.1. Overview

Lumbar spine sprain and lumbar spine strain are often used interchangeably. A strain refers to injury to a musculotendinous structure, whereas a sprain is a capsuloligamentous injury that arises when ligaments become torn from their attachments, affecting the important relationship between bone and ligament. LBP is sometimes diagnosed as a lumbar spine sprain or muscle strain. Symptoms can be localized to the lumbar spine or they can radiate down into the buttocks. In general, this pain will not spread into the legs, which differentiates lumbar sprain from certain other spinal injuries. Pain will be exacerbated during physical activity and should be reduced during periods of rest. The patient may experience occasional spasms in the lower back. These symptoms are all consistent with lumbar sprain and muscle strain, but if the patient feels weakness in the back, or has poor bowel or bladder control, it may be a more serious injury requiring immediate attention.

The structures of the spine are working almost constantly to maintain strength and balance during innumerable activities and therefore the muscles and ligaments of the lumbar spine can be prone to injury through repetitive overuse and micro-trauma. A single incident involving a twisting maneuver or sharp movement can cause injury. There are many other ways with which a sprain can occur, but some recurring contributing factors have been singled out. For instance, unsuitable lifting techniques and sustained awkward postures can cause injury to the lumbar spine. Other risk factors are a lack of sufficient flexibility and strength in the muscles of the back or lower extremities, especially if you rely greatly on the lumbar spine for static and dynamic postures. Additionally, obesity, smoking, deconditioning, poor body mechanics, limited hip flexibility/mobility, and poor trunk strength/dynamic stabilization may be contributing factors.

5.2. Initial Evaluation of a Patient With Lumbar Ligament Sprain

During the physical examination, patients usually present with painful, limited trunk motion in a given direction, whereas other motions may be within normal limits. Active and resistive hip motions may elicit symptoms, and a Gower sign may be present. In cases of complete ligamentous tear, excessive motion may be present but difficult to accurately assess. Clinical diagnosis of lumbar ligament sprain is highly difficult, and it will be based on the presence of a traumatic event as reported in the clinical history. Palpation of the ligament, for example, interspinous or iliolumbar, is usually extremely painful and can elicit pain referral.

5.3. Trigger Points and Lumbar Ligament Sprain

Clinicians should consider that lumbar ligament sprains can also be associated with muscle dysfunctions. Jinkins⁶⁹ observed that individuals with lumbosacral interspinous ligament sprain also exhibited associated intrinsic spinal muscle degeneration in the innervated muscles such as multifidi muscles. An important differential diagnosis of symptoms caused by TrPs in thoracolumbar paraspinal muscles includes articular dysfunctions. The chief

complaint cause by TrPs in thoracolumbar paraspinal muscles is pain in the back and buttocks. Pain with ligament sprain injury is usually located in the low back and buttocks as well. Trigger points in the following muscles must be considered in a patient with lumbar ligament sprain: thoracolumbar paraspinals, multifidi, lower rectus abdominus, iliopsoas, gluteus medius, gluteus maximus, and quadratus lumborum muscles.

Typical rehabilitation for this condition may begin with exercises in pain-free motions, followed by basic stabilization exercises of the abdominals, hip extensors, hip abductors, and spinal extensors, followed by dynamic and functional stabilization exercises. The only problems that may arise with an exercise regime is that if TrPs have developed in any of the muscles mentioned earlier, the effects of exercise could be limited. Exercises can exacerbate pain due to TrP referral even in the absence of reinjury.

6. SPONDYLOLYSIS AND SPONDYLOLISTHESIS

6.1. Overview

Spondylolysis and spondylolisthesis are common causes of LBP in young athletes where overloading of the posterior elements of the lumbar spine is repetitive or excessive.⁷⁰ Spondylolysis is a defect in the pars interarticularis, whereas a spondylolisthesis is a fracture defect that widens and allows the superior segment to slip forward on the inferior segment. The injury most often occurs in children and adolescents who participate in sports that involve repeated stress on the lower back, such as gymnastics, football, and weight lifting. People with this condition have no symptoms. In general, people with spondylolisthesis will report mild-to-moderate back and/or leg pain that is increased with extension positions. The pain may radiate into the buttocks, posterior thighs, or lower legs. Degenerative spondylolisthesis will present with more of a history of lumbar stenosis, and because of instability, patients may complain of catching or shifting in the back with motion. For most patients with these conditions, back pain and other symptoms will improve with conservative treatment. This always begins with a period of rest from sports and other strenuous activities. Patients who have persistent back pain or severe slippage of a vertebra may need surgery to relieve their symptoms and to allow for a return to sports and activities.⁷¹

6.2. Initial Evaluation of a Patient With Spondylolysis and Spondylolisthesis

The postural examination often reveals an increase in the lumbar lordosis, painful limited trunk extension, hamstring length deficits, weakness/pain in one or both lower extremities, and local pain with posterior–anterior provocation. Neurologic signs may be present depending on the severity of the condition, and in the case of spondylolisthesis, there may be a step-off deformity when palpating the spinous processes. Radiographs in the oblique plane will show a fracture in the region of the pars interarticularis, commonly referred to as “scotty dog collar fracture.”

6.3. Trigger Points and Spondylolysis and Spondylolisthesis

Rehabilitation includes avoiding activities that aggravate the symptoms and the administration of anti-inflammatories. Bracing with a thoraco-lumbo-sacral orthosis may be included along with exercises such as muscle strengthening for trunk stabilization biased toward flexion-based exercises and hip and hamstring mobility/flexibility exercises. Trigger points are not common with this condition; however, if pain is persistent in the low back, buttocks, and posterior thighs, then the associated TrPs for those areas should be examined and treated, especially the iliopsoas, quadratus lumborum, and abdominal muscles. In fact, there is evidence supporting that patients with isthmic spondylolisthesis suffer selective atrophy of their lumbar multifidi muscles, whereas their erector spinae muscles undergo a compensatory hypertrophy.⁷² This compensatory mechanism could activate TrPs in the paraspinal muscles.

7. ANKYLOSING SPONDYLITIS

7.1. Overview

Ankylosing spondylitis (AS) is a chronic inflammatory disease commonly referred to as one of the spondyloarthritides. Typically, it affects the spine and the SI joints. Occasionally, other joints such as the shoulders or hips are involved. Eye and bowel problems may also occur. Between 0.1% and 1.8% of people are affected.⁷³ Back pain of inflammatory features and morning stiffness are the characteristic symptoms of AS. Symptoms often have periods of exacerbation and dormancy that can result in a delay in the diagnosis.⁷⁴ Stiffness of the affected joints generally worsens over time. There is a 5:1 ratio of men to women affected, and onset is typically between the ages of 30 and 50, though it may occur earlier in life.⁷⁴ The cause of AS is currently unknown, but it is believed to involve a combination of genetic and environmental factors. The underlying mechanism is believed to be autoimmune or autoinflammatory. Diagnosis is typically based on the symptoms with support from medical imaging and blood tests. There is no cure for AS, but potential treatments, eg, medication, exercise, and surgery, may improve symptoms and slow the progression of the disease. Medications include nonsteroidal anti-inflammatory drugs (NSAIDs), steroids, disease-modifying anti-rheumatic drugs (DMARDs) such as sulfasalazine, and biologic agents such as infliximab.

Common symptoms are inflammatory lumbar pain rather than mechanically based pain. Patients typically report onset of gluteal pain and stiffness that is often described as dull and hard to localize. Pain may alternate from side to side and is typically intermittent at the onset, and as the pathology progresses, the pain usually affects both gluteal regions and becomes constant. The pain is occasionally referred toward the iliac crest, greater trochanter region, or down the posterior thigh with associated hamstring length deficits. One of the main features of lumbar pain associated with AS is that the pain wakes the patient up at night, and only walking relieves the pain. Lumbar pain and stiffness may

occur along with gluteal pain and is usually worse in the AM for approximately 1 to 2 hours after waking. Pain and enthesitis may be present in the Achilles tendon and plantar fascia and may also affect the knees and shoulders.⁷⁴ Redness in one eye at a time and photophobia may also be present. Among all therapeutic tools, exercise has been demonstrated to be the most effective for these patients.⁷⁵

7.2. Initial Evaluation of a Patient With Ankylosing Spondylitis

Postural examination typically reveals a flattening of the lumbar lordosis, an increased thoracic kyphosis, upper cervical spine extension with a forward head posture, and knees and hips in slight flexion. As the disease progresses, the intervertebral joints fuse, resulting in a Bamboo Spine.⁷⁴ There will be an associated loss of range of motion that correlates with these changes.

7.3. Trigger Points and Ankylosing Spondylitis

Because pain and stiffness can be a significant factor in the progression of the disease, it warrants an examination for the presence of TrPs as a contributing factor to the patient's pain complaints. A pain drawing will be beneficial to assist the clinician in identifying which muscles to examine. Very commonly, the patient may report symptoms in the gluteal region, lateral proximal thigh and down the posterior thigh, to heel and foot. Symptoms in the gluteal region can be induced by TrPs in the iliocostalis lumborum, longissimus thoracis, gluteus medius, minimus and maximus, and quadratus lumborum muscles. Symptoms in the hip and posterior thigh region can be related to TrPs in the quadratus lumborum, tensor fascia latae, hip lateral rotators, and hamstring musculature. Symptoms in the heel and plantar surface of the foot can be reproduced by stimulation of TrPs in the gastrocnemius, soleus, tibialis posterior, and the muscles on the plantar aspect of the foot. Rehabilitation programs should include treatment of those TrPs in conjunction with stretching and strengthening exercises that promote efficient posture and spinal mobility.⁷⁵ Diaphragmatic breathing exercises should be incorporated to increase thoracic, rib cage, and chest wall mobility, as well as pulmonary function. Cardiovascular endurance exercises will also help maintain and progress overall fitness. The prognosis for AS is good in the long term.

8. CHRONIC PELVIC PAIN

8.1. Overview

Chronic pelvic pain (CPP) is defined as “non-malignant pain perceived in the structures related to the pelvis of either men or women.”⁷⁶ CPP has multiple potential etiologic features, and its prevalence ranges from 15% to 20%.⁷⁷ Several pain syndromes are included within this term: bladder pain syndrome, endometriosis pain syndrome, interstitial cystitis, prostatic pain syndrome, dysmenorrhea, and vulvodynia are a few

examples.⁷⁶ Chronic pelvic pain syndrome (CPPS) is relatively poorly understood, even by some specialists in genitourinary dysfunction, and certainly by the general health care community. There is evidence suggesting that CPP can become chronic⁷⁸ and that sensitization of the central nervous system is involved in these syndromes^{76,79}; therefore, examination and treatment programs should be directed at both biomechanical and neurophysiologic issues.⁸⁰

From a biomechanical point of view, a connection between chronic sacroiliac dysfunction and a wide range of pelvic floor–related problems (CPP) has been suggested, and many patients diagnosed with SI pain also have CPP.⁸¹ In addition, there is evidence supporting an interaction between TrPs and central sensitization in women with CPP associated to endometriosis.⁸²

Considering psychological factors is important when treating patients with CPP, because they often exhibit anxiety, depression, alexithymia, catastrophizing beliefs, fear-avoidance behaviors, or hypervigilance.^{83,84} These psychological variables may be related to the fact that CPP is usually associated with sexual dysfunction.⁸⁵ Treatment of CPP should be biopsychosocial, in nature including physical and psychological approaches.^{86,87}

8.2. Initial Evaluation of a Patient With Chronic Pelvic Pain

Clinical examination of a patient with CPP should include active and passive movements of the lumbar spine and the reproduction of symptoms (directional preference) with movement or during a static position, for example, sitting. Symptoms usually appear with prolonged sitting positions when the pelvic floor musculature is under stress. There is not a clear posture of the spine (lordosis, flattened, sideways) associated with CPP. Women with CPP, particularly if they had endometriosis or pain related to the menstrual cycle, can adopt an antalgic posture in lumbar flexion during prolonged static positioning.

One of the most relevant examinations for patients with CPP is evaluation of abdominal wall muscles. In fact, motor control impairments, such as delayed transversus abdominis muscle activation, changes in multifidi muscle morphology, or pelvic floor musculature hypertonicity, can be present. Abdominal TrPs should be explored in all individuals with CPP because they are the most prevalent^{88,89} and also predict evidence of visceral disease in 90% of patients with symptoms compatible with CPP.⁹⁰ Other muscles that could exhibit TrPs in CPP include the gluteal, adductors, internal and external rotators of the hip, piriformis, iliopsoas, quadratus lumborum, lumbar multifidi, thoracolumbar paraspinals, and obviously, the pelvic floor muscles. In fact, examination of pelvic floor muscles is an important element of the clinical evaluation of women with CPP.⁹¹ The pelvic floor muscles may be hyper or hypotonic in patients with CPP; clinicians should also explore the SI and hip joints to determine any joint impairment that could be involved. Since abdominal TrPs may be perpetuated by paradoxical respiration, the examination of the breathing patterns and diaphragm muscle should also be conducted. Anderson⁹² has described palpation and treatment protocols for locating TrPs associated with prostatitis symptoms. Box 53-1 describes TrPs that may be associated with somatovisceral symptoms.

Box 53-1 Somatovisceral referred symptoms from trigger points in the abdominal muscles

Referred somatovisceral symptoms from abdominal muscle trigger points

Muscles	Referred symptoms
External abdominal oblique	Heartburn and symptoms associated with hiatal hernia, deep epigastric pain
Lateral abdominal wall (external and internal abdominal oblique)	Testicular pain, lower quadrant pain
Internal abdominal oblique	Pain in urinary bladder region, urinary frequency or retention, chronic diarrhea
Rectus abdominis (upper portion)	Nausea, epigastric distress, symptoms of cholecystitis, and peptic ulcer.
Rectus abdominis (umbilical level)	Abdominal cramping, abdominal colic
Rectus abdominis (lower portion)	Dysmenorrhea
Right lower abdominal region	Diarrhea, diverticulosis, gynecologic symptoms
Just proximal to pubis	Urinary frequency and retention, detrusor muscle spasm
Region of McBurney point	Ipsilateral lower quadrant and penis

8.3. Trigger Points and Chronic Pelvic Pain

It is important to consider that TrPs may mimic visceral pain and also induce visceral disorders, that is, the somatovisceral effect. Conversely, a visceral disease can also influence somatosensory perception and can activate TrPs, that is, the viscerosomatic effect, which may perpetuate pain and other symptoms after the patient has recovered from the initiating visceral disease.⁹³ Therefore, understanding the reciprocal somatovisceral and viscerosomatic effects regarding TrPs helps unravel some CPPSs. This connection is supported by the fact that abdominal TrPs have a 93% positive predictive value for visceral disease, particularly for CPP.^{90, 94} Studies have found that the presence of abdominal TrPs along with abdominal and perineal cutaneous allodynia discriminated visceral from somatic sources of pain.⁹⁴

There is clear evidence associating CPP with the presence of TrPs.^{95, 96} In fact, the clinical guideline published by the European Association of Urology suggests that TrPs should be considered in the diagnosis of CPP as there is evidence demonstrating the relationship between CPP and TrPs.⁷⁶ Moldwin and Fariello⁹⁷ observed that active TrPs of the pelvic floor muscles were responsible for some, if not all, symptoms related to these pain syndromes in as many as 85% of individuals suffering from urologic, colorectal, and gynecologic pain syndromes. Anderson et al⁸⁸ identified the most common location of TrPs in men with CPP: pubococcygeus or puborectalis (90%), external oblique (80%),

rectus abdominis (75%), adductors (19%), and gluteus medius (18%) muscles.

Therapeutic approaches aimed at deactivating TrPs, as well as normalizing joint and soft tissue imbalances, together with concomitant postural and breathing pattern retraining, have been shown to be effective for modulating associated symptoms in individuals with various CPPSs, including interstitial cystitis, stress incontinence, irritable bowel syndrome, and chronic prostatitis, among others.^{98–103} For that reason, the potential role of TrPs in CPPSs should always be considered when treating these patients.

9. THORACIC AND CHEST PAIN

9.1. Overview

Thoracic and chest pain are common presentations in general practice, which because of diverse and potentially serious causes, particularly related to potential underlying visceral diseases, requires careful and sometimes urgent assessment.¹⁰⁴ Although it is important to rule out life-threatening medical conditions in a primary care setting, musculoskeletal conditions are the most common causes of thoracic and chest pain.¹⁰⁵ Even so, they represent only 6.2% of patients presenting to hospital emergency departments with chest pain.¹⁰⁶ Briggs et al¹⁰⁷ found that the 1-year prevalence of musculoskeletal thoracic spine pain ranged from 3.0% to 55.0% in an adult working population. A systematic review identified that the point prevalence for thoracic pain of musculoskeletal origin ranged from 4% to 72%, the 1-year prevalence from 3.5% to 34.8%, and the lifetime prevalence from 15.6% to 19.5%.¹⁰⁸ The prevalence of thoracic spine pain is higher in women than in men, with a female-to-male ratio of 2:1.¹⁰⁹ Eslick et al¹¹⁰ found that 35% of individuals reporting noncardiac chest pain also described pain that could be musculoskeletal in origin. Leboeuf-Yde et al¹¹¹ reported a 1-year prevalence of radiating pain from the thoracic spine to the chest of 5%. Looking at the clinical features and causes of chest pain in children referred to a pediatric cardiology unit, Sert et al¹¹² found that the most common causes were musculoskeletal (37.1%), and only 0.3% were cardiac in nature.

It is suggested that the causes of musculoskeletal thoracic and chest wall pain can be grouped into three categories¹⁰⁵: (1) conditions causing isolated musculoskeletal pain (eg, costochondritis, lower rib pain syndromes, pain from thoracic spine/costovertebral joints, or muscle referred pain from TrPs); (2) rheumatic diseases (eg, fibromyalgia syndrome or rheumatoid arthritis); and (3) systemic nonrheumatologic conditions (eg, osteoporotic fracture, tumors). For instance, costochondritis, an acute and often temporary inflammation of the costal cartilage, is a common cause of chest pain¹¹³ with a prevalence of 13%.¹¹⁴ The report of symptoms from costochondritis is similar to that of chest pain associated with myocardial infarction.¹¹⁵ Severe cases of costal cartilage inflammation that also involve painful swelling are sometimes referred to as Tietze syndrome, a term usually used interchangeably with costochondritis. However, some clinicians view costochondritis and Tietze syndrome as separate disease states because of the absence of costal cartilage swelling in costochondritis.¹⁰⁴ Pain may be provoked at rest, during movement of the

ribcage, or related to breathing as both syndromes have been associated to repetitive physical activity. For this reason, a differential diagnosis of chest wall pain from other musculoskeletal structures is crucial.

It is also important to consider that several viscera refer to different levels of the thoracic spine, including the heart, aorta, lungs, esophagus, stomach, duodenum, pancreas, gall bladder, liver, kidney, and ureter. For instance, thoracic pain is highly prevalent in patients with chronic obstructive pulmonary disease.^{116, 117} An association between viscera disease and muscle thoracic pain is the activation of viscerosomatic reflexes, as it has also been commented in the Chronic Pelvic Pain section. Confirming this hypothesis, Bentsen et al¹¹⁸ postulated that thoracic pain and dyspnea could be related because primary and accessory muscles of breathing in patients with chronic obstructive pulmonary disease are frequently used to manage their breathlessness.

Current evidence suggests that musculoskeletal thoracic and chest pain should be treated with a multimodal program of care, including manual therapy, soft tissue therapy, exercises, heat/ice, advice, and educational sessions,¹¹⁹ supporting the complexity of the thoracic/chest pain conditions.

9.2. Initial Evaluation of a Patient With Thoracic and Chest Pain

Chest pain needs to be fully characterized by onset, site(s), radiation, and relieving and exacerbating factors (particularly any relationship to posture, specific activities, or acute trauma). Atypical symptoms, such as night pain or severe pain, alert the clinician to look for systemic causes such as fractures, infection, or neoplasm. Proper screening for underlying medical conditions is important to establish accurate diagnosis and develop the optimal plan of care. Localization of the symptoms, the presence of chest wall tenderness, or the reproduction of pain by movements are insufficient to justify ruling out serious nonmusculoskeletal causes.

The musculoskeletal examination includes evaluation of the posture of the ribs; chest wall; and cervical, thoracic, and lumbar musculature and vertebrae. A key point is to identify areas of tenderness in the thoracic spine, chest, and ribs. Muscle tenderness is usually associated with medical pathologies such as costochondritis. Important areas to palpate include costochondral joints, sternum, ribs, thoracic vertebrae, and associated muscles such as intercostals, paraspinal, trapezius, pectoral, and scalene muscles. Pain provocation during active or passive movements of the spine (ie, flexion, extension, lateral flexion, and rotation) should also be assessed.

Another important aspect for clinical evaluation is the assessment of facet joint mobility. The prevalence of thoracic pain from facet joints is reported to range from 34% to 48%.^{120, 121} In one study including four pain-free individuals, injecting facet joints with contrast caused two participants to report referral patterns toward the sternum.¹²² Similarly, injection of the costotransverse joints produced thoracic, but not chest, pain.¹²³ Segmental dysfunction in the lower cervical (C4-C7) and upper thoracic spine (T1-T8) may cause pain referred to the anterior aspects of the chest. Christensen et al¹²⁴ found that

18% of patients with chronic chest pain admitted for coronary angiography at a cardiology department exhibited cervicothoracic and thoracic spine dysfunctions reproducing their symptoms. It should always be considered that the reliability of manual palpation of mobility or tenderness in the chest wall is limited.^{125, 126}

The pain referral of thoracic interspinous ligaments¹²⁷ and paravertebral muscles¹²⁸ has also been investigated using injections of hypertonic saline that has shown referred pain to the anterior, lateral, and posterior chest and lower thoracic segments referring lower on the chest. In fact, individuals with costochondritis exhibiting pain during breathing may overactivate accessory muscles such as the scalene muscles secondary to pain, which will prevent expansion of the rib cage. Trigger points located in several muscles of the rib cage and thoracic region can be overloaded, including the lower cervical and thoracic multifidi, thoracic longissimus and iliocostalis, psoas, latissimus dorsi, serratus posterior inferior, rectus abdominus, scalenes, and rhomboid muscles.

9.3. Trigger Points and Thoracic and Chest Pain

The presence of chest pain of myofascial origin was described many years ago.¹²⁹ For instance, TrPs in the pectoralis musculature can stimulate the symptoms of angina pectoris. As described in Chapters 42, 43, and 44, the pain patterns of the pectoralis major, sternalis, and pectoralis minor muscles can mimic the pain referral patterns of cardiac ischemia. Lawson et al¹³⁰ described a patient with anterior chest pain and normal cardiac examination findings in which active TrPs in the pectoralis minor muscle reproduced the symptoms. After treatment of the TrP, the symptoms disappeared. Although the pain referral elicited by some muscles strongly mimics cardiac pain, TrP pain has a much wider variability in its response to day-to-day activity than the more consistent exercise response on angina pectoris. A definite diagnosis of active TrPs based on their characteristic signs and symptoms and a positive response to local treatment does not exclude cardiac disease. 20% of individuals referred for coronary angiography can also exhibit musculoskeletal chest pain.¹²⁴ It is also possible that the small musculature of the thoracic levels related to the affected viscera, including the thoracic multifidi muscles, also develops TrPs. The intercostal muscles have also been implicated in cardiac arrhythmia, and sternalis TrPs can closely mimic the substernal ache of myocardial infarction or angina pectoralis.⁴² All are examples of different viscerosomatic reflexes.

Abdominal visceral diseases can also produce pain patterns that closely resemble those from TrPs. These include diaphragmatic hernia, peptic ulcer, gastric carcinoma, chronic cholecystitis, gallstone colic, ureteral colic, inguinal hernia, hepatitis, pancreatitis, appendicitis, diverticulitis, colitis, cystitis, and endometriosis. Other common medical conditions include esophagitis, hiatal hernia with reflux, and spastic colon.⁴² Some infections, such as postherpetic neuralgia after herpes zoster, can also activate TrPs in the related muscles, like the intercostal muscles.¹³¹ Box 53-1 identifies TrPs that may be associated with somatovisceral symptoms.

Current evidence about the presence of TrPs in the thoracic spine is lacking. Roldan

and Huh¹³² investigated the pain of myofascial origin in 43 patients who presented to the emergency room with reports of pain in the back, chest, abdomen, or pelvis. The iliocostalis thoracis and lumborum muscles were examined for the presence of TrPs that reproduced the patient's report of pain. They injected the iliocostalis TrPs, and 2 weeks after injection, all patients had satisfactory control of symptoms and no return visits to the emergency room. There is also preliminary evidence suggesting that proper treatment of myofascial tissues is effective for the management of pain in patients with thoracic visceral diseases. Berg et al¹³³ described that soft tissue treatment was effective in patients with stable coronary heart disease and self-reported chest pain reproduced by the palpation of intercostal TrPs, supporting the role of muscle pain referral in chest pain of noncardiac origin. Fernández de las Peñas et al¹³⁴ discussed clinical evidence about the role of TrPs in thoracic spine pain and their management with dry needling. Rock and Rainey¹³⁵ reported a case series where the application of dry needling, combined with electrical stimulation on TrPs of the thoracic spine muscles, such as multifidi, longissimus, and iliocostalis muscles, was effective for reducing symptoms of nonspecific thoracic pain.¹³⁶

Hip, Thigh, and Knee Pain

Gluteus Maximus Muscle

“Swimmers Nemesis”

Joseph M. Donnelly, Paul Thomas, and Jennifer L. Freeman

1. INTRODUCTION

From an evolutionary perspective, the ability to walk bipedally is a uniquely human trait. The gluteus maximus muscle is the largest and most superficial of the gluteal muscles and the largest muscle in the body. The gluteus maximus muscle covers the posterior pelvis from the sacrum, ilium, coccyx, thoracolumbar fascia, lumbar multifidus, distally to the iliotibial tract of the fascia lata, and gluteal tuberosity of the femur. The gluteus maximus muscle primarily attaches to the fascia lata, which suggests a complex biomechanical function across the hip and knee as well as the lumbopelvic region. The gluteus maximus muscle stabilizes the pelvis on the femur and propels the body forward during ambulation. Activities such as walking uphill, swimming freestyle, and sprinting may overload the gluteus maximus muscle, activating and perpetuating trigger points (TrPs). Pain from the gluteus maximus muscle will typically remain in the buttock region, but these symptoms can mimic sacroiliac joint dysfunction, trochanteric bursitis, and high hamstring strain symptoms. Differential diagnosis should include lumbar radicular pain or radiculopathy, lumbar spine and sacroiliac joint dysfunction, piriformis syndrome, hamstring strain, and trochanteric bursitis. Corrective actions should include techniques to improve sitting posture, trunk control, gait mechanics, sleeping position, self-pressure release, and self-stretching techniques. Neuromuscular reeducation and progression to strengthening exercises is key for preventing exacerbation.

2. ANATOMIC CONSIDERATIONS

The gluteus maximus muscle¹ is the most superficial and largest of the three gluteal muscles. The gluteus maximus muscle in humans has a larger cross-sectional area and is much more extensive than in any other primate. This organizational structure of the gluteus maximus muscle supports the upright posture and bipedal walking in human

beings. From an evolutionary point of view, upright walking by true bipedal plantigrade progression has been singled out as a unique feature of human locomotion.² Humans alone, among mammals, can place the center of gravity of the head, arms, and torso over the hips.³ This function has been associated with evolutionary changes in the skeleton and gluteus maximus muscle that are uniquely human. These changes include shortening and tilting of the pelvis to permit extension of the thigh at the hip, angulation of gluteus maximus fibers more horizontally,³ and enlargement of the muscle to more than twice the size of the gluteus medius muscle.⁴ These evolutionary changes⁵ presumably freed the hands for other activities and were considered³ to be crucial to the development of the intelligence and unique manual dexterity of humans.

Anatomically, the remarkably large gluteus maximus muscle forms the prominence of the buttock. It is twice as heavy (844 g) as the gluteus medius and gluteus minimus muscles together (421 g),⁶ and it often measures more than 2.5 cm (1 in) in thickness. The gluteus maximus muscle originates from the posterior gluteal line of the ilium and the area of bone superior and posterior to it including the iliac crest, the posterolateral surface of the sacrum, and the lateral coccyx. It also has proximal attachments to the sacrotuberous ligament, the fascia covering the gluteus medius muscle, and the dorsal sacroiliac ligaments.⁷ Additional slips of muscle may arise from the ischial tuberosity or lumbar aponeurosis (Figure 54-1). The gluteus maximus muscle has attachments to the thoracolumbar fascia and the multifidus muscle at the gluteal raphe, which is located at the superomedial aspect of the gluteus maximus muscle at its attachment to the sacrum.⁸ The gluteal raphe serves as an important anatomic convergence joining the multifidus and superficial erector spinae muscles with the gluteus maximus muscle. This area conjoins and converts the three most powerful extensor muscles that cross the lumbar spine, pelvis, and hip on the posterior side of the body.⁸

Figure 54-1. Attachments of the right gluteus maximus muscle (red) in the posterolateral view. The gluteus maximus muscle covers the posterior portion of the gluteus medius muscle, but not its anterior portion. Note the expansive insertion into the fascia lata.

The gluteus maximus muscle is quadrilateral in shape, and its fibers descend inferolaterally. The superior portion of the muscle, together with the superficial aspect of the lower fibers, terminates in a thick expansive tendinous lamina and inserts into the fascia lata along the iliotibial tract and the lateral intermuscular septum.⁹ The majority of the gluteus maximus muscle inserts into the fascia lata.⁸ The deep fibers of the inferior portion of the gluteus maximus muscle attach to the gluteal tuberosity between the vastus lateralis

and adductor magnus muscles (Figure 54-1).^{7, 10}

The large trochanteric bursa separates the flat tendon of the gluteus maximus muscle from the greater trochanter.^{11, 12} An inconstant ischial bursa permits smooth gliding of the muscle over the ischial tuberosity. A third bursa separates the gluteus maximus tendon from that of the vastus lateralis muscle.⁷ Other small bursae form as needed throughout the gluteal region to support efficiency of movement.

2.1. Innervation and Vascularization

The gluteus maximus muscle is innervated by the inferior gluteal nerve that arises from the L5, S1, and S2 nerve roots. The inferior gluteal nerve forms from these roots and exits the pelvis through the greater sciatic foramen, inferior to the piriformis muscle and superficial to the sciatic nerve. This nerve usually perforates the inferior part of the gluteus maximus muscle.¹³

Vascularization of the gluteus maximus muscle is primarily supplied through the inferior gluteal artery that supplies approximately two-thirds of the overlying gluteus maximus muscle. The remaining third is supplied mainly by the superior gluteal artery.⁷

2.2. Function

The gluteus maximus muscle is a powerful hip extensor. When the hip is in extension, the gluteus maximus muscle acts as an external rotator. The superior portion of the muscle can contribute to hip abduction, whereas the inferior portion contributes to hip adduction. The superior portion of the muscle is more active during activities that involve hip extension, hip abduction, and/or hip external rotation. The inferior portion contributes to hip adduction, and along with the superior portion they are both active during activities utilizing hip extension.¹⁴ The activity of the gluteus maximus muscle can be enhanced by combining hip extension with abduction and external rotation.¹⁵

During functional activities, such as descending stairs, squatting, climbing, or transitioning from standing to sitting, the gluteus maximus muscle, contracting eccentrically, controls hip flexion. The gluteus maximus and hamstring muscles act together to bring the trunk from a forward flexed posture back to an upright erect posture.^{7, 16}

The gluteus maximus muscle stabilizes the pelvis and trunk on the thigh during ambulation and aids in forward propulsion.¹⁷ It is active during both walking and running. It has been found to have a peak muscle activation during lower extremity loading response (foot strike) and remains somewhat active through the stance phase of gait, and again, activation increases at the end of the swing phase to decelerate the lower extremity.¹⁶ As the speed of the lower extremity is increased during gait, and especially when running, the activity of the gluteus maximus muscle increases for both support and propulsion of the lower extremity.¹⁶ It has been shown to act as a control for the transverse plane rotation of the tibia during the gait cycle. Through its action as an external rotator, the gluteus

maximus muscle has the capacity to eccentrically control the internal rotation that occurs through the early stance phase of gait. Preece et al demonstrated that higher gluteus maximus muscle activation led to a more rapid deceleration of the tibia.¹⁸ Teng et al¹⁹ found that runners with weak hip extensors utilized a more erect posture during running, resulting in increased demand on their quadriceps muscles to attenuate ground reaction forces, leading to overuse running injuries of the knee.

The gluteus maximus muscle plays a role in the stability of the sacroiliac joint through force closure,²⁰ both independently and when working in concert with other muscles.²¹ One way that this stability is achieved is with the contraction of the biceps femoris muscle, which minimizes motion between the sacrum and the ilium through its attachments on the sacrotuberous ligament. Another mechanism of force closure may occur through the simultaneous contraction of the ipsilateral gluteus maximus and contralateral latissimus dorsi muscles, which increases compression between the sacroiliac joint surfaces because of their influence on the thoracolumbar fascia.⁸ Together, their contraction places tension on the posterior layer of the thoracolumbar fascia that crosses the sacroiliac joints perpendicularly, thus creating a compressive force.^{10, 20, 21}

In closed kinetic chain, the gluteus maximus muscle generates a strong influence on the position of the pelvis in the sagittal plane. With the foot fixed on the ground, a bilateral contraction of the gluteus maximus muscle results in a posterior rotary moment of the pelvis that creates a flexion moment at the lumbosacral junction.⁸ Through this closed kinetic chain action, the lumbosacral angle is reduced and, in turn, reduces anterior shear forces across the lumbosacral junction. This influence may be a very useful function for those individuals with spinal stenosis or degeneration of the lumbar zygapophyseal joints.⁸

Autopsy samples of normal adult gluteus maximus muscles from individuals under age 44 years have shown that 68% of fibers were slow-twitch (type 1) and 32% were fast-twitch (type 2) muscle fibers. The muscle demonstrated essentially the same composition in two groups of persons older than 44 years: 70% of the fibers were type 1 and 30% were type 2. Although individual variability is great, the percentage of type 1 fibers (those dependent largely on oxidative metabolism) always exceeded the number of type 2 (rapidly fatiguing) fibers that utilize chiefly glycolytic energy pathways.²² Because of this combination of different muscle fiber types, both low- and high-speed repetitions are necessary for effective training.

2.3. Functional Unit

The functional unit to which a muscle belongs includes the muscles that reinforce and counter its actions as well as the joints that the muscle crosses. The interdependence of these structures functionally is reflected in the organization and neural connections of the sensory motor cortex. The functional unit is emphasized because the presence of a TrP in one muscle of the unit increases the likelihood that the other muscles will develop TrPs. When inactivating TrPs in a muscle, one must be concerned about TrPs that may develop in muscles that are functionally interdependent. Box 54-1 represents the functional unit of

the gluteus maximus muscle.²³

Box 54-1 Functional unit of the gluteus maximus muscle

Action	Synergists	Antagonists
Trunk extension	Iliocostalis thoracis Iliocostalis lumborum Longissimus thoracis Hamstrings	Iliopsoas Rectus abdominis Internal abdominis oblique External abdominis oblique
Hip extension	Hamstrings Gluteus medius (posterior fibers) Gluteus minimus (posterior fibers) Obturator internus Adductor magnus	Iliopsoas Rectus femoris Tensor fascia lata
Hip abduction	Gluteus medius Gluteus minimus Tensor fascia lata Obturator internus	Adductor magnus Adductor longus Adductor brevis Pectineus Gracilis
Hip external rotation	Piriformis Obturator internus Obturator externus Quadratus femoris Gemelli superior and inferior	Adductor Tensor fascia lata

The gluteus maximus muscle works synergistically with the lumbar erector spinae and hamstring muscles to perform extension of the trunk from a forward flexed position in standing. Through acting on the relatively fixed femurs, the muscle works to posteriorly rotate the pelvis raising the trunk.⁷

The gluteus maximus muscle aids in providing stability of the sacroiliac joint and works synergistically with the bicep femoris muscle through attachments on the sacrotuberous ligament. It also works synergistically with the pelvic floor, transversus abdominis, erector spinae, multifidus, and latissimus dorsi muscles to provide force closure of the sacroiliac joints.^{20, 21}

3. CLINICAL PRESENTATION

3.1. Referred Pain Pattern

Trigger points in the gluteus maximus muscle may refer symptoms, including pain, to the sacrum, inferior buttock, gluteal fold, coccyx, sacrococcygeal region, and laterally, to the area inferior to the iliac crest (Figure 54-2). Trigger points in this muscle refer pain locally in the buttock region and typically do not extend into the lower extremity, unlike the gluteus medius and gluteus minimus muscles that may produce referred symptoms down the lower extremity. Trigger points found along the sacral attachment may refer pain along the gluteal cleft and may extend to the area near the sacroiliac joint or barely into the proximal posterior thigh. Trigger points found just above the ischial tuberosity will usually refer pain to the entire buttock and cause a deep tenderness in the buttock. Trigger points found along the inferomedial fibers of the gluteus maximus muscle will typically cause pain along the coccyx (Figure 54-2).

Figure 51-2. Referred pain patterns (solid red and stippled areas) of TrPs in the gluteus maximus muscle.

3.2. Symptoms

Patients with active TrPs in the gluteus maximus muscle may report having pain while sitting. They may try to avoid putting pressure on the area of active TrPs and lean on one side or squirm in their chair because of discomfort. Significant deformation of the inferior gluteus maximus muscle and soft tissues has been observed through positional magnetic resonance imaging in the sitting posture. The gluteus maximus muscle slides away from the ischium along with the subcutaneous fat in a three-directional manner.²⁴ Whether from ischemic pressure over the muscle itself or from the strain placed on the soft tissue from deformation, pain with sitting can occur when TrPs are present through the inferior aspect of the muscle.²³

Patients with active TrPs through the gluteus maximus muscle may also report having pain during walking, especially up a hill, as the forward trunk lean places increased demand on the muscle. These symptoms can mimic the symptoms of a sacroiliac joint dysfunction as the aggravating activities are typically the same. Pain from TrPs in this muscle is intensified by vigorous contraction in the shortened position, as when swimming freestyle.

This cramp-type pain is more likely to occur in cold water. Sporting activities that require explosive starts such as tennis and sprinting place an increased demand on the gluteus maximus muscle that may result in the patient reporting symptoms similar to those of a proximal hamstring strain.

3.3. Patient Examination

After a thorough subjective examination the clinician should make a detailed drawing representing the pain pattern that the patient has described. This depiction will assist in planning the physical examination and can be useful in monitoring the progression of the patient as symptoms improve or change. The type, quality, and location of the pain should be carefully assessed, and the utilization of standardized outcome tools is imperative when examining patients with low back pain and/or lower extremity dysfunctions.

For proper examination of the gluteus maximus muscle, the clinician should observe sitting and standing postures. Physical examination testing should be conducted to rule out lumbar, sacroiliac, or hip joint pathology. This may include range of motion testing of the hip and lumbar spine; passive accessory motion testing of the hip, sacroiliac joint, and/or lumbar spine; strength testing of the gluteus maximus and other hip muscles; and any appropriate neurologic testing or orthopedic special tests. A careful assessment should be made to rule out referral into the buttock from other muscles, joints, or neural tissues that can refer to the same region.

As the gluteus maximus muscle plays such a large role in maintaining stability of the pelvis over the lower extremity while walking, an observation of the patient's gait pattern is necessary.¹⁷ Common gait deviations include an antalgic gait pattern, an increased lordosis with anterior pelvic tilt,¹⁵ or a decreased stance phase on the affected side and a corresponding brief swing phase on the contralateral side. The regional interdependence of the lumbosacral spine and the hip joint makes it necessary to examine these relationships in a closed and open kinetic chain.

A functional activity that should be assessed in standing is the double-leg squat, which should be observed from a sagittal perspective (Figure 54-3A). The clinician should note any excessive movement in the lumbosacral region or hip joint. During a proper squat, the patient should be able to go through a good range of hip flexion without excessive anterior pelvic tilt or excessive lumbar hyperextension (Figure 54-3B). Movement from a standing to sitting position should be observed to examine eccentric gluteus maximus muscle control during sitting and hip flexion range of motion. Further regional interdependence testing may include quadruped rocking looking at hip flexion range of motion relative to lumbar spine position. The patient attempts to sit back on his or her heels utilizing hip flexion without excessive motion at the lumbosacral spine (Figure 54-4).

Figure 54-3. Double-leg squat. A, Neutral alignment of lumbar spine with good gluteus maximus muscle control. B, Excessive lumbar lordosis due to inhibited gluteal muscles.

Figure 54-4. Quadruped rocking. A, Starting position with the hip in approximately 90° and lumbar spine in neutral position. B, End position with maximum hip flexion and minimum lumbar flexion.

The patient should also be observed in an open kinetic prone position. The gluteal skyline may be assessed to determine gluteal atrophy and inhibition that may indicate L5-S2 nerve root or inferior gluteal nerve pathology (Figure 54-5). The patient's muscle bulk is first observed at rest with the patient prone and then the patient is instructed to contract both gluteal maximus muscles, and the clinician assesses these contractions for bilateral symmetry. If asymmetries in gluteal maximus muscle mass or activation are noted, further

evaluation to determine if the cause is neurologic or myofascial in origin is warranted.²⁵ As the gluteus maximus muscle tends to atrophy in women with low back pain, dysfunction of this muscle often requires a more global evaluation.²⁶

Figure 54-5. Assessment of gluteal skyline. A, First, the gluteal muscles should be assessed for resting symmetry. B, The patient is asked to contract both the left and right gluteus maximus muscles, and the control and strength of the contractions are then assessed for incongruences.

Gluteus maximus muscle control of hip extension should also be assessed in prone (Figure 54-6A). The clinician passively extends the hip while monitoring the position of the greater trochanter (Figure 54-6B). The clinician then slowly releases the lower extremity while the patient attempts to maintain the hip extension position (Figure 54-6C). The greater trochanter should stay in the same position if the hip extensors are able to maintain the femur in the center of rotation.²⁷

Figure 54-6. Assessment of motor control in prone hip extension. A, Clinician holds greater trochanter with key grip to monitor its position. B, Clinician passively places the hip into end range extension at the hip monitoring the greater trochanter position. C, The clinician releases the leg and monitors the position of the greater trochanter.

Hip range of motion, muscle strength, and muscle activation patterns should be assessed in all planes. Muscle length assessment of one- and two-joint hip flexor muscles should be performed (Figure 54-7). Hip extension range of motion and activation patterns should be assessed in prone, with the clinician noting the sequence of hip extension,

anterior rotation of the ilium, and timing of lumbar extension. Janda described a muscle activation pattern during hip extension that includes the following muscle firing sequence: hamstrings, gluteus maximus, contralateral paraspinal muscles followed by ipsilateral paraspinal muscles. The lumbar spine should be maintained in a neutral position, and any deviation would be indicative of movement impairment.²⁸ In supine, the bridging maneuver can be utilized to assess motor control and strength of the gluteus maximus muscle. The clinician observes both hip extension and the trunk position (Figure 54-8A and B). Reiman et al²⁹ found that the supine bridge exercise was able to induce a moderate contraction (25% maximum voluntary isometric contraction) of the gluteus maximus muscle. To further test the gluteus maximus muscle, the patient is asked to extend the opposite lower extremity, which challenges the muscle on the weight-bearing side. The clinician watches for the pelvis to drop or raise excessively on the unsupported side, assessing the ability of the gluteus maximus muscle on the weight-bearing side to control the position of the pelvis (Figure 54-8C). This can also be used as a home exercise to increase gluteus maximus muscle control. A traditional manual muscle test can be performed; although, in clinical experience, the gluteus maximus manual muscle may test “good” to “normal,” the patient may still demonstrate poor motor control during functional activities.

Figure 54-7. Thomas test position for hip flexor length assessment. A, One-joint muscles. B, Two-joint muscle.

Figure 54-8. Bridging maneuver for assessment of gluteus maximus muscle strength and motor control. A, Starting position. B, End position with trunk and hip in alignment. C, Challenging the right gluteus maximus muscle.

If the gluteus maximus muscle is found to have impaired muscle activation patterns, the patient should be immediately placed on a gluteus maximus muscle retraining program. Figure 54-9 and Box 54-2 illustrate one three-level progression for gluteus maximus muscle retraining. Selkowitz et al³⁰ found that retraining the gluteus maximus muscle in quadruped with hip and knee extension, and combined hip extension, abduction, and external rotation was effective at maximally activating the gluteus maximus muscle without excessive activation of the tensor fascia lata when compared with several other common exercises.³⁰ Researchers^{31,32} utilizing transmagnetic stimulation to measure corticomotor excitability of the gluteus maximus muscle found that this muscle activation training results in neuroplastic changes that increase activation during hip extension movements including movements that utilize synergistic muscles.^{31,32} Individuals may also benefit from performing trunk strengthening activities to reduce the demand that is placed on the gluteus maximus muscle.

Figure 54-9. Gluteus maximus muscle retraining. A, Starting position. B, Extending the knee with the gluteus maximus and hamstring muscles with the foot on the table. C, Straightening the knee with the gluteus maximus and hamstring muscles, followed by pointing the toes. D, Lifting the leg off the table.

Box 54-2 Gluteus maximus muscle retraining program

Starting position (Figure 54-9A)	A pillow is placed under the abdomen to keep the lumbosacral spine in a neutral position.
Level 1 (Figure 54-9B)	The patient points the toes into the supporting surface and attempts to straighten the knee using the gluteus maximus and hamstring muscles. The clinician should note any substitution with the quadriceps femoris muscles and/or the thoracolumbar paraspinal muscles.
Level 2 (Figure 54-9C)	From the position of level 1, the patient points the toes, so that the lower extremity is no longer supported, and holds this position for 6-10 seconds before slowly placing the toes back down as pictured in level 1. Finally, the patient slowly lowers the knee back to the starting position.
Level 3 (Figure 54-9D)	The patient lifts the leg off the surface leading with the hamstrings, gluteus maximus muscles, and contralateral and ipsilateral

paraspinal muscles, with no trunk rotation or excessive motion in the sagittal plane.

3.4. Trigger Point Examination

Trigger point examination requires specific knowledge of fiber direction of the gluteal muscles so that the clinician can be more confident regarding in which muscles the TrPs are found. Figure 54-10 is a depiction of the fiber arrangement of the gluteus maximus, gluteus medius, and gluteus minimus muscles. A cross-fiber flat palpation may be utilized for the examination of TrPs in the gluteus maximus muscle depending on the region of the muscle being examined. The gluteus maximus muscle can be accessed with the patient in the side-lying position (Figure 54-11), with the hips flexed to take up some tissue slack, or in the prone position. The superior fibers can be palpated utilizing a cross-fiber flat palpation (Figure 54-11A and B), whereas the lower fibers may be examined utilizing a cross-fiber pincer palpation (Figure 54-11C). However, all portions of the gluteus maximus muscle can be examined for TrPs using a cross-fiber flat palpation. For some patients, a greater degree of hip flexion may be useful to increase the sensitivity of the TrPs to palpation. Along the inferior and inferolateral aspects of the gluteus maximus muscle, careful examination should be made to differentiate gluteus maximus muscle fiber orientation from the piriformis and hip external rotator muscles. Examination along the lower border of the muscle can be performed using a cross-fiber pincer palpation or a cross-fiber flat palpation against the ischium.

Figure 54-10. Fiber orientation of gluteal muscles. A, Gluteus maximus. B, Gluteus medius. C, Gluteus minimus.

Figure 54-11. Examination for TrPs in the gluteus maximus muscle. A and B, Cross-fiber flat palpation. C, Cross-fiber pincer palpation for lower portion of the gluteus maximus muscle.

4. DIFFERENTIAL DIAGNOSIS

4.1. Activation and Perpetuation of Trigger Points

A posture or activity that activates a TrP, if not corrected, can also perpetuate it. In any part of the gluteus maximus muscle, TrPs may be activated by unaccustomed eccentric loading, eccentric exercise in an unconditioned muscle, or maximal or submaximal concentric loading.³³ Trigger points may also be activated or aggravated when the muscle is placed in a shortened and/or lengthened position for an extended period of time.

Gluteus maximus TrPs may be activated by actions that place the muscle under greater demand and overload its capacity. A fall or a near-fall can cause acute overload of the gluteus maximus muscle especially if the muscle sustains a vigorous eccentric contraction in an effort to prevent the fall. The impact of a direct blow on one buttock, as in a backward fall onto a step or the floor, may be responsible for initiating gluteus maximus TrPs. Sitting on a wallet placed in a back pocket that extends under the buttock can perpetuate and aggravate TrPs in the gluteal muscles by concentrating pressure on them. The resultant low back and buttock pain is likely to be erroneously attributed to nerve pressure and has been

called “back pocket sciatica.”³⁴ However, pain referred from TrPs in the gluteus maximus muscle alone would not have a full sciatic nerve distribution. Sleeping on one side with the thigh of the upper lower extremity sharply flexed can overstretch the uppermost gluteus maximus muscle and activate TrPs.

Another common, but avoidable, cause of activation of gluteus maximus or medius TrPs is the injection of an irritant medication intramuscularly into the gluteal area.³⁵ As the most superficial gluteal muscle, the gluteus maximus muscle is the most likely to be injected. Persons giving such injections should palpate the muscles for TrPs and avoid any hypersensitive spots. Diluting the material to be injected with an equal quantity of 2% procaine solution may prevent activation of a latent TrP in the event that the medication is accidentally injected into the region of the TrPs.

The gluteus maximus muscle provides stability of the trunk and pelvis and is innately involved with movement of the hip and lower extremity, ambulation, climbing, lifting, and throwing.^{16,21,36} Activities that would potentially perpetuate TrPs may include uphill walking or running, climbing a ladder, or returning to standing from a squatting position.

Biomechanical or motor control changes in the lumbopelvic and hip region can also affect the activation of the gluteus maximus muscle and cause the perpetuation of TrPs. Increased activity of the gluteus maximus muscle has been found to occur in patients with chronic low back pain.³⁷ Hip pathology has been shown to alter muscle recruitment patterns, either increasing or inhibiting activation of the gluteus maximus muscle.^{38–40} Hip arthritis has been demonstrated to cause increased activation of the gluteus maximus muscle during the mid-stance of gait.³⁹ Changes in foot function that lead to excessive pronation may also lead to activation of TrPs in the gluteal muscles. Abnormal pronation may cause excessive internal rotation of the hip during the stance phase in walking, and this movement is counteracted to some extent by the activity of the horizontal fibers of the gluteus maximus muscle, which may lead to overload of the muscle.

Altered activation patterns of the gluteal muscles and development of TrPs in the gluteus maximus muscle are a common clinical finding present in lower extremity dysfunctions, fibromyalgia,⁴¹ lower back syndromes,⁴² and sacroiliac joint dysfunction.^{43,44} Adelmanesh et al⁴² found associations between TrPs in the gluteal muscles and lumbar radiculopathy in 76.4% of patients when compared with 1.9% of control subjects. Trigger points in the gluteal muscles have also been found in other lower extremity conditions such as patellofemoral pain syndrome.⁴⁵

4.2. Associated Trigger Points

Associated TrPs can develop in the referred pain areas caused by primary TrPs.⁴⁶ Therefore, musculature in the referred pain areas for each muscle should also be considered. Examples of muscles in the hip that should be examined include the piriformis, gluteus medius, posterior portion of the gluteus minimus, quadratus lumborum, obturator internus and externus, superior and inferior gemelli, proximal hamstrings, adductor magnus, and coccygeus muscles.²³

Muscles that can refer into the buttock may also need to be assessed. These muscles include iliocostalis lumborum, longissimus thoracis, quadratus lumborum, semitendinosus, semimembranosus, rectus abdominis, pelvic floor, and soleus muscles.²³ The lumbar multifidus muscle also has been shown to refer pain into the buttock and can mimic the pain patterns associated with gluteus maximus, gluteus medius, gluteus minimus, or piriformis muscles.⁴⁷

The antagonistic iliopsoas and rectus abdominis muscles may also develop TrPs that require treatment to achieve release of gluteus maximus TrP and to attain full upright posture.

4.3. Associated Pathology

Differential diagnosis of clinical conditions should include lumbar pathology (including facet or intervertebral disc dysfunction), radicular pain or radiculopathy, sacroiliac joint dysfunction, coccydynia, or hip pathology. The buttock is a common area of referral from many other pathologies, so a thorough examination should be carried out. Lumbar facet joint and sacroiliac joint dysfunctions frequently will refer pain into the buttock.^{48,49} The sacroiliac joint refers pain to the buttock alone and, sometimes, to the buttock and other areas.^{50,51} The hip joint has been shown to refer pain into the buttock in as many as 71% of patients presenting with hip dysfunction.⁵² Although the most common report with femoroacetabular impingement is groin pain, buttock pain has been found to occur in 29% of patients.⁵³ Ischiofemoral ligament impingement may also cause inferior buttock pain mimicking gluteus maximus TrP referral.⁵⁴

Physical activities that can perpetuate gluteus maximus TrPs include swimming using the crawl stroke (freestyle), which requires hyperextension of the lumbar spine in addition to hip extension. This forceful contraction of the gluteus maximus and lower paraspinal extensor muscles in a strongly shortened position can activate and perpetuate their TrPs. A similar cause of gluteus maximus muscle overload may be conditioning exercises (leg lifts) that hyperextend the low back and hip, either in the prone or standing position. Repetitious tasks, such as frequently leaning over and lifting a baby out of the playpen or crib, lifting a box from the floor by leaning over, or weeding a garden may perpetuate gluteus maximus TrPs.

Some individuals with greater trochanteric tenderness that is relieved by injection of a local anesthetic have TrPs in the gluteus maximus muscle instead of, or in addition to, bursitis. Subacute trochanteric bursitis has been commonly associated with low back pain, hip disease, and/or leg length discrepancies, conditions often associated with TrPs of the gluteal musculature. However, the location of the bursa is more lateral than the area where gluteus maximus TrPs are usually found. If present, TrPs in this superficial muscle should be detectable by their taut bands, spot tenderness, and referred symptoms.

5. CORRECTIVE ACTIONS

Patients with active TrPs in the gluteus maximus muscle should limit the duration of time

spent sitting. Patients who primarily work on a computer should have an ergonomic assessment performed, and adjustments to the workstation should be made as needed. Behavioral modifications including taking short breaks to move, utilizing a standing desk, or improving postural support will also assist in reducing symptoms. Using a timer placed across the room to remind the patient to get up, walk across the room, and reset the device before returning to the chair can be a helpful strategy to encourage movement with minimal distraction from thought. Special consideration should be paid to the design of the chair and the material of the seat because they dictate the amount of pressure and the contact area on the buttocks, as well as the resulting tissue perfusion.⁵⁵

Improvements in posture and postural support may also assist in reducing pain from TrPs in the gluteus maximus muscle. Sleeping side-lying with the painful side up and placing a pillow between the knees may help reduce symptoms and improve sleep quality.

Gluteus maximus TrPs can be treated with self-pressure release techniques utilizing a lacrosse ball or other TrP self-pressure release tools, based on individual preference and general mobility (Figure 54-12A). The patient can place a rounded self-release tool like a ball or dome on the floor and slowly apply pressure to the TrPs by resting the buttocks on the tool and placing weight through the arms to moderate pressure (Figure 54-12B and D). This technique can also be used on a wall (Figure 54-12C). A wrap-around self-release tool can also be utilized in the standing position (Figure 54-12E). For all pressure release techniques, the patient should hold pressure for 15 to 30 seconds, repeating for six repetitions. Self-release can be repeated every 2 to 3 hours as long as relief of symptoms is achieved. Caution is warranted as excessive pressure (more than 4/10 pain scale) on the TrPs can actually cause activation and perpetuation of the TrPs.

Figure 54-12. Trigger point self-pressure release. A, Sample of TrP release tools. B, Pressure release with larger tool sitting. C, Standing against the wall. D, Side-lying with tennis ball. E, Self-release tool.

Foam rolling can be utilized to help release TrPs in the gluteus maximus muscle and is commonly used by athletes. The patient sits on the foam roller, leans back slightly onto both hands, and works slowly from the bottom of the gluteal region up toward the top. While rolling over the gluteus maximus muscle, the patient should stop and slowly rock over the area of tender spots that are felt to encourage the release of TrPs. Pressure should be mildly uncomfortable but not painful.

Specific stretching of the gluteus maximus muscle is difficult to achieve. To attempt to stretch this muscle, the patient lies face up (Figure 54-13A) or sits on the edge of a chair (Figure 54-13B), bringing the involved knee toward the chest and then crossing the leg over the body. The stretch is held for 30 seconds and repeated a minimum of four times. The patient can also use a hold-relax technique to improve the efficiency of the stretch. While sitting, the individual first pulls the knee toward his or her opposite shoulder in order to flex the hip by grasping the thigh behind the knee (Figure 54-13B). The patient then uses the hands to resist a gentle voluntary effort by the gluteal muscles to push the thigh down toward the floor for 6 to 10 seconds, immediately followed by relaxation. After relaxation, the patient then pulls the thigh a little higher, further stretching the buttocks, and repeats the sequence. This sequence can be repeated three to five times and two to three times per day.

Figure 54-13. Gluteus maximus muscle self-stretch. A, In supine, the patient pulls the knee toward her opposite shoulder in order to flex the hip by grasping the distal thigh (not the leg). This hold avoids excessive flexion pressure on the knee joint. A stretch should be felt in the buttocks and held for 30 seconds and repeated four times. B, Sitting, the individual first pulls the knee toward his opposite shoulder in order to flex the hip by grasping the distal thigh (not the leg). The patient uses the hands to resist a gentle voluntary effort by the lower extremity muscles to extend the thigh at the hip for 6 to 10 seconds followed by relaxation. The patient then pulls the thigh a little higher and repeats the sequence. Ward SR, Eng CM, Smallwood LH, Lieber RL. Gluteus Medius Muscle

“Lumbago Muscle”

Joseph M. Donnelly and Paul Thomas

1. INTRODUCTION

The gluteus medius muscle has been described as an analogist to the deltoid in the shoulder. It is a thick, multipennate muscle that provides most of the strength required for hip abduction. The gluteus medius and gluteus minimus muscles are active throughout the gait cycle and are key to supporting the lower extremity during the mid-stance phase of gait and stabilizing the pelvis in the frontal plane. Trigger points (TrPs) within the gluteus medius muscle can refer pain into the low back just above and below the beltline, the sacrum, the buttock, the lateral hip, and the posterior upper thigh. Patients may report difficulty with rising from a seated position due to the excessive load placed on the gluteus medius muscle, therefore activating and perpetuating its TrPs. Activities that can cause overload of the gluteus medius and gluteus minimus muscles include weight lifting, running, and habitually shifting weight onto one side as in carrying a child or heavy load on the hip. Trigger points in the gluteus medius muscle are commonly associated with other painful conditions of the lower quadrant. Low back pain caused by gluteus medius TrPs can be disabling and interfere with many functional activities. Differential diagnosis should include lumbar radicular pain or radiculopathy, sacroiliac joint dysfunction, greater trochanteric pain syndrome, hip joint pathology or dysfunction, and knee dysfunction. Corrective actions could include techniques to improve sitting and sleeping postures, trunk control, gait mechanics, self-pressure release, and self-stretching techniques. For resolution of symptoms, correction of altered biomechanics in the lower kinetic chain may need to be addressed.

2. ANATOMIC CONSIDERATIONS

The fan-shaped gluteus medius muscle lies deep to the gluteus maximus muscle and superficial to the gluteus minimus muscle. The gluteus medius muscle originates from the

external surface of the ilium along the anterior three-fourths of the iliac crest, between the anterior and posterior gluteal lines, and from the gluteal aponeurosis that covers the anterolateral two-thirds of the muscle.^{1,2} Figure 55-1 describes the three origins of the gluteus medius muscle. The deep fascicles arise from the gluteal fossa, extending from the posterior sacroiliac ligaments and posterior gluteal line, the body of the ilium above the anterior gluteal line, and the anterior superior iliac spine. The second attachment site is along the deep surface of the gluteal aponeurosis, and the fascia latae. The third site is from the posteroinferior aspect of the iliac crest.²

The muscle is multipennate with more fascicles and cross-sectional area in the anterior portion than in the middle or posterior portion.² Fibers in the anterior portion of the muscle are directed posterior and inferior, the middle portion fibers are directed vertically, and the posterior portion fibers are directed anteriorly and inferiorly, with some fibers nearly horizontal^{2,3} (Figure 55-1). These fibers converge to form a flat tendon that inserts along the lateral surface of the greater trochanter of the femur. Some authors have also described insertions on the superior, posteromedial, anterosuperior, or posterosuperior aspect of the greater trochanter.^{1,4,5} At its posterior edge, the gluteus medius muscle may also blend with the piriformis or the gluteus minimus muscle.^{1,5}

The trochanteric bursa of the gluteus medius muscle separates the tendon from the surface of the greater trochanter of the femur over which the tendon glides. The bursa lies between the trochanteric attachments of the gluteus minimus muscle proximally and the gluteus medius muscle distally.¹

Figure 55-1. Attachments of the right gluteus medius muscle (red) in the posterolateral view. The gluteus maximus muscle has been cut and removed; its distal end is reflected. Note the anteriorly directed posterior fibers and the posteriorly directed anterior fibers.

2.1. Innervation and Vascularization

The gluteus medius muscle is innervated by the superior gluteal nerve, which is mainly derived from the L4, L5, S1 nerve roots. The superior gluteal nerve passes between the gluteus medius and gluteus minimus muscles, sending branches to each muscle, and because of this relationship, it is vulnerable during surgical interventions (lateral or anterolateral approaches) that require splitting the gluteus medius muscle.¹ For instance,

the transgluteal approach used for total hip arthroplasty surgery often causes a partially denervated gluteus medius muscle.⁶

The vascular supply of the gluteus medius muscle is provided via the superior gluteal artery, which exits the pelvis through the greater sciatic foramen superior to the piriformis muscle, traveling anterior between the gluteus medius and gluteus minimus muscles along with the superior gluteal nerve.^{1,4} The superficial branch of the superior gluteal artery supplies the gluteus maximus muscle, whereas the deep branch of the superior gluteal artery supplies the gluteus medius, gluteus minimus, and tensor fascia latae muscles.^{1,7}

2.2. Function

The gluteus medius and gluteus minimus muscles typically function together as primary hip abductors. However, analysis of the moment arms of the gluteus medius muscle suggests that when the hip is flexed above 20°, the entire muscle is responsible for internal rotation and has limited ability to perform hip abduction in this position.^{8,9}

The gluteus medius muscle is frequently described as having three divisions. In addition to abduction, the anterior portion of the gluteus medius muscle internally rotates the femur.¹ Retchford et al¹⁰ suggest that the anterior portion of the gluteus medius muscle is active during hip extension in nonweight bearing, which may prevent anterior translation of the femoral head. The primary action of the middle portion of the gluteus medius muscle is hip abduction and hip internal rotation. The large cross-sectional area and vertical fiber orientation of the middle portion of the gluteus medius muscle would suggest that it plays a role in generating strong hip abduction and pelvic stabilization during the gait cycle. The middle portion of the muscle has also been found to be active in hip external rotation, but only at very low levels of intensity.¹¹ The smaller moment arm and the smaller cross-sectional area of the posterior fibers suggest that it likely plays a role in stabilizing the head of the femur in the acetabulum.¹² With the hip in a neutral and extended position, the posterior portion also boasts a moment arm for external rotation.⁸

One of the main functions of the gluteus medius muscle is to stabilize the pelvis on the femur and help maintain frontal plane alignment with the foot and knee in a closed kinetic chain during the unilateral stance phase of the gait cycle.^{12,13} During gait, the anterior fibers of the gluteus medius muscle assist the middle fibers in maintaining pelvic stabilization due to the large cross-sectional area, vertical fiber arrangement, and large moment arm. Also, the anterior fibers are believed to contribute to forward contralateral rotation of the pelvis in the transverse plane during the gait cycle.¹² Studies analyzing the activity of the gluteus medius muscle during gait also suggest a stabilizing effect of the pelvis on the hip by the activation prior to, and after, initial contact of the foot on the ground.

High levels of activation of the gluteus medius muscle take place during the gait cycle but are unaffected by ambulation on a sloped surface. Similar levels of activation occur regardless of walking on flat, inclined, or declined surfaces.¹⁴ The gluteus medius muscle does not show changes in activation with variations in the speed of ambulation.^{15,16}

During running, peak muscle force of the gluteus medius muscle has been shown to decrease during the stance phase of gait as step rate increases. The opposite is true for the swing phase, when peak force increases in the muscle as the step rate increases.¹⁷

Using surface electromyography (EMG), Lee et al¹⁸ found that, when the opposite upper extremity was carrying a load greater than 3 kg the posterior portion of the gluteus medius muscle on the opposite side of the load demonstrated significantly more EMG activity as opposed to no load and a 1 kg load.

Autopsy samples¹⁹ of gluteus medius muscles in normal adults under age 44 years showed 58% slow-twitch type 1 fibers and 42% fast-twitch type 2 muscle fibers. A relative (8%) loss of type 2 fibers in the gluteus medius muscle was observed in persons with osteoarthritis of the hip. Another adult group¹⁹ was divided equally between individuals older and younger than 65 years of age (individual variability was great in both groups), and in every subject, the number of slow-twitch type 1 fibers, which depend largely on oxidative metabolism, exceeded the number of fast-twitch type 2 fibers, which utilize glycolytic energy pathways. Therefore, the gluteus medius muscle may respond better to exercises with slow speeds and higher repetitions because a large part of its composition is made up of type 1 fibers.

2.3. Functional Unit

The functional unit to which a muscle belongs includes the muscles that reinforce and counter its actions as well as the joints that the muscle crosses. The functional interdependence of these structures is reflected in the organization and neural connections of the sensory motor cortex. The functional unit is emphasized because the presence of the TrP in one muscle of the unit increases the likelihood that the other muscles will develop TrPs. When inactivating TrPs in a muscle, one must be concerned about TrPs that may develop in muscles that are functionally interdependent. Box 55-1 represents the functional unit of the gluteus medius muscle.²⁰

Box 55-1 Functional unit of the gluteus medius muscle

Action	Synergists	Antagonists
Hip abduction	Gluteus minimus Gluteus maximus Obturator internus Tensor fascia latae Gemelli superior and inferior piriformis Obturator externus (external rotators can abduct the flexed thigh)	Adductor magnus Adductor longus Adductor brevis Gracilis Pectineus

Hip external rotation (hip neutral and extension; posterior fibers)	Gluteus minimus (posterior fibers) Gluteus maximus Obturator internus and externus Gemelli superior and inferior quadratus femoris	Gluteus medius (anterior fibers) Gluteus minimus (anterior fibers in extension, all fibers when the hip is flexed) Tensor fascia latae
Hip internal rotation (anterior fibers)	Gluteus minimus Tensor fascia latae	Gluteus medius (posterior fibers) Gluteus maximus Gluteus minimus (posterior fibers when in extension) Obturator internus and externus Gemelli superior and inferior piriformis Quadratus femoris

When the hip is flexed, the obturator internus and externus, gemelli superior and inferior, and piriformis muscles also assist with producing hip abduction.¹

When the hip is positioned in extension, the posterior fibers of the gluteus medius muscle work synergistically with the posterior fibers of the gluteus minimus, gluteus maximus, obturator internus and externus, gemelli superior and inferior, piriformis, and quadratus femoris muscles to produce external rotation of the hip.

The anterior fibers of the gluteus medius muscle in extension, and the entire muscle in flexion, produce internal rotation of the hip. This action is synergistic with the gluteus minimus and tensor fascia latae muscles.

3. CLINICAL PRESENTATION

3.1. Referred Pain Pattern

Trigger points in the gluteus medius muscle refer pain (or other symptoms) into the buttock, lower back, sacrum, posterior crest of the ilium, immediately lateral to the sacroiliac joint, from the lateral buttock to the hip, and to the posterior and lateral upper thigh (Figure 55-2). Any portion of the gluteus medius muscle can refer the symptoms noted. Commonly, TrPs found near the posterior portion of the muscle will refer pain near the sacroiliac joint, sacrum, and buttock. Trigger points found in the middle of the muscle will commonly refer more laterally and to the mid buttock, with occasional referral into the posterior and lateral upper thigh. Trigger points found along the anterior portion of the

gluteus medius muscle, where the muscle is more available to palpation, will refer pain and symptoms along the iliac crest, the lower portion of the lumbar spine, and over the sacrum. Trigger points in the gluteus medius muscle can be a commonly overlooked source of pain in the lower back.²⁰ This hypothesis was demonstrated by Iglesias-Gonzalez et al,²¹ who found that active gluteus medius TrPs were highly prevalent in patients with mechanical low back pain.

Figure 55-2. Pain patterns (bright red) referred from TrPs in the right gluteus medius muscle. The essential pain pattern is solid red, and the spillover pattern is stippled.

Other authors illustrate^{22–24} or describe²⁵ similar patterns of referred pain from this muscle. Two older papers describe referral of pain after injection of the gluteus medius muscle with hypertonic saline.^{26,27} A more recent study found that the gluteus medius muscle referred pain spread to the greater trochanter, buttock, posterior thigh, lateral thigh, knee, and leg after hypertonic saline injection.²⁸ Sola²⁴ described gluteus medius muscle referred pain as extending into the posterior thigh and calf, though it is the opinion of the authors that this pattern of pain probably arises from TrPs in the underlying gluteus minimus muscle (Chapter 56). Sola²⁴ also notes that the gluteus medius muscle is a frequent cause of hip pain in the later stages of pregnancy. The lateral hip pain pattern has been also noted with rare tear lesions of the proximal attachment of the gluteus medius muscle.²⁹

3.2. Symptoms

Patients with active TrPs in the gluteus medius muscle are likely to have a chief report of pain during walking and with weight-bearing activities. As the gluteus medius muscle is most active during weight-bearing activities, the patient will report increased pain and

discomfort with walking, running, and stair climbing. It is commonly seen in clinical practice that patients with TrPs in the gluteus medius muscle experience pain during prolonged periods of standing, for example waiting at the bus stop. To avoid the pain in these scenarios, the patient will often change the pelvic stance by shifting weight off the painful lower extremity. Pain with walking on inclines or declines is more commonly reported with gluteus maximus TrPs and is not typically associated with pain from TrPs in this muscle. Getting into and out of the car may be quite painful. The patient may report excruciating pain in the low back along the beltline on the side of the TrPs. Pain from these TrPs can be disabling and interfere with many functional activities. The patient may also report difficulty with rising from a seated position due to the excessive load placed on the gluteus medius muscle during this activity. Difficulty in sleeping may be reported, especially when lying on the involved side, due to pain caused by pressure on the TrPs. Bending and lifting activities will typically not be associated with gluteus medius TrP symptoms. TrPs in the gluteus medius muscles are often the cause of low back and hip pain during the later stages of pregnancy.

3.3. Patient Examination

After a thorough subjective examination the clinician should make a detailed drawing representing the pain pattern that the patient has described. This depiction will assist in planning the physical examination and can be useful in monitoring the progression of the patient as symptoms improve or change. The type, quality, and location of the pain should be carefully assessed, and the utilization of standardized outcome tools is imperative when examining patients with low back pain and lower extremity dysfunctions.

A physical examination should be conducted to rule out lumbar, sacroiliac, or hip joint dysfunctions. Range of motion testing of the hip and lumbar spine; passive accessory motion testing of the hip, sacroiliac joint, and/or lumbar spine; strength testing of the gluteus medius and gluteus minimus and other hip muscles; and any appropriate neurologic testing or orthopedic special tests should be performed. A careful assessment must be made to rule out referral into the buttock from other muscles, joints, or neural tissues.

Figure 55-3. Single-leg squat assessment of gluteus medius and gluteus minimus muscle of the knee in the frontal plane. A, Good control. B, Loss of control in the frontal plane with excessive valgus force (line) with increased stress at the medial knee (arrow).

Both the gluteus medius and gluteus minimus muscles function synergistically to provide frontal plane stability for the lumbopelvic region.³⁰ It is important to perform a postural examination in standing to identify a structural or functional scoliosis, the presence of an iliac upslip, anterior innominate rotation,³¹ and leg length discrepancy. A leg length discrepancy may be identified as a frontal plane asymmetry of the pelvis, with one side of the pelvis elevated and the opposite side depressed. This pelvic deviation could cause TrPs in the gluteus medius and gluteus minimus muscles on either or both sides from muscle overload. Functional activities such as sit-to-stand, single-leg stance, and double- and single-leg squat (Figure 55-3A) should also be examined. The clinician should take note of any frontal plane deviations in the pelvis, hip, and/or knee, and any excessive transverse plane motion at the ankle and foot (Figure 55-3B). The clinician should note gait deviations such as a Trendelenburg sign at mid-stance (Figure 55-4A and B), or forward lean of the trunk at heel strike, both of which indicate gluteus medius and gluteus minimus muscles weakness.³⁰

Lee et al³² investigated static and dynamic single-leg stance postures in 45 recreationally active women between 23 and 34 years of age. They found those with weaker hip abductor muscles demonstrated poor static and dynamic postural stability compared with those with stronger hip abductors. The investigators concluded that in the presence of weak hip abductors, the subjects relied more on their ankle for stability and control when standing on one leg.³²

Figure 55-4. Gluteus medius and gluteus minimus muscle weakness. A, Positive Trendelenburg sign. B, Compensated Trendelenburg Sign with shift of the center of gravity over the stance limb.

Because of regional interdependence of the hip and lumbar spine, specific testing should be carried out to identify interactive impairments. The prime movers for efficient hip abduction include the gluteus medius, gluteus minimus, and tensor fascia latae muscles. Oftentimes, the quadratus lumborum muscle compensates for weak gluteus medius or gluteus minimus muscles, which results in excessive forces in the lumbar spine. The role of the quadratus lumborum and abdominal muscles during limb movement are to stabilize the pelvis.³³ To assess the possibility of this compensation, the muscle activation pattern of side-lying hip abduction should be carefully examined. The patient's hip and lumbar spine

should be placed and supported in a neutral position prior to examining the side-lying hip abduction muscle activation pattern. The hip abduction muscle activation pattern has been described as beginning with the gluteus medius, gluteus minimus, and tensor fascia latae muscles activating in the first 20° of hip abduction followed by the quadratus lumborum and abdominal muscles.³³ Deviations in this activation pattern, especially pelvic elevation, may indicate gluteal weakness or inhibition due to TrPs. A common deviation to note is facilitation and early recruitment of the quadratus lumborum muscle (Figure 55-5A). If this deviation of the muscle activation pattern is observed, the pelvis should be stabilized during manual muscle testing to accurately assess the strength of the gluteus medius and gluteus minimus muscles (Figure 55-5B).

Hip abductor strength testing should be carried out bilaterally because both sides are responsible for lumbopelvic stability at different times during the gait cycle. If one side tests weaker than the other, excessive frontal plane motion can result in abnormal loading forces in the lumbar spine.

Gluteus medius and gluteus minimus muscle weakness or inhibition (which will present as weakness) can also lead to abnormal loading of the femoral head and cause excessive varus load in the lower extremity secondary to a relatively adducted position of the femur to the pelvis on the stance side.³⁴ This relative adducted position of the femur can also lead to compressive loading of the greater trochanter of the femur due to tensile loading of the gluteal muscles and may lead to abnormal compressive loading of the trochanteric bursa. The hip adductors should also be examined carefully for length and strength deficits as it is vital that the hip adductors and abductors work synergistically during weight-bearing activities, especially during gait.³⁰

If the gluteus medius and gluteus minimus muscles demonstrate impaired muscle activation patterns, release of TrPs should be the first priority for treatment, after which the patient should be placed on a gluteus medius and minimus muscle retraining program. Figure 55-6 and Box 55-2 illustrate a three-level progression for gluteus medius and gluteus minimus muscles retraining.

Figure 55-5. Side-lying hip abduction muscle activation pattern and strength test. A, Muscle activation pattern observing hip and pelvic motion. Note elevation of the left iliac crest as indicated by the solid white line demonstrating compensation by the quadratus lumborum muscle for inadequate strength or inhibition of the gluteus medius muscle. B, Stabilization

of the pelvis to inhibit the quadratus lumborum muscle for an accurate assessment of gluteus medius muscle inhibition or strength deficits. Note the change in the observed hip abduction range of motion.

Figure 55-6. Gluteus medius and gluteus minimus muscle retraining. A, Starting position, with the top hip flexed less than 20°. B, The upper hand is pressed into the table to stabilize the trunk. Keeping the feet together, the knee is lifted toward the ceiling by activating the gluteus medius, gluteus minimus, and gluteus maximus muscles (arrow). C, The foot is lifted away from the lower leg until it is parallel with the floor. Attention should be paid so that the foot does not rise above the knee. D, With the knee and hip aligned and straight, the leg is lifted toward the ceiling held for 6 to 10 seconds and lowered slowly.

Box 55-2 Gluteus medius and gluteus minimus muscles retraining

Starting position (Figure 55-6A)	The patient lies on the side, with the knees and hips slightly bent (<20°).
Level 1 (Figure 55-6B)	The patient lifts the knee while keeping the feet together, making sure not to allow the hips to rock back and the lumbar spine to rotate. The hand of the upper arm can press down into the surface to stabilize the trunk.
Level 2 (Figure 55-6C)	From the position of level 1, the patient lifts the top foot to the level of the knee but not above it, and holds this position for 6-10 seconds and then slowly lowers the leg to the starting position.
Level 3 (Figure 55-6D)	Starting with the knee and hip in line with the trunk, the patient lifts the entire lower extremity up without hiking the hip, holds for 6-10 seconds, and slowly lowers the leg back down.

Effective hip abduction training is essential for athletes because researchers have found that weak hip abductors play a role in anterior knee pain and are correlated to a higher incidence of anterior cruciate ligament ruptures.^{35,36} Lower activity of the gluteus medius muscle has been also found in patients after diagnosis of patellofemoral pain³⁷ or after reconstruction of the anterior cruciate ligament.³⁸ Additionally, this reduced activity in the gluteus medius muscle is higher in runners with rear foot strike and patellofemoral pain syndrome,³⁹ which suggests that the entire lower extremity should be evaluated. Nevertheless, others have observed that higher gluteus medius muscle activity during running is a risk factor for hamstring injury in football players.⁴⁰ Therefore, proper evaluation and treatment of the gluteus medius muscle is essential for athletes as part of a comprehensive lower extremity plan of care.

3.4. Trigger Point Examination

Trigger point examination requires specific knowledge of fiber direction of the gluteal muscles so that the clinician can be confident which muscles contain TrPs. Figure 54-10 illustrates the fiber arrangement and general size of the gluteus maximus, gluteus medius, and gluteus minimus muscles. Trigger points in the gluteus medius muscle are examined with the patient lying on the unaffected side. A pillow is placed between the knees to keep the hip in a neutral position and to avoid an aggravating stretch position. The clinician utilizes a cross-fiber flat palpation to examine the muscle (Figure 55-7A and B). The posterior portion is covered by the gluteus maximus muscle, making it more challenging to differentiate gluteus maximus TrPs from those of the gluteus medius muscle. If TrPs are felt in the gluteus maximus muscle, it may be necessary to inactivate those first to better evaluate the deeper gluteus medius muscle. Trigger points in the superficial fibers of the gluteus maximus muscle are easily palpated and are located just under the skin. Taut bands that feel deeper may be in deeper gluteus maximus muscle fibers or in the underlying gluteus medius muscle.

Figure 55-7. Cross-fiber flat palpation for TrPs in the gluteus medius muscle. A, Anterior portion. B, Middle and posterior portion.

Figure 55-8 illustrates the borders of each muscle and where the gluteal muscles overlap

to better inform palpatory exploration of these muscles. The gluteus medius muscle is limited superiorly by the rim of the pelvis (Figure 55-8A), in front by a line from slightly behind the anterior superior iliac spine to the greater trochanter, and below (posteriorly) by the piriformis line (Figure 55-8B) that runs along the upper border of the piriformis muscle (Figure 55-8A). The gluteus maximus muscle covers much of the posterior portion of the gluteus medius muscle, and the gluteus minimus muscle lies deep to the distal two-thirds of the gluteus medius muscle. In the region where the gluteus maximus, gluteus medius, and gluteus minimus muscles overlap, the insertion of a monofilament needle into the gluteus medius and gluteus minimus muscles to elicit a local twitch response or reproduce the patient's symptoms may improve accurate differentiation as dry needling can be a helpful diagnostic procedure.

Figure 55-8. Schematic drawing that shows overlap of gluteal and piriformis muscles from a slightly posterior, nearly lateral view. A, light red identifies the areas where only a single gluteal muscle may be palpated, except for the anterior part of the gluteus minimus muscle that is also covered by the tensor fasciae latae muscle (the iliac attachment is marked by a hatched line and is labeled). In these single-muscle areas, there is little likelihood of encountering misleading tenderness from another gluteal muscle or from the piriformis muscle. Medium red on the left side of A illustrates where either the gluteus medius or piriformis muscle may be palpated through the gluteus maximus muscle in an area free of deeper gluteus minimus muscle sensitivity; medium red on the right side of A illustrates

where the gluteus medius muscle overlies the gluteus minimus muscle. Dark red shows where three muscle layers—gluteus maximus, gluteus medius, and gluteus minimus muscles—are present. Note that the upper border of the piriformis muscle corresponds closely with the lower borders of the gluteus medius and gluteus minimus muscles. The gluteus medius muscle sometimes overlaps the piriformis muscle. B, The piriformis muscle line that corresponds closely to the upper border of the piriformis muscle runs from the proximal end of the greater trochanter of the femur (open square) to the upper end of the palpable free border of the sacrum where it joins the ilium (open circle). The piriformis muscle line is divided into thirds for convenience in locating TrPs in the posterior part of the gluteus minimus and piriformis muscles.

4. DIFFERENTIAL DIAGNOSIS

4.1. Activation and Perpetuation of Trigger Points

A posture or activity that activates a TrP, if not corrected, can also perpetuate it. In any part of the gluteus medius muscle, TrPs may be activated by unaccustomed eccentric loading, eccentric exercise in an unconditioned muscle, or maximal or submaximal concentric loading.⁴¹ Trigger points may also be activated or aggravated when the muscle is placed in a shortened and/or lengthened position for an extended period of time.

Activities that can cause overload of the gluteus medius and gluteus minimus muscles include weight lifting, running, and habitually shifting weight onto one side as in carrying a child or weighted object on the hip. The gluteus medius and gluteus minimus muscles can be overloaded from carrying heavy loads while walking, especially if the load is being handled unilaterally.¹⁸ Another factor to consider is strength imbalance between the gluteus medius and thigh muscles. When the strength ratio of the hip abductors was decreased in comparison with either that of the quadriceps or hamstrings, greater activation of the gluteus medius muscle occurred when carrying a moderately intense load in the upper extremities.⁴²

Any changes in the lower kinetic chain that place an increase demand on the gluteus medius muscle can activate or perpetuate TrPs. The gluteus medius muscle is active throughout the gait cycle and provides the majority of support through the mid-stance phase of gait.⁴³ Other abnormal intrinsic factors, such as excessive pronation or hip abductor or external rotator weakness, can contribute to excessive adduction and internal rotation of the hip through the stance phase of gait, resulting in a reduction in efficiency of the gluteus medius muscle in stabilizing the pelvis on the femur. This mechanical disadvantage may result in repetitive micro-trauma and overload of the gluteus medius muscle. Altered activation and reduced recruitment of the gluteus medius muscle has been identified in patients with increased hip joint adduction and internal rotation motion during stair climbing, squatting, and running.⁴⁴

4.2. Associated Trigger Points

Associated TrPs can develop in the referred pain areas caused by primary TrPs.⁴⁵ Therefore, musculature in the referred pain areas for each muscle should also be considered.

The TrPs in the posterior portion of the gluteus medius muscle may activate associated TrPs in the piriformis and the posterior portion of the gluteus minimus muscle. When TrPs in the anterior portion of the gluteus medius muscle are involved, associated TrPs may develop in the tensor fascia latae as part of the functional unit.

When the quadratus lumborum muscle has active TrPs, the gluteus medius muscle commonly develops associated TrPs as it lies in the pain referral zone of the quadratus lumborum muscle. In the presence of an active TrP in the quadratus lumborum muscle, treatment of the gluteus medius-associated TrP will offer only temporary relief. However, treating the active TrP in the quadratus lumborum muscle will often eliminate the associated TrP in the gluteus medius muscle.

Other muscles that should be evaluated because of the pain referral pattern from the gluteus medius muscle include the gluteus maximus, obturator internus and externus, superior and inferior gemelli, bicep femoris, semitendinosus, semimembranosus, lumbar multifidus, and iliocostalis lumborum muscles. Muscles that refer symptoms to the lateral hip and may activate associated TrPs in the gluteus medius muscle include the piriformis, gluteus maximus, and vastus lateralis muscles.

4.3. Associated Pathology

Differential diagnosis of clinical conditions should include lumbar pathology, sacroiliac dysfunction, and hip pathology. Symptom and pain referral patterns from the lumbar facet or sacroiliac joints overlap with the referred pain from TrPs in the gluteus medius muscle; therefore, examination of the lumbosacral region is indicated. Pain provocation studies looking at the referral zones for the sacroiliac joint have demonstrated referral frequently into the low back, buttock, and occasionally into the posterior or lateral thigh and leg.^{46, 47} Pain provocation studies mapping the referral zones for the hip joint have also demonstrated referral into the buttock, thigh, or groin in the majority of subjects.⁴⁸

Patients with L4, L5 lumbar radicular symptoms or radiculopathy have been found to have an increased frequency of TrPs in the gluteal muscles. Trigger points were found in 76% of patients with lumbar radiculopathy. The location of the TrPs matched the side of radiculopathy in 75% of subjects.⁴⁹ Trigger points in the gluteal muscles were found to be a highly specific indicator for individuals with radiculopathy.⁵⁰

Trigger points in the gluteal muscles have also been found in association with low back pain. Iglesias-Gonzalez et al²¹ found an association between active TrPs in the low back and hip muscles in participants with chronic lower back pain. Trigger points in the gluteus medius, iliocostalis lumborum, and quadratus lumborum muscles were the most prevalent. They also demonstrated a correlation between pain intensity and the number of active TrPs present, as well as a correlation between the number of active TrPs and lower sleep quality.²¹

Hip pathology can cause alterations in the patient's biomechanics or motor control,

activating TrPs in the gluteus medius muscle. Reduced activation of the gluteus medius muscle has been found in patients with symptomatic labral tears during both concentric and eccentric loading.⁵¹ Weakness of the hip abductor muscles has also been found in patients with femoroacetabular impingement or labral tears.⁵²

Altered activation of the gluteus medius muscle has been found with increasing severity of hip osteoarthritis. As the severity of osteoarthritis increases, the activation of the gluteus medius muscle becomes more prolonged between the normal peaks at initial contact and mid stance, leading to repetitive overload of the gluteus medius and gluteus minimus muscles.⁵³ Uemura et al⁵⁴ found that hip osteoarthritis can lead to atrophy of the gluteal muscles, but that the muscle volume can recover more than 2 years after total hip arthroplasty.

Additionally, researchers have found a correlation between weakness of the hip musculature, excessive hip adduction and internal rotation, and patellofemoral pain.^{55–59} Roach et al⁵⁵ found an increase in the prevalence of TrPs in the bilateral gluteus medius and quadratus lumborum muscles in patients with patellofemoral pain.

Gluteal tendinopathy is considered to be one of the major causes of greater trochanteric pain syndrome (GTPS). Bird et al⁶⁰ investigated the presence of gluteus medius tendon pathology in 24 subjects with signs and symptoms consistent with GTPS. They utilized magnetic resonance imaging, positive Trendelenburg sign, and pain with resisted hip abduction and hip internal rotation as predictors of a gluteus medius tendon tear. They found that the Trendelenburg sign had a sensitivity of 0.73 and a specificity of 0.80 in predicting a gluteus medius tendon tear in subjects who failed to respond to conservative care.⁶⁰ The recommended intervention for tears of the gluteus medius tendon is trochanteric micropuncture; however, there is a lack of long-term follow-up on this relatively new procedure.⁶¹

5. CORRECTIVE ACTIONS

Patients with gluteus medius TrPs having difficulty with sleeping may need to modify their sleeping posture. They may benefit from lying supine or sleeping on the opposite side. A pillow between the legs to avoid a painful stretch into adduction of the hip may be necessary if sleeping in side-lying (Figure 55-9). If an individual has TrPs in the posterior portion of the gluteus medius muscle, they may be compressed when lying on the back, resulting in pain in that position.

Figure 55-9. Sleeping position for gluteus medius and gluteus minimus muscles. Pillow is placed between the legs to keep the hip aligned with the trunk and shoulder.

Self-pressure release of TrPs in the gluteus medius muscle can be achieved with the utilization of a TrP release tool, tennis ball, or a lacrosse ball. To perform TrP self-pressure release with a TrP tool, the affected or painful side is up (Figure 55-10A). The tool can be used to locate a sensitive spot and then to apply light pressure (no more than 4/10 pain) for 15 to 30 seconds or until pain reduces. This release can be repeated five times, several times per day. The patient may also utilize a ball or other handheld tool by gently lying on top of the ball following the same procedure as in Figure 55-10B and C. While rolling over the gluteus medius muscle, attention should be paid to any tender spots. A slow rocking motion or a pause over the area can be used prior to moving to the next area. Pressure should be mildly uncomfortable but not overly painful (Figure 55-10C).

Figure 55-10. Gluteus medius muscle self-pressure release. A, Trigger point pressure-release tool. B, Tennis ball. C, Trigger point pressure-release tool (half round).

Self-stretch of the gluteus medius muscle can be achieved by lying on the uninvolved side on the edge of a firm surface, flexing the lower hip, so that the lower foot can support the top leg (Figure 55-11A). The top leg can then be lowered until a slight stretch or discomfort is felt over the hip. The lower leg supports the top leg so as not to stretch the TrPs in the gluteus medius muscle too aggressively (Figure 55-11B). The patient should take a slow inhalation and then relax during exhalation allowing gravity to assist in stretching the gluteus medius muscle (Figure 55-11B). If the bed is too soft, the same stretch maneuver can be performed at the top of a stair landing with a pillow under the bottom hip (Figure 55-11C and D).

Figure 55-11. Gluteus medius and gluteus minimus muscles self-stretch. A and B, Off the edge of the bed. A, Starting position. B, Ending position. C and D, Off the landing of a staircase. C, Starting position. D, Ending position.

Adequate strength of the gluteus medius and gluteus minimus muscles is vital to allow for proper mechanics during walking once the TrPs have been deactivated. Altered mechanics that cause the hip to turn in and/or adduct on the weight-bearing side while walking needs to be corrected. Careful muscle retraining to avoid aggravation of the condition will be beneficial to prevent recurrence. A licensed rehabilitation professional should be consulted for a proper exercise prescription.

Gluteus Minimus and Tensor Fasciae Latae Muscles

“Pseudo-Sciatica and Pseudotrochanteric Bursitis”

Paul Thomas, N. Beth Collier, and Joseph M. Donnelly

1. INTRODUCTION

The gluteus minimus muscle is the smallest of the gluteal muscles, but plays an important role in the normal biomechanics of the hip during the gait cycle. It is the deepest of the gluteal muscles and not only shares an intimate attachment with the hip joint capsule but also functions with it. Its primary function is hip abduction with the gluteus medius muscle and is active during several other motions of the hip. It is believed to contribute significantly to the stability of the hip during walking, running, and lateral movements. Individuals with trigger points (TrPs) in the gluteus minimus muscle may report excruciating pain in the hip and lower extremity down to the ankle. The extensive referral pattern of pain into the lower extremity that occurs when TrPs are present in the gluteus minimus muscle makes it necessary to perform a thorough lumbopelvic and hip examination. Differential diagnosis includes lumbar radicular pain or radiculopathy, sacroiliac joint dysfunction, trochanteric bursitis, and hip pathology. Corrective actions should include postural advice to improve sitting and sleeping postures, correction of gait abnormalities, self-pressure release, and self-stretching techniques.

The tensor fasciae latae muscle is a superficial muscle that works with the gluteus medius and minimus muscles to stabilize the pelvis during unilateral standing. It is the smallest of the hip abductors and also contributes to hip flexion and internal rotation. Trigger points in the tensor fasciae latae muscle refer pain to the lateral thigh and can be commonly mistaken for symptoms of trochanteric bursitis. Iliotibial band syndrome should be considered in the differential diagnosis in addition to those identified above for the gluteus minimus muscle. Corrective actions includes postural advice (especially for sitting and sleeping), maximizing efficiency during walking and running activities, self-pressure release, and stretching.

For resolution of symptoms in both the gluteus minimus and tensor fasciae latae muscles, correction of altered biomechanics in the lower kinetic chain will need to be

addressed.

2. ANATOMIC CONSIDERATIONS

Gluteus Minimus

The gluteus minimus muscle lies deep to the gluteus medius muscle and is the smallest in length and lightest in weight of the gluteal muscles.¹ Its fan shape corresponds closely to the overlying gluteus medius muscle. The muscle originates along the outer surface of the ilium between the anterior and inferior gluteal lines and approaches the greater sciatic foramen posteriorly (Figure 56-1). Fiber orientation of the muscle can be divided into two portions, with the anterior fascicles arranged more vertically and the posterior fascicles arranged more horizontally² (Figure 56-1). The muscle fibers converge into an aponeurosis that terminates in a tendinous attachment along the anterolateral surface of the greater trochanter, deep and anterior to the piriformis muscle attachment, and contributes a broad insertion superolaterally onto the joint capsule of the hip.³⁻⁶ Additional slips may pass to the piriformis, gemellus superior, or vastus lateralis muscles.⁴

Figure 56-1. Attachments of the right gluteus minimus muscle (red) in the posterolateral view. To a large extent, the overlying gluteus maximus and gluteus medius muscles have been removed.

The relative thickness of the gluteus minimus muscle and its anatomic relation to the tensor fasciae latae muscle are shown in the serial cross-sections of Figure 56-2. The greater thickness of the anterior part of the gluteus minimus muscle, when compared with its posterior part, is not generally appreciated. This difference in thickness is seen in the lowest section of Figure 56-2, the plane of which lies approximately midway between the anterior superior iliac spine and the anterior inferior iliac spine. The cross-section also illustrates how the anterior portion of the gluteus minimus muscle can be palpated both behind the posterior margin of the tensor fasciae latae muscle and between the tensor's anterior margin

and the anterior border of the ilium.

Figure 56-2. Serial cross-sections through the pelvis that show the gluteus minimus muscle (dark red). The three sections show the relation of the anterior portion of this muscle to the ilium, to neighboring muscles (light red), and to the skin. The level of the middle section passes through the anterior superior iliac spine. The plane of the lowest section lies between

the anterior superior iliac spine and the anterior inferior iliac spine. At the latter level, the thickest part of the anterior portion of the gluteus minimus muscle may be subcutaneous between the tensor fasciae latae and gluteus medius muscles. This anterior portion is palpated for TrPs along the posterior margin of and deep to the tensor fasciae latae muscle.

The trochanteric bursa of the gluteus minimus muscle, which lies between the anterior part of the muscle's tendon and the greater trochanter, facilitates gliding movement of the tendon over the trochanter.⁴ This gliding movement of the tendon is necessary for the anterior fibers of the muscle to reach full stretch range of motion.

Tensor Fasciae Latae

The tensor fasciae latae muscle originates from the anterior part of the outer lip of the iliac crest, the lateral aspect of the anterior superior iliac spine, and to the deep surface of the fascia latae.⁴ Superiorly, it lies between the gluteus medius and the sartorius muscles. Proximally, the tensor fasciae latae muscle inserts to the aponeurotic fascia superficial to the gluteus medius muscle. It descends and attaches to the two layers of the iliotibial tract and terminates approximately one-third of the way down the thigh, though it may descend as far as the lateral femoral condyle (Figure 56-3).

Figure 56-3. Side view of attachments of the right tensor fasciae latae muscle (red, fascia cut). Above, the muscle attaches along and below the crest of the ilium just posterior to the anterior superior iliac spine. Below, the anteromedial tendinous fibers attach to the fascia at the knee, and the posterolateral tendinous fibers anchor to the iliotibial tract, which continues down to the lateral tubercle of the tibia.

2.1. Innervation and Vascularization

Gluteus Minimus

The gluteus minimus muscle is innervated by the superior gluteal nerve (L4, L5, and S1).

The gluteus minimus muscle receives its vascularization from the superior gluteal artery which exits the pelvis through the greater sciatic foramen superior to the piriformis muscle,

traveling anterior between the gluteus medius and minimus muscles.² The superficial branch supplies the gluteus maximus muscle, the deep branch supplies the gluteus medius, gluteus minimus, and tensor fasciae latae muscles.^{4,7} The superior gluteal nerve and artery travel between the gluteus medius muscle and the gluteus minimus muscle.⁴

Tensor Fasciae Latae

The tensor fasciae latae muscle is innervated by the superior gluteal nerve, derived from the L4, L5, S1 spinal nerves. The muscle receives its vascular supply from a large ascending branch of the lateral femoral circumflex artery. The superior aspect of the muscle receives its supply from the superior gluteal artery.⁴

2.2. Function

Gluteus Minimus

The anterior fibers of the gluteus medius and minimus muscles function to abduct the thigh and internally rotate the femur.^{4,5} The gluteus minimus muscle may function as a dynamic stabilizer of the hip^{6,8} and may retract the hip joint capsule during hip abduction.⁵ Biomechanical studies of the gait cycle have shown that muscular forces acting across the hip joint provide 95% of the contact force.⁹ Fibers of the gluteus minimus muscle attach to the superoanterior hip joint capsule and may reduce superolateral translation of the head of the femur during gait.⁸ Beck et al¹⁰ described the gluteus minimus muscle as a hip abductor and hip flexor but also as a hip internal or external rotator depending on the position of the femur relative to the pelvis.¹⁰ In hip extension, the anterior fibers can produce internal rotation and posterior fibers can produce external rotation.¹⁰ At 90° of hip flexion, all fibers produce hip internal rotation.¹⁰ When the anterior and posterior fibers contract concurrently, the gluteus minimus muscle also pulls the head of the femur into the acetabulum to increase stability, especially with the hip in extension.^{10,11} Tightening of the joint capsule may also aid in stability regardless of position.^{6,10}

During the gait cycle, the posterior portion of the gluteus minimus muscle demonstrates a large burst of activity early in the stance phase that may be due to its role as a stabilizer of the femoral head. Both the anterior and posterior portions are active through mid-to-late stance. The role of the anterior gluteus minimus muscle during this phase may minimize forces at the anterior hip joint (acetabulum, capsule, and anterior superior acetabular labrum) through its ability to stabilize the femoral head with the iliopsoas muscle.¹² Anderson et al¹³ found that the gluteus medius and gluteus minimus muscles provided nearly all of the support of the pelvis during the mid-stance of the gait cycle.

Tensor Fasciae Latae

The tensor fasciae latae muscle assists flexion, abduction, and internal rotation of the hip.⁴

It is considered to be a hip abductor that acts with the gluteus medius and minimus muscles; however, it accounts for only 11% of the total cross-sectional area of the hip abductors.¹⁴ The most posterolateral fibers are also involved in locking the knee in full extension with the hip maintained in internal rotation.¹⁵ Bouillon et al¹⁶ investigated eight muscles utilizing surface electromyography and percent maximum voluntary isometric contractions (%MVIC) during a step down, forward lunge, and side-step lunge. They found that the gluteus maximus and gluteus medius muscles had high %MVIC during the step down, and moderate %MVIC in side step, whereas the tensor fasciae latae (TFL) had low %MVIC during all three activities.

As is the case for most other lower extremity muscles, the tensor fasciae latae muscle functions during the stance phase of gait, more specifically mid-stance, and acts primarily with the gluteus medius and minimus muscles to control frontal plane movement of the pelvis. Paré and associates¹⁵ have shown that the anteromedial half and the posterolateral half of the tensor fasciae latae muscle are active at different times for different reasons. During gait, the most anteromedial fibers were active in the swing limb (mid-swing) and the most posterolateral fibers were activated in the stance limb. The posterolateral fibers assist the gluteus medius and gluteus minimus muscles in stabilizing the pelvis, countering the tendency of a contralateral pelvic drop in mid-stance.¹⁷ The most posterolateral fibers are also involved in stabilizing the knee.¹⁵

The posterolateral fibers are also active at heel-strike during jogging, running, sprinting,^{15, 18} stepping up on a platform, and climbing a ladder. The more vigorous is the activity, the more vigorous are the muscle contractions. During bicycling,¹⁹ this muscle was electromyographically active during the period when the hip flexors became active as the pedal progressed upward from horizontal through the top of its stroke.

2.3. Functional Unit

The functional unit to which a muscle belongs includes the muscles that reinforce and counter its actions as well as the joints that the muscle crosses. The interdependence of these structures is functionally reflected in the organization and neural connections of the sensory motor cortex. The functional unit is emphasized because the presence of the TrP in one muscle of the unit increases the likelihood that the other muscles will develop TrPs. When inactivating TrPs in a muscle, one must be concerned about TrPs that may develop in muscles that are functionally interdependent. Box 56-1 represents the functional unit of the gluteus minimus muscle and Box 56-2 represents the functional unit of the tensor fasciae latae muscle.²⁰

Box 56-1 Functional unit of the gluteus minimus muscle

Action	Synergists	Antagonists
Hip abduction	Gluteus medius	Adductor magnus

	Gluteus maximus Obturator internus Tensor fasciae latae Gemellus superior and inferior Piriformis Obturator externus	Adductor longus Adductor brevis Gracilis Pectineus
Hip external rotation (posterior fibers of gluteus minimus when the hip is extended)	Gluteus medius (posterior fibers) Gluteus maximus Obturator internus and externus Gemellus superior and interior Piriformis Quadratus femoris	Gluteus minimus (anterior fibers in extension, all fibers when the hip is flexed) Tensor fasciae latae
Hip internal rotation (anterior fibers when the hip is extended, all fibers when the hip is flexed)	Tensor fasciae latae Gluteus medius (anterior fibers)	Gluteus minimus (posterior fibers when in extension) Gluteus maximus Gluteus medius (posterior fibers) Obturator internus and externus Gemellus superior and inferior Quadratus femoris Piriformis

Box 56-2 Functional unit of the tensor fasciae latae muscle

Action	Synergists	Antagonists
Hip flexion	Rectus femoris Iliopsoas Pectineus Gluteus medius and minimus (anterior fibers)	Gluteus maximus Hamstring muscles
Hip internal rotation	Gluteus medius (anterior fibers) Gluteus minimus (anterior fibers when the hip is	Gluteus minimus (posterior fibers when in extension) Gluteus maximus Gluteus medius (posterior

	extended, all fibers when the hip is flexed)	fibers) Obturator internus and externus Gemellus superior and inferior Quadratus femoris Piriformis
--	--	---

All fibers of the gluteus minimus muscle are active to produce internal rotation of the hip when it is flexed, and the anterior fibers produce hip internal rotation with the anterior fibers of the gluteus medius muscle when the hip is extended.

3. CLINICAL PRESENTATION

3.1. Referred Pain Pattern

Gluteus Minimus

Pain and symptoms from TrPs in the gluteus minimus muscle can be quite severe and persistent. The pain referral pattern of the gluteus minimus muscle can be extensive, making it easy to overlook this muscle as the source of the symptoms. Lower extremity paresthesia and dysesthesia oftentimes accompany the pain referral pattern from TrPs in the gluteus minimus muscle. These symptoms are commonly referred to as “sciatica,” which serves as merely a description of pain in the lower extremity and not a diagnosis. Travell in 1946 first distinguished different typical pain referral patterns from the anterior and posterior portions of the gluteus minimus muscle.²¹

Trigger points found within the anterior portion of the gluteus minimus muscle will typically refer pain and tenderness along the lower lateral portion of the buttock, lateral thigh, and lateral leg to the ankle, mimicking L5 radicular symptoms²¹ (Figure 56-4).

Figure 56-4. Referred pain patterns from TrPs in the gluteus minimus muscle. Referred pain and symptoms can be felt into the buttock, lateral and/or posterior thigh, posterior and/or lateral calf as distal to the lateral malleolus.

Trigger points located in the posterior portion of the gluteus minimus muscle will refer pain throughout the buttock, especially the medial lower buttock, into the posterior thigh, posterior knee, and posterior calf, mimicking S1 radicular symptoms²¹ (Figure 56-4).

Tensor Fasciae Latae

Patients with TrPs in the tensor fasciae latae muscle often describe pain in the hip joint region spanning inferiorly along the anterolateral aspect of the thigh, occasionally extending as far as the knee (Figure 56-5). The term “psuedotrochanteric bursitis” often applies to the

pain produced by active TrPs in the tensor fasciae latae muscle. The pain is more severe during movement of the hip.^{22–24}

Figure 56-5. Referred pain pattern from TrPs in the tensor fasciae latae muscle (red).

3.2. Symptoms

Gluteus Minimus

Individuals with TrPs in the gluteus minimus muscle may report significant hip pain, which causes an antalgic gait pattern and difficulty with weight bearing on the affected side. It may be painful while walking, lying down, or when trying to get up from sitting. Symptoms arising from TrPs in the gluteus minimus muscle can be constant and excruciating. Pain may occur while the patient tries to lie on the affected side, making it necessary to lie on the opposite side or stay awake during the night because of discomfort. The patient may not be able to find a stretching movement or change of position that relieves the pain and can neither lie down comfortably nor walk normally. Coughing and

sneezing will typically not aggravate symptoms generated from TrPs in the gluteus minimus muscle. As with gluteus medius TrPs, patients with TrPs in the gluteus minimus muscle usually experience pain during prolonged standing. Patients typically report that they have to shift their weight side to side to avoid pain in their hip and leg.

Tensor Fasciae Latae

Typically, patients with TrPs in the tensor fascial latae muscle will report poor tolerance for prolonged sitting, with the hip flexed to 90° or more. They may also report pain when transitioning to standing after a period of prolonged sitting. These patients are usually unable to lie comfortably on the affected side because of the pressure on the area of referred tenderness over the greater trochanter of the femur as well as directly on the TrPs. They are sometimes unable to lie on the opposite side without a pillow between the knees because of a prolonged stretch on the tensor fasciae latae muscle.

Long-distance runners may report functional limitation because of increased pain in the thigh area from the increased load placed on the tensor fasciae latae muscle during running.

3.3. Patient Examination

After a thorough subjective examination the clinician should make a detailed drawing representing the pain pattern that the patient has described. This depiction will assist in planning the physical examination and can be useful in monitoring the progression of the patient as symptoms improve or change.

Gluteus Minimus

A thorough physical examination of the lumbopelvic and hip regions is indicated when a patient is reporting referred pain and symptoms from TrPs in the gluteus minimus muscle. Because of the extensive referral of symptoms down the lower extremity, the clinician will need to differentiate these symptoms from those of sciatic or radicular origins. Neurodynamic testing should be performed to differentiate signs and symptoms originating from neural tissues from symptoms generated by TrPs in the gluteus minimus muscle. The hip and sacroiliac joints should also be evaluated to determine if there are any biomechanical deviations that could contribute to the activation and perpetuation of TrPs in the gluteus minimus muscle.

The physical examination for the gluteus minimus muscle is the same as that for the gluteus medius muscle, which is detailed in Chapter 55. This assessment includes static and dynamic posture, gait analysis, double- and single-leg squat, muscle activation pattern in side-lying hip abduction, and strength testing of the hip and thigh muscles. Because of the anatomic projection of the gluteus medius and gluteus minimus muscles, confirmation of TrPs in this deep muscle would be feasible with the application of dry needling obtaining a local twitch response or the pain referral pattern.

Tensor Fasciae Latae

The physical examination for the tensor fasciae latae muscle is similar to that of the gluteus medius and gluteus minimus muscles; however, the patient may demonstrate an anterior pelvic tilt and an increased lumbar lordosis while standing. Oftentimes, patients with tensor fasciae latae TrPs may keep the hip slightly flexed when standing or shift their weight to one leg and translate their pelvis laterally. They may demonstrate a lack of hip extension during gait. Ambulation with the hips flexed is typically not painful; however, their pain may prevent the patient from walking rapidly. In a common syndrome of muscle imbalance, tight tensor fasciae latae and quadratus lumborum muscles overpower an inhibited or weak gluteus medius muscle. Trigger points in the facilitated or tight muscles must be released preceding efforts to activate and strengthen the gluteus medius muscle.

The patient may be examined for muscle tightness in a Thomas test position, with the patient at the edge of a table holding one hip in full flexion to maintain a neutral spine and the hip to be inspected lowered into hip extension. In this testing position, the affected thigh can be tested for muscle length restriction by pressing the thigh of the extended limb medially, assessing hip adduction range of motion²⁵ (Figure 56-6). When the tensor fasciae latae muscle is tight, adduction is limited to a range of less than 15°. Contraction of the tensor fasciae latae muscle is tested with the patient lying on the contralateral side. The patient is asked to raise the foot of the affected leg into abduction and slight hip flexion while the clinician palpates both the gluteus medius and tensor fasciae latae muscles with one hand and tests for strength by applying graded resistance to the limb with the other hand. Loading the muscle during either test is likely to cause pain in the region of the affected hip joint if the muscle has active TrPs.

Figure 56-6. Thomas test assessing the length of the tensor fasciae latae muscle. A, Two joint hip flexor muscle length assessment. B, One joint hip flexor muscle length assessment.

A tight tensor fasciae latae muscle can contribute to perceived iliotibial band tightness. Iliotibial band restriction can be assessed with the Ober or modified Ober test.²⁵ Clinically, a positive Ober test would prompt the clinician to check the length of the gluteus maximus, gluteus medius and tensor fasciae latae muscles as all three of these muscles attach to the fascia latae. Tightness of the tensor fasciae latae muscle can also produce the appearance of a shorter limb on the involved side when the patient is examined in a supine to long sit position.

3.4. Trigger Point Examination

Gluteus Minimus

Trigger points in the gluteus minimus muscle lie deep to the gluteus maximus, gluteus medius, or tensor fasciae latae muscles, making them challenging to palpate. If the superficial muscles are fully relaxed, sometimes the practitioner can palpate some of the TrPs deep in the buttock. Commonly, the taut bands are unlikely to be palpated, but TrP tenderness can be localized. Occasionally, it is possible to reproduce the pain referral pattern with palpation of the TrP, but many times it will be elicited only when stimulated with a filiform or injection needle. The anterior fibers of the gluteus minimus muscle can

be palpated with the patient lying supine or in hook-lying (Figure 56-7A). Using deep, cross-fiber flat palpation, the clinician can evaluate the fibers of the gluteus minimus muscle anterior, and then posterior, to the tensor fasciae latae muscle below the level of the anterior superior iliac spine. In some patients, the gluteus medius muscle may lie superficial to the gluteus minimus muscle up to the posterior border of the tensor fasciae latae muscle. To examine the posterior aspect of the gluteus minimus muscle, patients will lie on their side with the hip flexed to about 30° and adducted (Figure 56-7B).

Figure 56-7. Palpation of TrPs in the gluteus minimus muscle using cross-fiber flat palpation. A, Supine anterior portion of the muscle. B, Side-lying through the gluteus medius muscle.

Tensor Fasciae Latae

Trigger points in this superficial muscle can be identified in a supine (Figure 56-8A) or side-lying position with cross-fiber flat palpation (Figure 56-8B). The muscle can be located by palpating its tension while the patient performs a gentle isometric contraction of hip abduction and internal rotation. When the patient is fully relaxed and the muscle is placed under slight stretch, the entire muscle belly should be palpated for the presence of TrPs. Trigger points in this muscle may take up to 10 seconds, when compressed, to produce the pain referral pattern into the lateral thigh.

Figure 56-8. Palpation of TrPs in the tensor fasciae latae muscle using cross-fiber flat palpation. A, Supine. B, Side-lying.

4. DIFFERENTIAL DIAGNOSIS

4.1. Activation and Perpetuation of Trigger Points

A posture or activity that activates a TrP, if not corrected, can also perpetuate it. In any part of the gluteus minimus or tensor fasciae latae muscles, TrPs may be activated by unaccustomed eccentric loading, eccentric exercise in an unconditioned muscle, or maximal or submaximal concentric loading.²⁶ Trigger points may also be activated or aggravated when the muscle is placed in a shortened and/or lengthened position for an extended period of time.

Gluteus Minimus

Because the gluteus minimus muscle is active throughout the stance phase of gait, any alterations of the mechanics of walking or running gait may play a role in the development of TrPs. Excessive adduction moment on the hip and pelvis due to hip abductor weakness/inhibition, genu valgum, abnormal foot pronation, or gait deviation from an injury to another joint could increase the demand on the gluteus minimus muscle during the stance phase of gait.^{27–29}

Trigger points in the gluteus minimus muscle may also be activated by an acute overload due to a fall. Excessive use of the muscles during an unaccustomed activity such as hiking over uneven ground, running, or racquet sports may overload the gluteus minimus muscle, causing development of TrPs.²¹

Sitting on a wallet placed in the back pocket can compress gluteus minimus TrPs and produce referred pain into the lower extremity. Prolonged immobility from standing in line or at a cocktail party, or prolonged sitting while driving, can also aggravate TrPs in the gluteus minimus muscle.

Lumbar radicular pain or radiculopathy in the L4, L5, or S1 nerve roots can activate and perpetuate TrPs in the gluteal muscles. Treatment of the TrPs will give the patient temporary relief of symptoms; however, the source of the radicular symptoms must be treated for long-lasting relief. Following a transforaminal epidural spinal injection or lumbar surgery for the treatment of radicular pain, the intensity of symptoms subsides, but there are often residual symptoms in the referral zones from TrPs in the muscles that are innervated by these nerve roots. Treatment of these TrPs will typically resolve the residual pain and symptoms.

Tensor Fasciae Latae

Activation of tensor fasciae latae TrPs may be due to sudden trauma, as when landing on the feet from a high jump, or chronic overload. Chronic overload may be caused by jogging uphill and downhill without appropriate support for an excessively pronated foot. Similarly, regular walking or running on surfaces that are uneven or sloped to one side, as on the edge of a paved street in a road race, can lead to tensor fasciae latae dysfunction because these

slants increase genu varus and supination in one leg and genu valgus and pronation in the other. Poor conditioning and inadequate warm-up stretching exercises can lead to injuries that activate or perpetuate TrPs in runners. Weakness or inhibition from TrPs in the gluteus medius and gluteus minimus muscles may also cause overload to the tensor fasciae latae muscle because of its synergistic role in stabilizing the pelvis in the frontal plane. Allison et al³⁰ found in individuals with gluteal tendinopathy that the tensor fasciae latae muscle was activated quicker when compared with controls in the early mid-stance phase of gait to assist the gluteal muscles in lateral hip stability.

As in other muscles, TrPs in the tensor fasciae latae muscle are aggravated by immobilization in the shortened position for long periods. This happens during prolonged sitting with the hip at an acute angle or while sleeping in a tightly flexed fetal position. Walking with heavy loads can place increased stress on the tensor fasciae latae muscle.

Maintaining a seated position where the hips are flexed past 90° or habitual sleeping a fetal position will aggravate and perpetuate TrPs in this muscle.

4.2. Associated Trigger Points

Associated TrPs can develop in the referred pain areas caused by primary TrPs.³¹ Therefore, musculature in the referred pain areas for each muscle should also be considered.

Gluteus Minimus

Active TrPs in the gluteus minimus muscle rarely present as a single-muscle syndrome. The TrPs in this muscle are most often observed in association with TrPs in the quadratus lumborum, piriformis, gluteus medius, vastus lateralis, and fibularis longus muscles, and sometimes, in the gluteus maximus muscle. The two muscles that are most closely associated functionally with the gluteus minimus muscle (the gluteus medius and the piriformis muscles) are also the most likely to develop associated TrPs. The anterior fibers of the gluteus minimus and the tensor fasciae latae muscles are closely related functionally and may develop associated TrPs.

Trigger points commonly develop in the posterior portion of the gluteus minimus muscle, and less frequently in the anterior portion, as associated to quadratus lumborum TrPs. This coupling can be so strong that pressure exerted on the quadratus lumborum TrPs induces not only the expected referred pain in the buttock but also unexpected pain referred down the back of the lower extremity.²¹ This additional pain results from an activation of associated TrPs in the posterior part of the gluteus minimus muscle; pressure applied to these gluteal TrPs elicits the same lower extremity pain. Sometimes, elimination of the quadratus lumborum TrPs inactivates the associated gluteal TrPs. In other patients, TrPs in the two muscles must be inactivated separately.

Similarly, the fibularis longus and fibularis brevis muscles, which lie in the pain reference zone of the anterior part of the gluteus minimus muscle, have been seen to develop associated TrPs. Other muscles that should be evaluated for TrPs for being in the zone of the referred pain pattern from the gluteus minimus muscle include the obturator

internus and externus, gemellus superior and inferior, quadratus femoris, bicep femoris, semitendinosus and semimembranosus, gastrocnemius, soleus, popliteus, posterior tibialis, flexor digitorum longus, and flexor hallucis longus muscles.²¹

Tensor Fasciae Latae

Pain referred from TrPs in the tensor fasciae latae muscle can easily be mistaken for pain arising from TrPs in the gluteus minimus, gluteus medius, or vastus lateralis muscles. Trigger points in the quadratus lumborum muscle also refer pain and tenderness to the greater trochanter.

Trigger points in the tensor fasciae latae muscle may occur as a single-muscle syndrome or, more commonly, may develop secondary to TrPs in the anterior gluteus minimus and, sometimes, in the rectus femoris, iliopsoas, or sartorius muscles. Tensor fasciae latae TrPs cannot be eliminated if active TrPs remain in the anterior gluteus minimus muscle, which prevent its full stretch range of motion.

4.3. Associated Pathology

Gluteus Minimus

Altered activity of the gluteus minimus muscle has been observed in individuals with hip pain.³² Earlier onset of activity of the gluteus minimus muscle was observed during step-down activity in a study of participants with hip pain. They also demonstrated increased gluteus minimus muscle activity during swing phase compared with control subjects.³² Because the gluteus minimus muscle mitigates translation of the hip during the stance phase of gait, overload of the muscle may occur in individuals with instability of the hip.¹¹ Instability or micro-instability may result from trauma to the ligamentous structures from repetitive loading, bony abnormalities such as anteversion or retroversion, dysplasia, labral tears, sports-related traumas, or connective tissue disorders.³³

Trigger points in the gluteal and hip muscles have been found in association with lower back pain including the gluteus minimus muscle. Iglesias-Gonzalez et al found an association between active TrPs in the lower back and hip muscles in participants with chronic lower back pain. In their study, they showed a correlation between the intensity of pain and the number of active TrPs and also a correlation between the number of active TrPs and sleep quality.³⁴

Adelmanesh et al³⁵ investigated the prevalence of gluteal TrPs in 271 patients diagnosed with lumbar radiculopathy compared with 152 healthy controls. They found that 76% of patients with unilateral radicular symptoms had gluteal TrPs on the painful side when compared with 2% of the control group. Based on previous work, Adelmanesh et al³⁶ investigated the diagnostic accuracy of gluteal TrPs to differentiate radicular from nonradicular low back pain. They determined the diagnostic value of identifying gluteal TrPs by manual palpation (gluteal TrP test) in the superior-lateral quadrant in the gluteal

region. They found a specificity of 0.91 and a sensitivity of 0.74 of the gluteal TrP test. They conclude that the presence of TrPs in the superolateral quadrant of the gluteal region is a highly specific indicator for individuals with radicular symptoms.³⁶

Tensor Fasciae Latae

Radicular pain from the L4 nerve root or the peripheral nerve entrapment of the lateral femoral cutaneous nerve (meralgia paresthetica) may produce symptom distribution confusingly similar to the pattern of pain referred from tensor fasciae latae TrPs. When patients have symptoms of meralgia paresthetica, they may, in addition, have active TrPs in the tensor fasciae latae muscle that contribute to their symptoms.

Patients with tensor fasciae latae TrPs are often misdiagnosed as having trochanteric bursitis. Although patients with TrPs in the tensor fasciae latae muscle do have pain and tenderness over the area of the bursa, the symptoms are referred from the TrPs and are not caused by inflammation of the bursa itself.

Iliotibial tract friction syndrome, or Iliotibial band syndrome, causes diffuse pain and tenderness of the lateral femoral condyle. This condition is common in runners with genu varum and pronated feet and is seen in those who wear shoes with worn lateral soles.³⁷ Often, TrPs of the tensor fasciae latae, gluteus maximus, and vastus lateralis muscles can mimic or contribute to the pain of this condition.

Alternate minimally invasive total hip arthroplasty (THA) techniques access the hip joint through the interval between the tensor fasciae latae and the gluteus medius muscles, attempting to maintain the integrity of the superior gluteal nerve.³⁸ Recent investigation of patients' status post THA with an anterior approach reveals that 74% of patients participating in a study ($n = 17$) show signs of denervation injury after surgery, including denervation hypertrophy, atrophy, and fatty infiltration.³⁸ Likewise, a case report identified similar denervation hypertrophy in a patient with chronic L5 radiculopathy.³⁹ It is possible that these areas of denervation hypertrophy could be confused with the presence of TrPs in these muscles. Specific palpation to identify a hyperirritable spot tenderness in a taut band within the muscle fibers will aid in determining a specific source of symptoms in these cases.

5. CORRECTIVE ACTIONS

Gluteus Minimus

Patients with gluteus minimus TrPs may need to modify their sleeping posture. Lying supine or sleeping on the opposite side is often more comfortable than sleeping on the painful side. Using a pillow between the legs to avoid a painful stretch into adduction of the hip may be necessary if sleeping in side-lying (see Figure 55-9). Using a cane on the opposite side to offload the gluteus minimus muscle may be helpful if significant pain is experienced with walking and standing. Sitting down when possible to avoid aggravation is beneficial. If prolonged standing is unavoidable, then shifting weight from one foot to the

other may help reduce the constant demand on the muscle, and standing with the feet wider than shoulder width may be more comfortable. More vigorous exercise or activities such as running, sports, or hiking should be avoided or slowly progressed with incremental conditioning. Altering training programs for more mild symptoms may help avoid the need for complete activity cessation. If an individual is experiencing pain from TrPs in the gluteus minimus muscle during walking or running, he or she might benefit from training on sloped terrain because there is reduced demand on the gluteus minimus muscle during walking on an incline or decline surface when compared with a level surface.⁴⁰

Self-pressure release of TrPs in the gluteus minimus muscle can be achieved with utilization of a TrP release tool, tennis ball, or a lacrosse ball. To perform TrP self-pressure release with a TrP tool, the patient lies on the back with a $\frac{1}{4}$ turn to the opposite side and the hip and knee of the side to be treated bent and supported by a pillow (Figure 56-9A). The sensitive spot is located with the tool and light pressure (no more than 4/10 pain) is applied and held for 15 to 30 seconds until pain reduces. This technique can be repeated five times per session, several times per day. To utilize a ball or other tool, the ball is placed on the floor and the patient gently lies on top of the ball over the tender area of the gluteus minimus muscle and follows the same procedure as Figure 56-9B. While rolling over the gluteus minimus muscle, patients should pay special attention to any tender spot by slowly rocking over the area or pausing to wait for it to release prior to moving to the next area. Pressure should be mildly uncomfortable but not overly painful (Figure 56-9B).

Figure 56-9. Gluteus minimus muscle self-pressure release. A, Using a TrP release tool. B, Utilizing a tennis or lacrosse ball.

Stretching of the gluteus minimus muscle can be achieved by lying on the uninvolved side on the edge of a firm surface, flexing the lower hip so that the lower foot can support the top leg (see Figure 55-11A). The top leg can be lowered until a slight stretch or discomfort is felt over the hip. The stretch should be held for 30 seconds and be repeated four times. The lower leg supports the top leg so as not to stretch the TrPs in the gluteus minimus muscle too aggressively (see Figure 55-11B). The patient should take a slow inhalation and then relax during exhalation, allowing gravity to apply the stretch to the gluteus minimus muscle (see Figure 55-11B). If the bed is too soft, the same stretch maneuver can be performed at the top of a stair landing with a pillow under the bottom hip

(see Figure 55-11C and D). To focus on the back portion of the muscle, the top hip can be moved forward slightly (approximately 30° of hip flexion). Gravity alone should be able to provide adequate stretch to the tight muscle. To focus on the front part of the muscle, the top hip can be moved back so the leg is just behind the pelvis.

Tensor Fasciae Latae

Patients with TrPs in the tensor fasciae latae muscle need to avoid prolonged flexion of the hip caused by positions such as sitting in a chair with the knees above the hips, or sleeping in the fetal position with the hips and knees bent up toward the chest. During sleep, the hip should be kept in a position with the leg straight or slightly bent.

Chairs in which the patient sits for any length of time should provide the ability to increase the angle between hips and trunk. Either the backrest should be reclined to allow the patient to lean back against it most of the time or the front of the seat should be downwardly sloped. A firm pillow can be placed across the rear of the seat to achieve this desired slope in a nonadjustable chair.

On long trips in an automobile, cruise control permits change of position of the lower extremities to allow the driver to avoid holding the hip flexor muscles immobilized in a shortened position for long periods. Intermittent breaks during car travel to allow for standing and walking are highly recommended.

To reduce irritability of tensor fasciae latae TrPs, it is important to avoid walking or jogging up hills, which requires leaning forward and flexing the hips. It is also important for a runner to avoid shoes that are excessively worn and to avoid running on surfaces that slope from side to side. Runners with tensor fasciae latae TrPs may benefit from running on a level track, running on one side of the road in one direction and on the same side of the road for the return trip, or running only on the crown of a traffic-free road.

Self-pressure release of TrPs in the tensor fasciae latae muscle can be achieved using a TrP release tool, roller, or ball. To perform TrP self-pressure release with a TrP tool, the patient stands with the affected leg slightly in front of the other (Figure 56-10A). Starting just below the top of the pelvis bone and applying moderate pressure, the patient rolls along the length of the muscle to the outer portion of the thigh. If one spot is more sensitive than other places in the muscle, pausing to apply specific pressure for 10 to 15 seconds, relaxing, and repeating this cycle up to six times may be helpful.

Figure 56-10. Tensor fasciae latae muscle self-pressure release. A, Using a TrP release roller. B, Utilizing a tennis or lacrosse ball.

To utilize a ball or other tool, the patient can place the ball on the front of the hip near the top of the pelvis (Figure 56-10B). While rolling over the tensor fasciae latae muscle, patients should pay special attention to any tender spot by slowly rocking over the area or pausing to wait for it to release prior to moving to the next area. Pressure should be mildly uncomfortable but not overly painful (Figure 56-10B).

An ideal stretch for the tensor fasciae latae muscle consists of hip adduction, extension, and knee flexion.^{41, 42} This combination can be performed independently in a half-kneeling position with the involved knee on the floor and the opposite knee flexed up at least to 90°. The patient should shift the body weight into hip extension and adduction and hold the stretch for 30 seconds, repeating the stretch four times (Figure 56-11).

Figure 56-11. Self-stretch of the tensor fasciae latae muscle in half kneeling. A, Starting position. B, The hip and thigh is placed in external rotation and adduction. The patient leans slightly on the affected knee. A stretch should be felt on the front side of the hip.

After successful inactivation of TrPs, strength training of the gluteus medius, gluteus minimus, and tensor fasciae latae muscles is vital for efficient biomechanics during walking and running. Altered mechanics that cause the hip to turn in and/or adduct on the weight-bearing side while walking need to be corrected. Careful muscle retraining to avoid aggravation will be beneficial to prevent recurrence. A licensed rehabilitation professional should be consulted for a proper exercise prescription.

Piriformis, Obturator Internus, Gemelli, Obturator Externus, and Quadratus Femoris Muscles

“Double Devils”

Jennifer Marie Nelson and Joseph M. Donnelly

1. INTRODUCTION

Historically, the piriformis muscle has been the star of the short external rotators of the hip, but more recently, the rest of the rotators have been receiving more attention in the literature, most notably, the obturator internus muscle because of its relationship to the pelvic floor. The exact attachments of the deep hip rotator muscles are variable, but generally, the piriformis and the obturator internus muscles attach to the internal side of the pelvis and form the posterolateral, and part of the anterolateral, portion of the true pelvis before attaching to the greater trochanter of the femur. The superior and inferior gemellus as well as the quadratus femoris muscles all attach from the ischium to the greater trochanter of the femur. These muscles have traditionally been thought to be external rotators of the femur; however, more recent research suggests that they are hip stabilizers. The obturator externus muscle is an adductor anatomically and, like the other adductors, it is innervated by the obturator nerve. The referred pain pattern from trigger points (TrPs) in the piriformis and obturator internus muscles are mostly in the gluteal region and down the posterior one-third of the thigh. Studying the pain referral patterns and function of the other deep hip external rotators is complicated because of the depth and proximity to the neurovascular structures. Trigger points in the deep rotators are commonly associated with other conditions. Piriformis syndrome has been used to describe a general distribution of pain but often involves more structures than just the piriformis muscle, and sometimes the piriformis muscle itself is not even involved. Differential diagnosis should include lumbosacral radicular pain or radiculopathy, sacroiliac joint dysfunction, hip and knee dysfunction or pathology. For resolution of symptoms, correction of altered biomechanics in the lower kinetic chain will need to be addressed. Corrective actions should include techniques to improve sitting and sleeping postures, gluteus maximus neuromuscular re-education, self-pressure release, and self-stretching techniques.

2. ANATOMIC CONSIDERATIONS

Piriformis

The name “piriformis” is derived from the Latin *pirum* (pear) and *forma* (shape); it was coined by Adrian Spigelius, a late 16th- and early 17th-century Belgian anatomist.¹ The piriformis muscle can be small with only one or two sacral attachments. Conversely, it can be so broad that it joins with the capsule of the sacroiliac joint above, and also with, the anterior surface of the sacrotuberous and/or sacrospinous ligaments below.^{2,3}

Most authors agree that the piriformis muscle has a sacral origin, but the exact attachment sites vary.⁴ This muscle originates from the anterior (internal) surface of the sacrum usually by three digitations between the pelvic sacral foramina and anterior sacral foramina (Figures 57-1A and 57-2).^{2,4} However, the exact number of digitations can vary.⁴ Some fibers may attach to the upper margin of the greater sciatic notch⁴ at the capsule of the sacroiliac joint,^{2,3,5} the sacrotuberous ligament,^{2,4,6} and the posterior inferior iliac spine.² The piriformis muscle has no hip joint capsule contribution.⁷

Figure 57-1. Attachments of the right piriformis muscle (red). A, Seen from inside the pelvis in mid-sagittal view showing the attachment of the muscle on the inside of the sacrum, usually between the first four anterior sacral foramina. The fourth foramen is not shown. B, Seen from behind (posterior view). In this figure, a relatively small muscle exits the pelvis through a relatively large sciatic foramen. Its rounded tendon attaches laterally to the superior surface of the greater trochanter. The muscle traverses the greater sciatic foramen just above the sacrospinous ligament. Most of the muscle is accessible to external palpation, and nearly half of the muscle belly is accessible to palpation inside the pelvis.

Figure 57-2. Internal palpation of the left piriformis muscle (dark red within the pelvis and light red outside the pelvis) via the rectum, viewed from in front and above. The levator ani muscle is medium red; the coccygeus and obturator internus muscles are light red. The sacrospinous ligament (covered by the coccygeus muscle) is the last major transverse landmark identified by the palpating finger before it reaches the piriformis muscle. The sacrospinous ligament attaches cephalad mainly to the coccyx, which is usually easily palpated and mobile. The posterior wall of the rectum and the S3 and S4 nerve roots lie between the palpating finger and the piriformis muscle.

The piriformis muscle inserts laterally and distally via a rounded tendon onto the greater trochanter on the medial side of its superior surface (Figures 57-1B and 57-3).² This tendon often blends with the common tendon of the obturator internus and gemelli muscles,^{2,4,8,9} and the muscle may fuse with the gluteus medius muscle.^{2,4}

Figure 57-3. Piriformis muscle, regional anatomy: posterior view of anatomic relations of the right piriformis muscle (dark red) to neighboring muscles (light red). The gluteus maximus and gluteus medius muscles have been cut and removed; the distal cut ends of these gluteal muscles are not shown because they would obscure the attachment of the piriformis muscle to the femur.

Variations of the piriformis muscle can also include two distinct heads of the muscle. In fewer than 20% of cadavers, it is divided into two distinct portions.^{4,10,11} However, most variations have to do with where the sciatic nerve passes in relation to the piriformis muscle. Within the pelvis, the piriformis muscle abuts the sacrum, rectum, sacral plexus, and branches of the internal iliac vessels.² The piriformis muscle exits the inside of the pelvis through the greater sciatic foramen.^{2,8} This rigid opening is formed anteriorly and superiorly by the posterior part of the ilium, posteriorly by the sacrotuberous ligament, and inferiorly by the sacrospinous ligament.^{2,8} When the muscle is large enough to fill this space, it has the potential to compress the numerous vessels and nerves that exit the pelvis with it.² The piriformis muscle then passes the gluteal region, abutting posteriorly to the gluteus maximus muscle,^{2,8} anteriorly to the capsule of the hip joint,^{2,9} inferiorly to the gluteus medius muscle and superior gluteal vessels and nerve,^{2,9} and superiorly to the

coccygeus and gemellus superior muscles. Between the gemellus superior and piriformis muscles run several nerves and vessels.² The piriformis muscle then joins the obturator internus/gemelli complex to attach on the upper side of the greater trochanter.^{2,4,8,9}

The other short hip external rotators of the thigh, the four GOGO muscles (superior gemellus, obturator internus, inferior gemellus, and obturator externus muscles) and the quadratus femoris muscle, lie distal to the piriformis muscle. They are deep to the gluteus maximus muscle, but in contrast to the usual position of the piriformis muscle, they pass anterior to the sciatic nerve (Figure 57-3).

Obturator Internus

The obturator internus muscle is both an intrapelvic muscle and a hip muscle (Figure 57-3).² Within the pelvis, the obturator internus muscle makes contact with the obturator fascia, levator ani muscle, pudendal vessels and nerve, and ischiorectal fossa. It originates medially and proximally and covers the inner surface of the obturator membrane and attaches to the rim of the obturator foramen, except where the obturator nerve and vessels leave the pelvis through the lateral part of the membrane. Specifically, it attaches to the inferior ramus of the pubis, ischial ramus, behind and below the pelvic brim from the greater sciatic notch to the obturator foramen, medial pelvic surface of the obturator membrane, the tendinous arch and the obturator fascia covering the muscle.^{2,4} Before the obturator internus muscle exits the pelvis, it heads toward the lesser sciatic foramen and takes a lateral right-angle turn between the ischial spine and the ischial tuberosity.^{2,9} As it makes this turn, the obturator internus muscle is separated from the ischium by a bursa and hyaline cartilage.² The obturator internus muscle inserts laterally and distally by converging onto a tendon that is usually shared with the gemelli muscles.² This tendon inserts on the anterior part of the medial surface of the greater trochanter, proximal to the trochanteric fossa of the femur, and attaches on the greater trochanter near but distal to the piriformis tendon.^{2,12} The subtendinous bursa of the obturator internus muscle lies between its tendon and the capsule of the hip joint and may communicate with the ischiadic bursa between the obturator internus muscle and the ischium.²

Superior and Inferior Gemelli

The superior and inferior gemelli muscles attach medially/proximally to the ischium and laterally/distally to the medial surface of the upper part of the greater trochanter, proximal to, and nearly parallel with, the quadratus femoris muscle (Figure 57-3). The inferior gemellus muscle attaches below the groove of the obturator internus muscle on the lateral ischial tuberosity² and occasionally at the sacrotuberous ligament and lesser sciatic notch.⁴ It then joins the extrapelvic obturator internus muscle before inserting into the greater trochanter.² The superior gemellus muscle is smaller than the inferior gemellus muscle and is sometimes absent.² It originates from the dorsal side of the ischial spine² and occasionally from the lesser sciatic foramen and notch⁴ before joining superiorly to insert on the medial

aspect of the greater trochanter with the obturator internus and inferior gemellus muscles.² Accessory gemelli and obturator internus muscles arising from the lesser sciatic notch have also been reported.⁴ These three muscles are also called the “triceps coxae,” and exactly how much they join together rather than fuse together is a matter of controversy.⁴

Obturator Externus

The obturator externus muscle is considered part of the adductor group by Hollinshead¹³; however, he notes that its primary action would be external rotation, and not adduction, of the thigh. The obturator externus muscle originates medially to the external surface of the anteromedial two-thirds of the obturator membrane, the pubic and ischial rami.^{2,4} The fibers run laterally, caudally, and posteriorly, and pass across the distal part of the capsule of the hip joint to insert laterally to the femur at the intertrochanteric fossa^{2,4,14} deep to the quadratus femoris muscle. In fact, from the posterior view, it is nearly covered by the quadratus femoris muscle (Figure 57-3).^{2,15,16} A bursa often intervenes where the obturator externus muscle crosses the lesser trochanter.²

Quadratus Femoris

The quadratus femoris muscle is a rectangular muscle with parallel fibers that originate from the anterolateral surface of the ischial tuberosity, caudad to the inferior gemellus and posterior to the obturator externus muscles. Laterally, it inserts onto the femur on the quadrate tubercle and along the intertrochanteric crest, which extends longitudinally about halfway between the greater and lesser trochanters (Figure 57-3).^{2,4} The quadratus femoris muscle is situated between the superior portion of the adductor magnus and gemellus inferior muscles and is in close proximity to the medial circumflex femoral artery.² It is occasionally missing^{2,4} and can be prone to impingement at the ischiofemoral space as well as acute strains.^{4,17}

2.1. Innervation and Vascularization

The piriformis muscle is usually innervated by the L5 nerve and S1 and S2 nerves; however, variation of this innervation pattern has been described. It can also be innervated by only one of the sacral nerves as it emerges from the anterior sacral foramina.² Other variations described in the literature include branches of the posterior rami of the sacral plexus; nerve to the piriformis muscle from S1 and S2; directly from the anterior rami of S1 and S2; anterior rami of branches from L5, S1, and S2; and from L4, L5, and S1.⁴

The piriformis muscle receives its primary vascularization extrapelvically through the superior gluteal artery and by gemellar branches of the internal pudendal artery. Intrapelvically, the piriformis muscle receives its vascularization from the lateral sacral artery along with the superior and inferior gluteal arteries.²

The nerve to the obturator internus muscle innervates the gemellus superior (L5, S1, and S2) and obturator internus (L5 and S1) muscles.² However, other variations have been

described, including: L5, S1, and S2; S1, S2, and S3¹³; branches of the sacral plexus; nerve to the obturator internus muscle; or branches of L5 and S1.⁴

The extrapelvic portion of the obturator internus muscle receives its vascularization from the gemellar branches of the internal pudendal arteries, whereas the intrapelvic and extrapelvic portions receive vascularization from the branches of the obturator artery. The gemellus superior muscle receives its vascularization from the internal pudendal artery and inferior gluteal artery and occasionally by the superior gluteal artery.²

The nerve to the quadratus femoris muscle sends a branch to the inferior gemellus muscle, containing fibers from L4-S1, and to the quadratus femoris muscle, containing fibers from L5 and S1.² Other innervations described in the literature include the following: branches of the sacral plexus or nerve to the quadratus femoris muscle alone; nerve to the quadratus femoris muscle or the branches of L4, L5, and S1; and nerve to the quadratus femoris muscle or the branches of L5, S1 (L4 inferior gemellus muscle), L5, S1, and S2.⁴

The quadratus femoris muscle receives its vascularization from the inferior gluteal artery and the medial circumflex femoral artery. The gemellus inferior muscle primarily receives its vascularization by the medial circumflex femoral artery.²

Unlike all the other short external rotators, the obturator externus muscle receives its innervation from a posterior branch of the obturator nerve, containing fibers from L3 and L4,² but it has also been described as the branches of L2, L3, and L4.⁴

The obturator externus muscle receives its vascularization from the obturator and medial circumflex femoral arteries.²

Because of the size of the greater sciatic foramen and the number of structures that pass through it, there is potential for nerves and vessels to become crowded as they pass through it. The superior gluteal nerve and blood vessels usually pass between the superior border of the piriformis muscle and the upper (sacroiliac) rim of the foramen. This nerve supplies the gluteus medius, gluteus minimus, and tensor fasciae latae muscles.¹⁸ The sciatic nerve usually exits between the piriformis muscle and the rim of the greater sciatic foramen (Figure 57-3). It supplies the skin and muscles of the posterior thigh and most of the leg and foot. Numerous variations of how the sciatic nerve courses from the pelvis down the leg have been described in the literature.^{10, 19–22} Recent studies have shown that anatomic variations of the sciatic nerve around the piriformis muscle are present in around 6% to 11% of individuals.^{23, 24} The relationship between the sciatic nerve and the piriformis muscle follows the typical anatomic pattern of an undivided sciatic nerve passing below the muscle, in around 90% of the subjects. Other anatomic variations are as follows: the common fibular nerve passed through and the tibial nerve below a double piriformis muscle (4%-10%); the common fibular nerve coursed superior and the tibial nerve below the piriformis muscle (0.5%), or both nerves penetrated the piriformis muscle (0.5%).^{23, 24} These anatomic variations are described in Figure 57-4 and Table 57-1.

Figure 57-4. Four routes by which portions of the sciatic nerve may exit the pelvis: A, The usual route, in which all fibers of the nerve pass anterior to the piriformis muscle between the muscle (red) and the rim of the greater sciatic foramen, seen in about 85% of cadavers; B, The peroneal portion of the nerve passes through the piriformis muscle and the tibial portion travels anterior to the muscle, as seen in more than 10% of cadavers; C, The peroneal portion of the sciatic nerve loops above and then posterior to the muscle and the tibial portion passes anterior to it; both portions lie between the muscle and the upper or lower rim of the greater sciatic foramen, as seen in 2% to 3% of cadavers; D, An undivided sciatic nerve penetrates the piriformis muscle in less than 1% of cadavers. Also exiting the pelvis along the lower border of the piriformis muscle are the pudendal nerve and vessels. The pudendal nerve then crosses the spine of the ischium and re-enters the pelvis through the lesser sciatic foramen (Figure 57-3). It supplies the external anal sphincter muscle and helps supply the skin of the posterior thigh and scrotum or labia majora. Innervation of the pelvic floor muscles by the pudendal nerve is presented in Chapter 52. The inferior gluteal nerve, which exclusively supplies the gluteus maximus muscle, the posterior femoral cutaneous nerve, and the nerves to the gemelli, obturator internus, and quadratus femoris muscles, also passes through the greater sciatic foramen with the piriformis muscle.²⁵ Collectively, these nerves are responsible for all gluteal muscle sensation and function, anterior perineal sensory and motor function, and nearly all of the sensation and motor function in the posterior thigh and calf. These symptoms are described as deep gluteal pain syndromes.²⁶ It is apparent that chronic compression of these nerves would cause buttock, inguinal, and posterior thigh pain, as well as pain lower in the limb.²

2.2. Function

The six “short external rotators” are the piriformis, the superior and inferior gemelli, the obturator internus and externus, and the quadratus femoris muscles.²⁷

The piriformis muscle is primarily an external rotator when the hip is in a neutral or

extended position. It is also considered a secondary hip abductor, and this function increases as the hip moves toward 90° of hip flexion. Giphart et al²⁸ found the piriformis muscle to be most active during prone heel squeezes and single-leg bridges.

In weight-bearing activities, the piriformis muscle is often needed to restrain (control) vigorous and/or rapid internal rotation of the thigh, especially during the early-stance phase of walking and running. The piriformis muscle is also thought to stabilize the hip joint and to assist in holding the femoral head in the acetabulum.⁴

The remaining five short external rotator muscles have been traditionally thought of almost exclusively as external rotators²⁹ in either hip flexion or extension. However, more recently, it is being suggested that they are more postural stabilizers of the hip than primary movers^{2,28,30} and that hip flexion and extension may change the function of the muscles.^{2,30-34} Examination of an articulated skeleton theoretically demonstrates that the degree of flexion of the thigh profoundly affects the function of the piriformis muscle: at 90° of flexion, it produces horizontal abduction of the thigh.^{13,35} The obturator internus muscle's primary function in a closed kinetic chain when the foot is firmly planted on the ground is to rotate the pelvis and trunk relative to the femoral head (relative hip external rotation on the stance side). This force compresses the hip joint surfaces, resulting in a portion of dynamic stability to the hip joint. All of the external rotators act with the gluteus maximus muscle to change directions by rotating the trunk and pelvis backward on a fixed femur when the foot is planted.²⁷

Electromyographic (EMG) study of the functional kinesiology of any of these muscles has been difficult to perform because of the depth and close proximity to neurovascular structures. However, recent research using fine-wire EMG has produced some varying results. Giphart et al²⁸ looked at the EMG activity of 10 volunteers performing 13 hip exercises (only 6 produced acceptable EMG signals). They found that the piriformis muscle was most active during static external rotation and abduction when the hip was in slight extension and during activities that required hip stabilization. The investigators conclude that the piriformis muscle has more of a hip stabilizer function than a primary mover function.²⁸

Hodges et al³¹ investigated fine-wire EMG with ultrasound guidance into the right obturator internus, quadratus femoris, piriformis, and gluteus maximus muscles of 10 human subjects during maximum isometric hip flexion, extension, external rotation, internal rotation, abduction, and adduction, with the hip in neutral and at 60° of flexion. They found that the obturator internus muscle was activated first during abduction and external rotation when compared with the other muscles, regardless of position. However, all four muscles were most active with extension and least active during hip flexion, adduction, and internal rotation. When comparing external rotation and abduction activation, they found that the obturator internus and quadratus femoris muscles were more active with external rotation than the piriformis muscle. The piriformis muscle was the most active muscle during abduction. The quadratus femoris muscle was the most active during extension. They also demonstrated that the amount of activation changed

depending on if the hip was in neutral or flexed. When the hip was flexed to 60°, there was increased obturator internus and quadratus femoris muscle activation during external rotation but decreased activation of the piriformis muscle. The opposite happened during hip abduction.

String models have been a popular way to investigate the function of these muscles because EMG studies are difficult. Gudena et al³⁰ used 18 hips from 22 cadavers and found that the obturator externus muscle was an external rotator when the hip was flexed and a hip stabilizer in extension and internal rotation. Vaarbakken et al³² looked at three cadavers and found the motion arm switched from external rotation to internal rotation at 95° of hip flexion for the obturator internus muscle and 65° hip flexion for the piriformis muscle. When looking at the function of the quadratus femoris and obturator externus muscles, Vaarbakken et al³³ found that the quadratus femoris muscle is primarily a hip extensor from a flexed position and the obturator externus muscle flexed and adducted an extended hip.

Three-dimensional computer models have also been used to help understand the function of the hip muscles. Delp et al³⁴ looked at the hip muscles' moment arms as the hip was flexed from 0° to 90°. They found that the obturator externus, quadratus femoris, and obturator internus muscles did not become internal rotators; however, the obturator internus muscle significantly reduced its external rotation moment arm in flexion. The piriformis muscle, however, did become an internal rotator based on their computer model.³⁴

The obturator internus muscle also plays a role in pelvic floor function. This function is discussed in detail in Chapter 52. Strengthening the hip external rotators, and specifically targeting the obturator internus muscle, has been shown to increase pelvic floor muscle strength measured with peak vaginal squeeze pressure⁴¹ and produces a greater decrease in stress urinary incontinence⁴² compared with the control group. However, no studies have looked at how much the pelvic floor is active during hip external rotation exercises and therefore a question arises whether the external rotation exercises were effective or whether the pelvic floor was actually trained more because it was active during the additional exercises.⁴¹ Hip abduction strength has been shown to have no correlation in women with or without stress urinary incontinence.⁴³ However, the obturator internus muscle is more of an external rotator and stabilizer than a hip abductor, which may be why no correlation was found.

2.3. Functional Unit

The functional unit to which a muscle belongs includes the muscles that reinforce and counter its actions as well as the joints that the muscle crosses. The interdependence of these structures is functionally reflected in the organization and neural connections of the sensory motor cortex. The functional unit is emphasized because the presence of a TrP in one muscle of the unit increases the likelihood that the other muscles of the unit will also develop TrPs. When inactivating TrPs in a muscle, one must be concerned about TrPs that

may develop in muscles that are functionally interdependent. Box 57-1 grossly represents the functional unit of the piriformis and external rotator muscles.⁴⁴

Box 57-1 Functional unit of the piriformis and external rotator muscles

Action	Synergists	Antagonists
Hip external rotation	Gluteus maximus Long head of biceps femoris Sartorius	Semitendinosus Semimembranosus Tensor fasciae latae Anterior fibers of gluteus medius and minimus Psoas major Gracilis (with knee flexion)

The piriformis muscle and the other five short external rotator muscles, together with the gluteus maximus muscle, are the prime external rotators of the thigh.^{2,13,29,45} The short external rotator muscles also aid in stabilization of the hip joint.

3. CLINICAL PRESENTATION

3.1. Referred Pain Pattern

Piriformis TrPs frequently contribute significantly to complex myofascial pain syndromes of the pelvis and hip regions. The myofascial pain syndrome of the piriformis muscle is well recognized⁴⁶⁻⁵¹ and can sometimes overlap with signs and symptoms associated with piriformis pain syndrome. Trigger points in the piriformis muscle refer pain primarily to the sacroiliac region, to the buttock generally, and over the hip joint posteriorly. The referred pain and symptoms can also extend over the proximal two-thirds of the posterior thigh (Figure 57-5). Additional pain referred from TrPs in the adjacent members of this external rotator group may be difficult to distinguish from pain originating in the piriformis TrPs.

Figure 57-5. Composite pattern of pain referred from TrPs in the right piriformis muscle medial to sacrum and lateral buttock (darker red) and proximal one-third of the posterior thigh (stippled).

Trigger points in the obturator internus refer to the coccyx region and the posterior middle thigh (see Figure 52-3). A case study in a person with a strain to the obturator internus muscle showed that this muscle can produce pain in the groin.⁵² George et al⁵³ found that dry needling the gluteal and pelvic floor muscles with focus on the obturator internus muscle reduced pelvic pain. Dalmau-Carolà⁵⁴ found that TrP injections to the piriformis muscle reduced trochanteric gluteal pain by 50%, adding that injection of the obturator internus muscle abolished the rest of the pain, and additionally, the reported cold feeling the patient had in the ipsilateral foot was also abolished. Clinically, TrPs in both the obturator internus and piriformis muscles have been seen to refer into the dorsum of the foot with and without pain down the back of the thigh and into the calf. These symptoms were only produced by intravaginal palpation.

The referral pattern of TrPs in the quadratus femoris muscle was not described by Travell and Simons⁴⁴; however, case studies⁵⁵⁻⁵⁷ have shown that tears and strains to the quadratus femoris muscle can refer to the gluteal region, groin, posterior thigh, or hip with

the posterior thigh being the most common. There has also been one case study that showed that a strain to both the obturator internus and externus muscles can produce sharp pain deep in the buttocks and a constant ache radiating into the hip; however, it is not clear which muscles were referring pain to which areas.⁵⁸

3.2. Symptoms

Patients with TrPs and injuries in the deep hip external rotators will often report pain in the gluteal region^{17,52,56} but may also describe pain in the low back, groin,^{17,52,56} perineum, hip,^{56,58} and posterior thigh.^{17,52,55,56} Patients may report sharp pain on occasion, but often they describe their symptoms as an ache.⁵⁸ Because of the area and behavior of their pain, patients may think they have injured a hamstring or adductor muscle, or that they have a groin strain or sciatica.

Patients may also report a loss in their hip range of motion or flexibility^{55,58} into internal rotation and adduction. Often, they would have identified tenderness in the area of the ischial tuberosity, and the symptoms are aggravated in the seated position.^{55,58} A recent review has reported that the four most common symptoms of piriformis muscle syndrome are buttock pain, pain aggravated on sitting, external tenderness near the greater sciatic notch, pain on any maneuver that increases piriformis muscle tension, and limitation of straight leg raising.⁵⁹

3.3. Patient Examination

After a thorough subjective examination, and establishing the event(s) associated with the onset of reported symptoms, the clinician should make a detailed drawing representing the pain pattern that the patient has described. This depiction will assist in planning the physical examination and can be useful in monitoring the progression of the patient as symptoms improve or change. Prior to beginning a physical examination, the clinician should do a thorough medical screening, and any concerns regarding the involvement of the gastrointestinal or urogenital systems as a source of symptoms should result in an immediate referral to a physician. All potential perpetuating factors should be noted and mechanical factors considered.

Because of the close association these external hip rotator muscles have with the nerves in the sciatic foramen, a thorough and careful neurologic examination of the lower extremity neural tissue is indicated. The clinician should perform a screening examination of the lumbosacral spine, the knee, foot, and ankle, as well as an assessment of the patient's posture and gait. Several neurodynamic tests can be used for assessing mechanical nerve sensitivity. Specifically, the slump test has been found to be sensitive for diagnosis of neuropathic pain in the lower extremity.⁶⁰ A careful assessment should be made to rule out referral into the buttock from other tissues, including muscles and joints that can refer to the same region.

In standing, the clinician should observe the pelvis for symmetry in the frontal and sagittal planes. Functional activities such as sit to stand, single-leg stance, and double- and

single-leg squat (see Figure 55-3A) should be examined. The clinician should take note of any frontal plane deviations in the pelvis, hip and/or knee, and any excessive transverse plane motion at the ankle and foot (see Figure 55-3B). Deviations in the frontal plane at the knee and transverse plane at the foot and ankle may indicate gluteal and external hip rotator muscle weakness because the activation of the piriformis and obturator internus muscles as hip abductors increases as hip flexion increases.³¹

During examination of the patient's gait, the clinician should note any deviations such as a Trendelenburg sign at mid-stance (see Figure 55-4A and B). This is a sign of weakness in the hip abductor muscles. The patient may also have pain with unilateral stance during gait and with static standing on one leg because of the increased use of the external hip rotator muscles for static stability.

In sitting, the patient may sit with external rotation or abduction of the hip because of shortening of the hip external rotator muscles and frequently shift in the seat to take pressure off the piriformis and/or obturator internus muscles.

Because of the varying muscle activation patterns of the external hip rotators, a thorough examination of hip muscle activation patterns and strength should be carried out. All six of the deep hip rotators are tested as one for strength in hip external rotation. The obturator internus and piriformis muscles differ in activation of external rotation and abduction depending on the position of the hip in flexion or extension. Increased pain or weakness during hip external rotation while the hip is flexed would be indicative of obturator internus TrPs or dysfunction because it is most active when the hip is in flexion. The piriformis muscle is a secondary hip abductor and increases activation significantly with the hip in 90° of flexion. The Pace Abduction Test is effective in testing hip abduction strength and activation when the hip is flexed.^{51, 61, 62} While the patient is in the seated position with the hips flexed to 90°, the clinician places the hands on the lateral aspects of the knees and asks the patient to push the hands apart. Pain and/or weakness will be observed on the affected side if the test is positive.⁴⁸ The muscle activation patterns of hip extension and hip abduction should also be examined to identify inhibition or weakness of the gluteal muscles.

Hip abduction and external rotation strength testing should be carried out bilaterally as both sides are responsible for lumbopelvic stability at different times during the gait cycle. If one side is weaker than the other, excessive frontal plane motion results, which can cause abnormal loading forces in the lumbar spine and hip musculature.

Muscle length of the deep hip rotators can be tested with the patient in supine. Pain and limitation of passive internal rotation of the affected thigh with the hip in neutral and the patient in the supine position was first described by Freiberg. This test was illustrated by TePoorten, and is frequently referred to^{35, 48, 51, 63-65} as Freiberg's sign. The movement of the test increases the tension on an already tight piriformis muscle. More recently, the flexion adduction internal rotation (FAIR) test has been identified as one of the special tests to confirm a diagnosis of piriformis muscle syndrome. None of the investigators mention or examine the piriformis muscle for the presence of TrPs; however, all patients responded favorably to anesthetic injection of the piriformis muscle,^{66, 67} leading us to believe that the

investigators were treating TrPs in the piriformis muscle.

Fishman et al⁶⁶ investigated the diagnostic utility of the FAIR to identify an operational definition of piriformis muscle syndrome and found it to have a sensitivity of 0.81 and a specificity of 0.83. They concluded that piriformis muscle syndrome is accurately identified by the FAIR test and effectively treated with injection coupled with physical therapy.

Chen and Nizar⁶⁷ investigated the prevalence of piriformis muscle syndrome in patients with chronic low back pain (LBP) utilizing a combination of the FAIR test with the Laseque sign (tenderness in the gluteal region near the piriformis muscle) to diagnose piriformis syndrome. They found that 17% of patients presenting with chronic LBP had a positive combined FAIR and Laseque sign, indicating the presence of piriformis muscle syndrome. These individuals received a piriformis muscle injection with an anesthetic under fluoroscopic guidance into the most tender point in the muscle.⁶⁷ The investigators did not attempt to identify the presence of TrPs in the piriformis muscle, but they did identify the most tender region of the piriformis muscle (which could have, in the authors' opinion, been a TrP) to determine placement of the injection, with 100% of patients having 50% reduction of their symptoms immediately post injection.⁶⁷

3.4. Trigger Point Examination

To locate the hip external rotator muscles in patients, it is helpful to note that the piriformis and the upper three GOGO muscles form a fanlike arrangement spreading out from the upper end of the greater trochanter. Manual examination of this group of external rotator muscles for TrPs is complicated by the fact that all of them lie deep to the gluteus maximus muscle, as seen in Figure 57-3. The piriformis muscle can be examined through a relaxed gluteus maximus muscle for most of its length. Its medial end is accessible to nearly direct palpation by rectal or vaginal examination. The femoral (lateral) ends of the gemelli and obturator internus muscles are not individually distinguishable by external palpation, but much of the intrapelvic obturator internus and piriformis muscles is directly palpable from inside the pelvis (Figure 57-2). Tenderness in the femoral end of the quadratus femoris muscle may be palpable through the gluteus maximus muscle. Using this approach, tenderness is less likely to be palpable in the underlying obturator externus muscle. Obturator externus muscle tenderness is best located by palpating between and deep to the pectineus and adductor brevis muscles in the groin. Though this muscle cannot be readily palpated, tenderness in the pectineus muscle may be due to TrPs in the pectineus or underlying obturator externus muscles. Diagnosis of TrPs may be determined by the use of a filiform or injection needle when a local twitch response or pain referral is elicited.

Piriformis

The location of the piriformis muscle is determined for external examination by drawing a line from the uppermost border of the greater trochanter through the sacroiliac (cephalad) end of the greater sciatic foramen (Figure 57-6). When the gluteus maximus muscle is relaxed, the greater trochanter may be located by circular deep palpation with the flat of the

hand over the hip laterally, revealing the underlying bony prominence. The crescent-shaped medial boundary of the sciatic foramen along the lateral border of the sacrum (dotted line, Figure 57-6) is palpable inferior to the posterior inferior iliac spine through the relaxed gluteus maximus muscle.

Figure 57-6. External cross-fiber flat palpation to identify TrPs in the right piriformis muscle through a relaxed gluteus maximus muscle. The solid line (piriformis line) overlies the superior border of the piriformis muscle and extends from immediately above the greater trochanter to the cephalic border of the greater sciatic foramen at the sacrum. The line is divided into equal thirds. The dotted line marks the palpable edge along the lateral border of the sacrum, which corresponds closely to the medial margin of the greater sciatic foramen.

Cross-fiber flat palpation is used to locate TrPs in the piriformis muscle (Figure 57-7A). The outline of a tense piriformis muscle is sometimes palpable along the piriformis line, and the muscle may show marked tenderness throughout its length.^{64,68} Figure 57-3 illustrates how closely the lower borders of the gluteus medius and gluteus minimus muscles approximate the upper border of the piriformis muscle, permitting palpation of the piriformis muscle without interference from them. If one palpates too far cephalad, the gluteus medius and minimus muscles, and not the piriformis muscle, will be palpated deep to the gluteus maximus muscle.

Figure 57-7. Palpation for TrPs in the external rotator muscles of the hip. The X represents the posterior superior iliac spine (PSIS) and the half moon represents the greater trochanter of the femur. A, Cross-fiber flat palpation for TrPs in the piriformis muscle. B, Cross-fiber flat palpation for TrPs in the gemelli and obturator internus muscles along the upper one-third of the greater trochanter. C, Cross-fiber flat palpation of the quadratus femoris and obturator externus muscles along the lower two-thirds of the greater trochanter.

Kipervas et al⁶⁹ established the location for palpating the piriformis muscle through the skin somewhat differently. They selected the junction of the middle and lower thirds of a line drawn between the anterior superior iliac spine and the ischiococcygeus muscle.

If any doubt exists as to the cause of tenderness over the greater sciatic foramen, the medial end of the piriformis muscle should be palpated within the pelvis by the rectal or vaginal route.^{47, 48, 61, 65, 69} This examination is performed most effectively with the clinician's longest finger and may not be possible for a clinician with smaller than average hands (Figure 57-2). The technique is also illustrated by Thiele.⁶⁵ The patient is placed side-lying with the affected side uppermost and with that knee and hip flexed. The transversely oriented sacrospinous ligament is felt as a firm band stretching between the sacrum and the ischial spine and is normally covered by the fibers of the coccygeus muscle⁵¹ that can also have TrPs. The piriformis muscle lies just cephalad to this ligament and, if involved, is tender and feels tense.^{48, 50, 65, 69, 70}

Clinicians can often examine the muscle bimanually, with one hand pressing externally on the buttock while the other hand palpates internally. The greater sciatic foramen presents an unmistakable soft spot through which palpation pressure from one finger

outside the pelvis can be transmitted to another finger inside the pelvis. To confirm identification of the piriformis muscle, the clinician palpates for contractile tension in the muscle while having the patient attempt to abduct the thigh by trying to lift the uppermost knee.

The sacral nerve roots lie between the clinician finger and the piriformis muscle (Figure 57-2). If the nerve roots are irritated by entrapment at the greater sciatic foramen, they may also be tender and are likely to project pain in a sciatic distribution.

Gemelli and Obturator Internus

Figure 57-3 shows that, in the anatomic position, all of the piriformis muscle lies above the level of its attachment to the uppermost part of the greater trochanter. Cross-fiber flat palpation at the level of, and medial to, the upper one-third of the greater trochanter (Figure 57-7B) is used to identify TrPs in the gemelli and obturator internus muscles. Deep tenderness (deep to the gluteus maximus muscle) inferior to the piriformis muscle is most likely tenderness of one of the gemelli or of the obturator internus muscles. If TrPs in the obturator internus muscle are responsible for this tenderness, it can be palpated directly by rectal or vaginal examination, as described in Chapter 52. The obturator internus muscle can also be palpated along the medial border of the obturator foramen utilizing cross-fiber flat palpation (Figure 57-8).

Figure 57-8. Cross-fiber flat palpation of the obturator internus muscle at the medial aspect of the right ischial tuberosity and the obturator foramen muscle.

Figure 57-3 reminds clinicians that the sciatic nerve is also compressed as pressure is applied medial to a point midway between the greater trochanter and the ischial tuberosity. The nerve usually emerges between the piriformis and superior gemellus muscles and

continues its course superficial to the superior gemellus, obturator internus, inferior gemellus, obturator externus, and quadratus femoris muscles.

Quadratus Femoris and Obturator Externus

Cross-fiber flat palpation is utilized at the lower two-thirds of the greater trochanter to locate TrPs in these muscles. Deep tenderness probably arises in the quadratus femoris muscle or, possibly, in the even deeper obturator externus muscle (Figure 57-7C). Trigger points in the quadratus femoris muscle can also be palpated along the lateral side of the ischial tuberosity.

Tenderness due to TrPs in the obturator externus muscle may also be detected in the groin. One must first palpate the pectineus and adductor brevis muscles to confirm that they do not have TrPs that would obscure a deeper source of tenderness. Deep pressure is then applied between the pectineus and adductor brevis muscles against the outer surface of the obturator membrane that is covered by the obturator externus muscle (Figure 57-9). This muscle cannot be directly palpated and therefore a monofilament needle or injection needle may be necessary to elicit a local twitch response or reproduce the pain or pain referral pattern of these muscles.

Figure 57-9. Cross-fiber flat palpation of obturator externus muscle through the pectineus and adductor brevis muscles. This muscle can't be directly palpated.

4. DIFFERENTIAL DIAGNOSIS

4.1. Activation and Perpetuation of Trigger Points

A posture or activity that activates a TrP, if not corrected, can also perpetuate it. In any part

of the gluteus maximus muscle, TrPs may be activated by unaccustomed eccentric loading, eccentric exercise in an unconditioned muscle, or maximal or submaximal concentric loading.⁷¹ Trigger points may also be activated or aggravated when the muscle is placed in a shortened and/or lengthened position for an extended period of time.

The deep hip rotators can become overloaded when they undergo a strong lengthening contraction to restrain vigorous and/or rapid internal rotation of the weight-bearing limb such as with running and walking and especially if the gluteal muscles are weak or inhibited. The gluteus maximus muscle is the strongest of the external rotators of the hip; therefore, if it is weak or inhibited, it will place an overload on the smaller hip external rotator muscles.

Overload can also occur in the piriformis muscle when one catches oneself from falling when the foot slips,⁴⁸ with lifting or lowering heavy objects with the legs in a wide base of support,⁴⁸ twisting sideways while bending and lifting an object,⁷² or forceful rotation while standing on one leg.^{48,68} These are common movements in many athletic and sporting activities and can also occur with yard and housework. Activities that would potentially perpetuate TrPs may include uphill walking or running, climbing a ladder, or returning from a squatting position especially if the lower extremities are placed in a wide base of support and the gluteus maximus muscle is weak and or inhibited.

Sitting on a wallet placed in a back pocket that extends under the buttock can perpetuate and aggravate TrPs in the hip external rotators, especially the piriformis muscle, by concentrating pressure on them. The resultant low back and buttock pain is likely to be erroneously attributed to nerve pressure and has been called “back pocket sciatica.”⁷³ However, pain referral from TrPs in the piriformis muscle or other external rotator muscles alone would not have a full sciatic nerve distribution.

Flexing the thighs at the hips with the knees spread apart for sitting, as in driving a car with the foot on the accelerator for long periods or sitting on one foot⁶⁸ are activities that can perpetuate piriformis TrPs. These positions, which combine a shortened position of the piriformis muscle, with the sciatic nerve held in a lengthened or stretched position, along with a lack of mobility, create a vulnerability for piriformis muscle syndrome. Obstetric or urologic procedures, as well as coitus, also put the piriformis muscle in a shortened position that has been associated with onset of the piriformis muscle syndrome.^{68,72}

Chronic infections are known to perpetuate TrPs. Specifically, chronic pelvic inflammatory disease⁷⁴ and infectious sacroiliitis⁷² have been identified in piriformis muscle syndrome. Other conditions that may perpetuate piriformis TrPs include arthritis of the hip joint, sciatica, chronic LBP, and conditions that lead to total hip arthroplasty.⁴⁸

4.2. Associated Trigger Points

Trigger points can also develop in the referred pain areas of primary TrPs.⁷⁵ Therefore, TrPs in the deep hip rotators can be due to active TrPs in other muscles, including the quadratus lumborum, multifidi, longissimus thoracis, iliocostalis lumborum coccygeus, levator ani, tensor fasciae latae, gluteus maximus, gluteus medius, gluteus minimus,

hamstrings, vastus lateralis, and soleus muscles. In addition, active TrPs in the pectineus, external and internal oblique, and psoas major muscles can produce TrPs in the obturator externus muscle. Active TrPs in the deep hip external rotators can also contribute to associated TrPs in other muscles including the gluteus maximus, gluteus medius, gluteus minimus, hamstrings, adductors, levator ani, coccygeus, and vastus lateralis muscles.

When the deep hip rotators have TrPs, the antagonists are likely to develop associated TrPs, including the adductor magnus, adductor longus, adductor brevis, semitendinosus and semimembranosus, tensor fasciae latae, anterior fibers of the gluteus medius and gluteus minimus muscles, and the pectineus muscle.

4.3. Associated Pathology

Differential diagnosis should include lumbar pathology, sacroiliac dysfunction, and hip pathology. Symptom and pain referral patterns from the lumbar facet or sacroiliac joints overlap with the referred pain from TrPs in the piriformis muscle; therefore, examination of the lumbosacral region and hip region is indicated. Pain provocation studies looking at the referral zones for the sacroiliac joint have demonstrated referral frequently into the low back, buttock, and occasionally into the posterior or lateral thigh.^{76,77} Pain provocation studies mapping the referral zones for the hip joint have also demonstrated referral into the buttock, thigh, or groin in the majority of subjects.⁷⁸

Some medical conditions give rise to symptoms that can appear similar to those produced by TrPs in the piriformis, GOGOs, and quadratus femoris muscles or may be present concurrently. Piriformis myofascial pain syndrome is recognized by the characteristic pain pattern projected by its TrPs, by pain and weakness on resisted abduction of the thigh with the hip flexed 90°, by eliciting tenderness of the piriformis muscle using external palpation, and by palpating taut bands and tenderness via intrapelvic examination. Piriformis muscle syndrome may be the cause of a “post-laminectomy syndrome” or of coccygodynia.

Piriformis muscle syndrome remains a controversial condition. There is no constant definition for this syndrome, and the literature consists of mostly case studies and narrative reviews.⁷⁹ Piriformis muscle syndrome is commonly used to describe pain in the low back, groin, perineum, buttocks, hip, posterior thigh, and foot when it is thought that the piriformis muscle is causing irritation to the sciatic nerve. However, sometimes, the piriformis muscle is not involved at all.⁷⁹ Sometimes, other deep hip rotators cause the nerve irritation or pain, and there may be an absence of nerve irritation. Occasionally, articular dysfunctions are the source of the symptoms. Symptoms are generally aggravated by sitting, prolonged combination of hip flexion, adduction, internal rotation, or by activity. In addition, the patient may report swelling in the painful limb and of sexual dysfunction, dyspareunia in women and impotence in men.⁸⁰ The variety of causes of piriformis muscle syndrome are further discussed in Chapter 62.

Nerve entrapment is suggested by paresthesias and dysesthesias in the distribution of nerves passing through the greater sciatic foramen and by sensory disturbance extending

well beyond midthigh. Malignant neoplasm, neurogenic tumors, and local infection^{81–85} can compress the sciatic nerve at the greater sciatic foramen. These conditions have been identified by computed tomography scanning.⁸⁶

Another source of pain referred to the buttock and lateral thigh is an episacroiliac lipoma.⁸⁷ These herniated nodules of fat are exquisitely tender to palpation and are responsive to injection of a local anesthetic. Sometimes they require surgical removal under local anesthesia for lasting relief.

Symptoms of piriformis TrPs or syndrome are easily confused with radicular pain from compression of the lower lumbar and sacral nerve roots. Absence or marked weakness of the Achilles tendon reflex⁸⁸ and motor denervation shown by EMG, suggest a radiculopathy. Conversely, slowing of conduction velocity in the sciatic nerve through the pelvis suggests piriformis muscle entrapment. Palpation for piriformis muscle tenderness is essential to confirm or rule out entrapment and should be performed in all cases of “sciatica.” Incidental radiographic reports of “narrowing of the disc space” or “degenerative changes with spur formation” or “disc herniation” are not by themselves sufficient to account for the pain characteristic of piriformis muscle syndrome or LBP. Degenerative changes occur in the spine with aging and do not correlate well with clinical symptoms.^{89–91}

Symptoms of a facet syndrome with LBP and sciatica may be difficult to distinguish from a myofascial piriformis muscle syndrome until the muscle is examined.⁶¹ A facet block may relieve the back pain of a facet syndrome, but only successful inactivation of piriformis TrPs relieves the antalgic gait pattern and the buttock and posterior thigh pain of myofascial and related entrapment origin.⁴⁸ Huang et al⁹² looked at 52 patients with chronic myofascial pain in the piriformis muscle who received a facet injection at L5/S1. Eighty-eight percent of the patients had a reduction in their pain or complete relief of symptoms. At the 6-month follow-up, 35 patients had lasting results.

Piriformis muscle syndrome may develop secondary to sacroiliitis (sacroiliac arthritis). The diagnosis of sacroiliitis is confirmed by radiography. Sacroiliitis affects one or both SI joints and may cause pain and tenderness in the low back, buttock, and lateral thigh that may also extend as far as the ankle on one or both sides. Patients with sacroiliitis are usually young people who are HLA-B27 positive and may have ankylosing spondylitis (see Chapter 53),⁹³ usually bilaterally symmetric sacroiliitis,⁹⁴ psoriatic arthritis or Reiter disease (usually asymmetric sacroiliitis),⁹⁴ or arthritis related to inflammatory bowel disease.^{94, 95}

A venous thrombosis can also present as a myofascial syndrome of the piriformis or gluteus medius muscles. At least one case has been presented in the literature of an 18-year-old woman with pain in the left lumbosacral region and referral into the posterior thigh. The pain was of insidious onset in the buttock and thigh without a report of paresthesias or dysesthesias. There was tenderness with palpation in the left piriformis and gluteus medius muscles. Two days following treatment, the patient developed severe abdominal pain with heaviness in the leg and swelling in the calf.⁹⁶ Venous thrombosis is more common in women of childbearing age, but after age 60, it is more common in men and yet most common over the age of 70 and slightly more common in the left leg than in the right.⁹⁷

Risk factors for a venous thrombosis include a trauma or surgery (the more major the trauma or surgery the greater the risk),^{97,98} active cancer,⁹⁷ chemotherapy,⁹⁸ oral contraceptives,^{97,98} marked immobility,^{97,98} pregnancy,⁹⁸ central venous line,⁹⁸ obesity,⁹⁸ and varicose veins.⁹⁸ A venous thrombosis is diagnosed by a venous Doppler ultrasound. It is important to diagnose these quickly because proximal deep vein thrombosis is more likely to cause a pulmonary embolism than a distal vein thrombosis.⁹⁸

In patients with chronic kidney disease who are undergoing dialysis, calcium phosphate can be deposited into the muscles and form calcification near the larger joints.⁹⁹ This condition is called tumoral calcinosis and is rare, but when it does occur around the hip joint, it can produce pain in the buttocks, pain in the lateral hip, and tenderness at the piriformis muscle and greater trochanter.⁹⁹ The calcium phosphate deposits can be seen on ultrasound, radiographs, and magnetic resonance imaging (MRI).⁹⁹

Surgeries such as transvaginal tape or total hip arthroplasty can also have an effect on the hip external rotator muscles. TVT ABBREVO tape is used for urinary stress incontinence, and it is supposed to use less foreign material in hopes of reducing groin pain.¹⁰⁰ It is attached to the obturator membrane on both sides of the pelvis.¹⁰⁰ However, when investigating where the insertion points actually ended up on eight embalmed female cadavers who had received this procedure by very experienced surgeons, the tape attached only to the obturator membrane 50% of the time.¹⁰⁰ It attached to the obturator internus muscle one time, went through the obturator membrane and onto the obturator externus muscle five times, and through the obturator internus muscle, obturator membrane, and the obturator externus muscle onto the adductor muscles two times.¹⁰⁰ Total hip arthroplasty can also contact or change the course of the obturator externus muscle. In MRI of 40 patients with total hip replacement, 13 showed contact with the obturator externus muscle and 9 showed clear displacement of the muscle's course. However, these findings were not correlated to visual analog pain scores or patient satisfaction scores.¹⁰¹

Ischiofemoral impingement is a crowding of the quadratus femoris between the lesser trochanter and the ischial tuberosity or ischium-hamstring tendon.^{102,103} It can cause damage to the quadratus femoris muscle and mimic TrPs in the quadratus femoris muscle. Ischiofemoral impingement can be diagnosed with MRI.¹⁰² There is also an association of femoroacetabular impingement and TrPs in the deep hip external rotators. When there is a dysfunction in the deep hip external rotators, the muscles lose the ability to dynamically stabilize the hip especially in a closed kinetic chain. This loss of stability can lead to maltracking of the hip joint and possible anterior impingement. If this maltracking persists, it can lead to increased friction on the labrum, which makes it more vulnerable to increased micro-trauma and subsequent tears.

5. CORRECTIVE ACTIONS

Patients with TrPs in the piriformis and deep external rotator muscles of the hip will have to modify their sitting and sleeping postures. While sitting, the knees should be kept in alignment with the hips and shoulders. Keeping the knees placed in or out for prolonged

periods of time should be avoided. When sitting, patients should be encouraged to move as much as possible. Sitting in a rocking chair or using a foot rest helps encourage movement. A patient who tends to sit with the knees rotated outward (abducted) can occasionally pull the legs inward (adduct) by squeezing knees together and rotating the feet outward. When sleeping, pillows can be used as described in Figure 57-10 to help keep the hips and spine in a neutral position and reduce pressure on the lower hip.

Figure 57-10. Proper positions to improve sleep when lying on the unaffected side. A, A pillow is placed between the knees and ankles in order to avoid adduction of the uppermost thigh at the hip. B, A small pillow or folded towel under the waist line can prevent side bending away from the hip on against the bed and reduce the pressure on the lower hip.

Because the deep hip external rotator muscles are also hip stabilizers, activities, such as standing on one leg, that require hip stabilization may need to be avoided if the TrPs are too irritable. However, exercises to target these muscles and the gluteus maximus muscle should be started as soon as tolerable.

A TrP self-pressure release tool or tennis ball may be used for self-treatment of the piriformis and deep external rotator muscles of the hip (Figure 57-11). These techniques should be employed cautiously because of the muscles' proximity, and therefore the potential to cause irritation of the nerve tissue. This treatment can be helpful for lateral piriformis TrPs and for the other five short external rotator muscles. The tennis ball must be placed far enough laterally to avoid the sciatic nerve where pressure causes numbness and tingling below the knee. The patient should use the TrP self-pressure release tool or tennis ball to rub the area and provide friction instead of just sustained pressure.

Figure 57-11. Piriformis muscle self-pressure release. A, Using a TrP release tool. B, Using a tennis ball. C, Self-pressure release of other deep external rotator muscles.

To perform the piriformis muscle self-stretch, the patient lies supine (Figure 57-12), crosses the leg of the involved side over the opposite thigh, and flexes the hip up to about 90°, resting the opposite hand on the knee of the uppermost affected limb. This hand is used to assist bringing the involved thigh across midline. The patient stabilizes the hip on the involved side by pressing down on the pelvis with the ipsilateral hand. Release of muscle tension is augmented by the patient “thinking” of gently lifting the weight of the affected leg (but not actually moving it) during slow inhalation and then, during slow exhalation, having the muscle relax and slowly allowing the piriformis muscle to stretch.

Figure 57-12. Self-stretch of the right piriformis muscle. The right thigh is flexed nearly 90° at the hip with the right foot on the treatment table. To adduct the thigh at the hip, pressure is exerted downward with both hands (large arrows), one on the thigh and the other on the pelvis, pulling against each other. To perform postisometric relaxation, the individual then attempts to abduct the thigh by pressing it *gently* against the resisting left hand for a few seconds (isometric contraction of abductors), then relaxes and gently moves the thigh into adduction, which gradually lengthens the piriformis muscle.

A more dynamic stretch, such as the seated hip internal rotation stretch, may be more appropriate if there is any nerve involvement because nerves do not respond well to sustained “stretching”¹⁰⁴ or sustained pressure.¹⁰⁵ The patient sits on a firm surface with an erect posture and places a small towel roll under the back of the thigh near the knee to place the hip at 90° or more of flexion (Figure 57-13A). Rotate the foot on the affected side outward so the femur internally rotates, hold for 3 to 5 seconds, then slowly lower the leg back to the starting position (Figure 57-13B). To keep the body better aligned, this motion can be performed with both legs at the same time (Figure 57-13C). Flexing the hip past 90° may also augment the stretch.¹⁰⁶

Figure 57-13. Reciprocal inhibition of external rotator muscles. A, Sit with knees aligned with

the hips and shoulders. B, Rotate the foot outward on the affected side so the femurs internally rotate, hold and slowly lower leg to starting position. C, Rotate the feet outward so the femur internally rotates, hold and slowly lower legs to starting position.

Quadriceps Femoris and Sartorius Muscles

“Four-Faced Troublemaker and Surreptitious Accomplice”

Beth Collier and Joseph M. Donnelly

1. INTRODUCTION

The muscles of the anterior compartment of the thigh are informally termed the “quadriceps” when discussed as a group. The main four muscles that make up the quadriceps femoris muscles are the rectus femoris, vastus lateralis, vastus medialis, and vastus intermedius muscles. The quadriceps femoris muscles merge into a common tendon that attaches to the patella that then attaches to the tibial tuberosity by the patellar ligament and allows for knee extension. The three vasti muscles only cross the knee joint and act to extend the knee. As the rectus femoris muscle crosses both the hip and knee joint, it also contributes to hip flexion. The sartorius muscle also lies in the anterior compartment of the thigh and contributes to hip flexion, abduction, and external rotation as well as knee flexion. Trigger points (TrPs) in the quadriceps femoris and sartorius muscles can refer pain to the thigh anteriorly, laterally, and to the knee region medially, laterally, and posterolaterally. Trigger points in the quadriceps femoris muscle can be debilitating and can cause buckling or giving way of the knee during walking or descending stairs. Clinicians should consider TrPs in these muscles when patients present with a diagnosis of L4 radicular pain or radiculopathy, patellofemoral pain syndrome, knee osteoarthritis, iliotibial band syndrome, patellar tendinopathy, or greater trochanteric bursitis. To treat TrPs in the quadriceps femoris and sartorius muscles, patients may perform self-pressure release techniques and self-stretching of the involved muscles. Patients may also benefit from improving or supporting static and dynamic postures that contribute to overuse or shortening of these muscles.

2. ANATOMIC CONSIDERATIONS

Rectus Femoris

The two-joint rectus femoris muscle lies between the vastus medialis and vastus lateralis

muscles and covers the vastus intermedius muscle. The rectus femoris muscle originates from the pelvis by two tendons, one attached to the anterior inferior iliac spine and the other to a groove above the posterior brim of the acetabulum. It then inserts to the proximal border of the patella and through the patellar ligament to the tuberosity of the tibia (Figure 58-1). Proximally, the rectus femoris muscle is covered by the sartorius muscle at, and just inferior to, the anterior inferior iliac spine.¹

Figure 58-1. Attachments (anterior view) of the right rectus femoris muscle (dark red) in relation to the vastus lateralis and vastus medialis muscles (light red).

Vastus Intermedius

The vastus intermedius muscle lies deep to the rectus femoris and vastus lateralis muscles. It originates from the anterior and the lateral surfaces of the upper two-thirds of the shaft of the femur and from the distal aspect of the lateral intermuscular septum. It inserts on the lateral border of the patella, the lateral condyle of the tibia and through the patellar ligament to the tibial tuberosity (Figure 58-2). The vastus intermedius muscle is clearly separated on its medial side from the vastus medialis muscle, but laterally, the vastus intermedius fibers merge with those of the vastus lateralis muscle.¹

Figure 58-2. Attachments (anterior view) of the right vastus medialis (light red), vastus intermedius (dark red), and vastus lateralis (light red) muscles of the quadriceps femoris muscle group. The bulk of the overlying rectus femoris muscle has been cut and removed. Part of the anterior attachment of the vastus medialis muscle to the aponeurosis of the

quadriceps femoris tendon along the medial edge of the vastus intermedius muscle has been cut and pulled aside by the lower hook. This reveals the deeper fibers of the vastus medialis muscle as they disappear to attach behind the femur, and it exposes the bone deep to the fibers anteriorly. The upper hook pulls the vastus lateralis muscle aside to show the underlying portion of the vastus intermedius muscle.

Vastus Medialis

The vastus medialis muscle originates from the distal half of the intertrochanteric line, the medial lip of the linea aspera, and the upper part of the medial supracondylar line of the femur.¹ The vastus medialis muscle attaches to the aponeurosis of the quadriceps femoris tendon with the vastus intermedius muscle, and its fibers wrap around the femur angling anteriorly and inferiorly from its posterior attachments. The vastus medialis muscle inserts on the medial border of the patella and through the patellar ligament to the tibial tuberosity. It also inserts by a slip of muscle to the medial patellar retinaculum that reinforces the capsule of the knee joint, and it ultimately terminates at the medial tibial condyle¹ (Figure 58-2).

The distal fibers of the vastus medialis muscle are markedly angulated in the region of the patella and can be clearly separated from the rest of the vastus medialis muscle by fiber direction and also by a fascial plane. These distal angulated fibers often attach chiefly to the adductor magnus muscle, partly to the adductor longus muscle, and to the medial intermuscular septum. These obliquely oriented fibers are often referred to as the vastus medialis obliquus (VMO).^{1,2} In fact, the insertion of these fibers is variable and changes significantly with advancing age and the presence of knee degeneration.³ Some authors, who deem the VMO a separate muscle, have proposed the term “vastus medialis longus” for those fibers with a more vertical orientation that originate from the medial lip of the linea aspera and the medial intramuscular septum and travel to the medial margin and anterior surface of a quadriceps tendon aponeurosis. Controversy continues as to whether the vastus medialis muscle should be classified as one or two muscles.⁴

Vastus Lateralis

The vastus lateralis muscle is the largest component of the quadriceps femoris muscle group. It originates by way of a broad aponeurosis from the superior portion of the intertrochanteric line, the anterior and inferior borders of the greater trochanter, the lateral lip of the gluteal tuberosity, and the proximal half of the lateral lip of the linea aspera of the femur¹ (Figure 58-3). Some fibers also originate from the tendon of the gluteus maximus muscle as well as the lateral intermuscular septum between vastus lateralis muscle and the short head of biceps femoris muscle.

Figure 58-3. Attachments (lateral view) of the right vastus lateralis muscle (dark red) in relation to the rectus femoris muscle (light red).

The aponeurosis deep to the muscle inserts on the lateral border of the patella and blends into the common quadriceps femoris tendon. It also contributes to the capsule of the knee joint that descends to the lateral condyle of the tibia and the iliotibial band.¹ However, the gross anatomy of the vastus lateralis muscle described in the literature is inconsistent.⁵

Tensor of the Vastus Intermedius

Recent cadaveric research has identified a fifth major contribution to the quadriceps femoris muscle group, termed the tensor of the vastus intermedius (TVI) muscle. Specific dissection of 26 specimens identified a separate TVI muscle in all cases that received separate nervous and vascular supply from the femoral nerve and lateral femoral circumflex artery. The TVI muscle is a separate muscle that lies between the vastus intermedius and the vastus lateralis muscles and attaches distally to the medial aspect of the patella by way of its own aponeurosis that adjoins the quadriceps femoris tendon.⁶ The TVI muscle has also been demonstrated via magnetic resonance imaging (MRI) to blend with fibers of the vastus lateralis and vastus medialis muscles dorsally into its attachment at the lateral lip of the linea aspera.⁷

The articularis genu muscle is a tiny, deep muscle that occasionally blends with the vastus intermedius muscle but is often separate. It originates from the anterior surface of the distal femoral shaft and attaches to the proximal aspect of the synovial membrane of the knee joint.¹

Sartorius

The sartorius, a narrow strap muscle, is the longest muscle in the body. It originates from the anterior superior iliac spine and descends obliquely across the front of the thigh, lateral to medial. The tendon of the sartorius muscle forms an additional aponeurosis that sends fibers into the deep fascia of the quadriceps femoris muscle.⁸ The sartorius muscle forms a roof over the femoral artery, vein, and nerve in the adductor canal. In the distal part of the thigh, it descends nearly vertically, passing over the medial condyle of the femur. The distal tendon of the sartorius muscle curves obliquely and anteriorly to insert on the medial surface of the body of the tibia just anterior to the attachments of the gracilis and semitendinosus tendons (Figure 58-4). Thus, it is the most anterior of the “pes anserinus” muscles. A slip of the superior margin blends with the knee capsule and another slip from the inferior margin blends with the fascia of the medial side of the leg.¹

Figure 58-4. Attachments of the right sartorius muscle (red), viewed from in front and somewhat from the medial side. It attaches proximally to the anterior superior spine of the ilium and distally to the medial aspect of the upper tibia.

2.1. Innervation and Vascularization

All the muscles of the quadriceps femoris group, including the TVI and articularis genu muscles, are supplied by branches of the femoral nerve composed of fibers from L2, L3, and

L4 spinal nerves. Interestingly, Günel et al⁹ found that the VMO fibers have additional femoral nerve branches, explaining its relevance for stabilization of the patella. Jojima et al¹⁰ observed that the main trunk of the femoral nerve ran in the mid-portion of the vastus medialis muscle before dividing into multiple branches that entered the distal oblique fibers of the muscle. The sartorius muscle is also innervated by the femoral nerve from L2 and L3 nerve roots.¹

As a group, the quadriceps femoris muscles receive arterial supply from a branch of the profunda femoris or lateral femoral circumflex arteries. Evidence also suggests that the vastus medialis muscle receives vascular supply directly from the superficial femoral artery.¹¹

The proximal third of the sartorius muscle receives its arterial supply from the common femoral, the profunda femoris, and the lateral circumflex femoral arteries, as well as the artery to the quadriceps femoris muscle. The middle third of the muscle receives its supply from the superficial femoral artery. The distal third of the muscle receives its supply from the superficial femoral and descending genicular arteries.¹

2.2. Function

Quadriceps Femoris

In open kinetic chain, the quadriceps femoris muscles act together as prime extensors of the knee. The rectus femoris muscle can also flex the hip. A recent study found that proximal fibers of the rectus femoris muscle can be activated independently from distal fibers. Therefore, the activation succession between fibers could change direction (from proximal to distal, or inversely) and depends on the context of the movement.¹² Collectively, the vastus medialis, vastus lateralis, and vastus intermedius muscles respond simultaneously to vigorous effort¹³; however, contributions from the rectus femoris muscle depend on demands at the hip joint. The four main muscles of the quadriceps femoris group trade-off among themselves in variable ways during slow increase of knee extension force to a maximum effort.¹⁴ Balanced tension on the patella between the vastus medialis and vastus lateralis muscles maintains normal positioning and tracking of the patella.^{15–17} Nevertheless, some authors have suggested that the main medial stabilizer of the patella is the VMO muscle as it reduces lateral pressure of the patella cartilage.¹⁸

In weight-bearing positions, the quadriceps femoris muscle group functions to control trunk extension and knee flexion as with squatting, sitting down from the standing position, and descending stairs. However, the quadriceps femoris muscles are not active in static standing.^{13,19,20} During gait, the quadriceps femoris muscles are active immediately after heel strike to control knee flexion during weight acceptance and again at toe off to stabilize the knee in extension. They are not active during the period that the knee is extending during stance. The quadriceps femoris muscle group is not active in extension of the leg during the early swing phase, but it is active in the last part of the swing phase, in preparation for weight bearing. Stance phase quadriceps femoris muscle activity is either

prolonged or increased (or both) under certain circumstances, such as when there is significant loss of function in the plantar flexors, when heavy loads are carried on the back, when walking speed is increased, and when one wears high heels.^{13, 21–25} The quadriceps femoris muscle also serves an important function during rising from sitting and in ascending stairs.¹⁹ A strong peak of activity appears in the middle of the down stroke during upright cycling.^{26, 27}

Sartorius

The sartorius muscle earned its name as the muscle that assists the hip movements necessary to assume the position of a cross-legged tailor. This muscle, like the tensor fasciae latae muscle, is a flexor and abductor of the thigh, but the sartorius muscle rotates the thigh externally instead of internally.¹ Activation of this muscle by knee flexion or extension is highly variable.^{28, 29} It is more likely to assist knee flexion when the hip is also flexed.²⁹

During the swing phase of gait, sartorius muscle activity peaks to assist the iliacus and tensor fasciae latae muscles in hip flexion, and the muscle assists the short head of the biceps femoris muscle in knee flexion. It may assist the vastus medialis, gracilis, and semitendinosus muscles in supporting the knee medially against the valgus thrust that occurs during single limb balance.³⁰ During bicycling, the sartorius muscle is active as a hip flexor.

2.3. Functional Unit

The functional unit to which a muscle belongs includes the muscles that reinforce and counter its actions as well as the joints that the muscle crosses. The interdependence of these structures is functionally reflected in the organization and neural connections of the sensory motor cortex. The functional unit is emphasized because the presence of a TrP in one muscle of the unit increases the likelihood that the other muscles of the unit will also develop TrPs. When inactivating TrPs in a muscle, one must be concerned about TrPs that may develop in muscles that are functionally interdependent. Box 58-1 grossly represents the functional unit of the quadriceps muscle group and the sartorius muscle.³¹

Box 58-1 Functional unit of the quadriceps femoris muscle group and sartorius muscle

Action	Synergists	Antagonists
Knee extension	Rectus femoris Vastus medialis Vastus intermedius Vastus lateralis Tensor of the vastus	Semimembranosus Semitendinosus Biceps femoris Gastrocnemius Popliteus

Hip abduction (sartorius)	Piriformis Gluteus medius Gluteus minimus	Pectineus Adductor longus Adductor brevis Adductor magnus Gracilis

3. CLINICAL PRESENTATION

3.1. Referred Pain Pattern

Trigger points in all four main muscles of the quadriceps femoris muscle group refer pain to the thigh and knee region. Rectus femoris and vastus medialis TrPs produce anterior and medial knee pain. The referred pain from rectus femoris TrPs is more likely to be felt deep in the knee joint than is the knee pain referred from the vastus medialis or vastus lateralis muscles. Trigger points in the vastus lateralis muscle cause hip, lateral thigh, and posterolateral knee pain.

Rectus Femoris (Two-jointed Puzzler)

Trigger points in the rectus femoris muscle are extremely common and frequently overlooked. This muscle rarely undergoes full stretch in daily activities. The rectus femoris muscle is a two-joint puzzler because TrPs are commonly identified proximally, just below the anterior inferior iliac spine. However, the pain is typically felt at the anterior knee in and around the patella and sometimes deep in the knee joint (Figure 58-5). Patients with TrPs in the rectus femoris muscle often have severe deep aching pain at night over the distal thigh above the knee anteriorly. They are typically unable to find a position or movement that provides relief until they learn how to fully stretch this muscle. Trigger points can occasionally be found in the distal end of the rectus femoris muscle just proximal to the patella and may refer pain deep into the knee joint.

Figure 58-5. Referred pain patterns from TrPs in the rectus femoris muscle. Solid bright red denotes the essential pattern of pain from TrPs in the rectus femoris muscle. Red stippling indicates the occasional extension of its essential referred pain pattern.

Vastus Intermedius (Frustrator)

The vastus intermedius muscle is a “frustrator” because it develops TrPs that cannot be palpated directly due to coverage from the more superficial rectus femoris muscle. The pain from these TrPs extends over the anterior aspect of the thigh nearly to the knee but is most intense at the mid-thigh. Trigger points at the vastus intermedius muscle may refer pain and tenderness that extends over the upper thigh anterolaterally (Figure 58-6). Kellgren³² reported that 0.1 mL of 6% hypertonic saline solution injected into the vastus intermedius

muscle caused pain in the knee joint.

Figure 58-6. Referred pain pattern from TrPs in the vastus intermedius muscle. Dark solid red denotes the essential pattern of pain felt with TrPs in the vastus intermedius muscle. Red stippling indicates occasional extension of the essential referred pain pattern.

Vastus Medialis (Buckling Knee Muscle)

Trigger points in the vastus medialis muscle more commonly occur distally in the muscle and refer pain to the anterior knee area. Proximal vastus medialis TrPs commonly refer an aching pain in a linear distribution over the anteromedial aspect of the knee and lower

thigh (Figure 58-7).

Figure 58-7. Referred pain patterns from TrPs in the vastus medialis muscle. Solid dark red depicts the essential pattern of pain experienced with TrPs in the vastus medialis muscle. Red stippling indicates the occasional extension of the essential referred pain pattern.

Trigger points in this muscle are easily overlooked because the taut muscle fibers only minimally restrict knee flexion range of motion and the TrPs may not produce intense pain. Commonly, TrPs of the vastus medialis muscle tend to produce more motor dysfunction (inhibition weakness) after the initial acute pain phase. The pain from TrPs in the muscle may be replaced by unexpected episodes of quadriceps femoris inhibition that result in buckling of the knee. This sudden perceived weakness may cause the individual to fall, often inflicting injury. Vastus medialis TrPs are frequently seen in adults and children. Nguyen³³ proposed a hypothetical pain model in which TrPs in the knee muscles can cause muscle tightness, pain, and weakness leading to early pathologic neuromuscular changes including knee instability and consequently, falls. In this hypothetical model, long-lasting

TrPs may promote knee instability and therefore facilitate degenerative changes in the knee, which will, in turn, present as typical arthrogenic muscle inhibition seen in patients with knee osteoarthritis.³³ However, there is no research supporting this hypothesis.

Vastus Lateralis (Stuck Patella Muscle)

The vastus lateralis muscle characteristically develops multiple TrPs along the lateral aspect of the thigh. This muscle has the largest mass of the four heads of the quadriceps femoris muscle group. TrPs in this muscle can refer pain throughout the full length of the thigh laterally and to the posterolateral aspect of the knee (Figure 58-8). Occasionally, the referred lateral thigh pain extends as high as the pelvic crest. Superficial TrPs in this muscle are more likely to have a local pattern, whereas TrPs located deep in the muscle usually produce a widespread pain throughout the thigh. When vastus lateralis TrPs refer pain and tenderness to the proximal thigh region, the patient may be unable to lie on that side, disturbing restful sleep. In an older report, Good³⁴ found that “myalgic spots” (probably TrPs) in the lateral edge of the vastus lateralis muscle referred pain to the knee.

Figure 58-8. Referred pain pattern from TrPs in the vastus lateralis muscle. Solid bright red denotes the basic pain experienced by nearly everyone with TrPs in the vastus lateralis muscle. Red stippling indicates the occasional extension of the essential referred pain pattern.

A distinctive feature of TrPs in the distal portion of the vastus lateralis muscle is the feeling of a “stuck patella” in addition to pain around the lateral border of the patella that sometimes extends upward over the lateral region of the thigh (Figure 58-8). Trigger points located in the more posterior distal portion of the vastus lateralis muscle also cause pain lateral to the patella, but these TrPs refer pain more extensively up to the lateral aspect of the thigh and sometimes down the lateral aspect of the leg. Trigger points commonly

located posterolaterally at the mid-thigh level refer pain that travels the entire length of the posterolateral region of the thigh and includes the lateral half of the popliteal space. It is the one quadriceps femoris TrP area that can produce posterior knee pain.

Trigger points located at mid-thigh level in the anterior portion of the muscle, just above the iliotibial band, are common and likely to cause severe pain over the entire length of the lateral thigh, slightly anterior to the iliotibial band, and extending upward almost to the pelvic crest. Distally, the pain referred from this area of the muscle can refer pain anteriorly around the lateral border of the patella rather than posteriorly to the popliteal space. Trigger points in the proximal area of the vastus lateralis muscle refer pain and tenderness only in its immediate vicinity (Figure 58-8).

Sartorius

Trigger points in the sartorius muscle produce superficial, sharp, or tingling symptoms or pain along the anterior and medial thigh, as well as to the medial knee. These TrPs are commonly mistaken for knee pathology (Figure 58-9).

Figure 58-9. Referred pain patterns of TrPs at different levels in the sartorius muscle (red stippled), anteromedial view.

3.2. Symptoms

Referred pain is commonly the presenting symptom of the quadriceps femoris muscle group with two exceptions, muscle inhibition of the vastus medialis muscle causing buckling (giving way) of the knee and restricted patellar mobility from the vastus lateralis muscle.

Rectus Femoris

Patients who experience TrPs in the rectus femoris muscle commonly report pain at the anterior knee and thigh that may wake them at night. Often, these patients may sleep with the rectus femoris muscle in a maximally shortened position with the knee extended and slight hip flexion in side-lying. Pain may be relieved with a full muscle stretch in hip extension with knee flexion. Patients with TrPs in the rectus femoris muscle may also report difficulty or weakness in the knee when descending stairs.

Vastus Intermedius

Patients with TrPs in the vastus intermedius muscle have difficulty fully straightening the knee actively, especially after it has been immobile for some time during sitting. They often report difficulty with ascending stairs or with transitioning from sit-to-stand after prolonged sitting. Typically, the patient will report increased pain during knee movement, as opposed to pain at rest. Clinically, the patient may report buckling or giving way of the knee if TrPs in the vastus intermedius muscle occur in conjunction with TrPs in the two heads of the gastrocnemius muscle near their femoral attachments.

Vastus Medialis

When a patient has TrPs in the vastus medialis muscle, they report an aching pain deep in the knee joint, which often interrupts their sleep pattern. It may be misinterpreted as being due to inflammation of the knee joint.³⁵ Over time, the concerning knee pain will fade and the patient will instead experience episodic inhibition of quadriceps femoris muscle function that causes unexpected buckling (inhibition weakness) of the knee during walking.³⁶ This buckling response may cause the individual to fall. Baker³⁶ cites the case of an incapacitated 12-year-old athlete with knee buckling, which completely resolved upon inactivation of the vastus medialis TrPs.

Vastus Lateralis

Patients who have TrPs in the vastus lateralis muscle exhibit pain with walking that extends along the lateral aspect of the thigh including the knee. Patients with TrPs in the vastus lateralis may report difficulty lying on the involved side, and pain may disturb their sleep. The patient may also report a feeling of “stiffness” in the knee as TrPs in the distal end of the vastus lateralis muscle can also reduce accessory mobility of the patella. This reduction in patellar mobility may cause difficulty both in flexing and in extending the knee after periods of prolonged sitting or immobilization. These TrPs, unlike any other quadriceps TrPs, can also refer pain into the posterior aspect of the knee joint. This muscle should always be thoroughly examined when the patient reports pain or symptoms in the lateral aspect of the thigh, and the knee. Oftentimes, this muscle is overlooked as a source of the patient’s symptoms or a contributing factor when a patient reports symptoms consistent with greater trochanteric bursitis or iliotibial band syndrome.

Sartorius

Typically, patients with TrPs in the sartorius muscle have poor tolerance for prolonged sitting, with the hip flexed to 90° or more. They may also report pain and difficulty when transitioning to standing after a period of prolonged sitting. Pain arising from TrPs in the sartorius muscle is often difficult to differentiate from pain arising from TrPs in the vastus medialis and intermedius muscles; however, pain arising from TrPs in the sartorius muscle is usually more diffuse and superficial. It is very rare to have pain from TrPs in isolation from the sartorius muscle. Patients who run long distances may report difficulty and limitation due to pain in the thigh area.

3.3. Patient Examination

After a thorough subjective examination the clinician should make a detailed drawing representing the pain pattern the patient has described. This depiction will assist in planning the physical examination and can be useful in monitoring the progression of the patient as symptoms improve or change. If TrPs in any of the quadriceps femoris muscles are suspected, clinicians should perform a thorough examination of the knee, hip, foot, ankle, and possibly the pelvis if the rectus femoris muscle is involved. Accessory motion of the patellofemoral and tibiofemoral joints should be carefully assessed.

Functional activities such as sit-to-stand, stair descent, single-leg stance, double-leg squat, and single-leg squat (Figure 55-3A) should be examined. The clinician should take note of any frontal or sagittal plane deviations noted in the pelvis, hip and/or knee, and any excessive transverse plane motion at the ankle and foot (Figure 55-3B). The clinician should note any gait deviations such as a Trendelenburg sign at mid-stance (Figure 55-4A and B), or forward lean of the trunk at heel strike.³⁷ These deviations could be indicative of gluteal muscle weakness or lower extremity biomechanical faults. The quadriceps femoris muscle group can be overloaded in the presence of gluteal muscle weakness or lower extremity biomechanical malalignment, especially during sit-to-stand and single- and double-leg squat activities.³⁸

With the patient supine, knee flexion range of motion can be assessed by bringing the heel toward the buttock with the hip flexed. Trigger points in the vastus intermedius muscle can significantly restrict flexion range of motion at the knee. Typically, the heel does not reach the buttock by several fingerbreadths. However, TrPs in the vastus lateralis muscle also cause this restriction if the patella is hypomobile. Trigger points in the vastus medialis muscle cause minor restrictions of knee flexion range of motion. In order to fully assess the extensibility of the rectus femoris muscle, the patient must demonstrate simultaneous hip extension and knee flexion, as in the Thomas test (see Figure 56-6) or Ely test. Restriction of this range from muscle length deficits caused by TrPs in the rectus femoris muscle occurs commonly. A tight iliopsoas muscle group restricts extension at the hip, but does not affect flexion at the knee.

Hip abduction and adduction strength should be evaluated bilaterally as both sides are responsible for lumbopelvic stability at different times during the gait cycle. The strength of

the quadriceps femoris muscles should be tested and compared to the unaffected side. Trigger points induce intermittent weakness inhibition of knee extension without muscle atrophy.³⁹ The presence of marked quadriceps femoris muscle atrophy is usually associated with knee joint pathology. Patients with patellofemoral pain syndrome exhibit quadriceps femoris muscle atrophy, though it is not clear if this atrophy is mostly related to the vastus medialis,⁴⁰ the vastus lateralis, or all the quadriceps femoris muscles.⁴¹

Clinicians may also consider performing isokinetic testing of the quadriceps femoris and hamstring muscles within the same limb to identify the hamstring:quadriceps femoris ratio. Aagaard et al⁴² proposed considering functional ratios of strength in which eccentric hamstring:concentric quadriceps femoris identifies functional extension ratios, and concentric hamstrings:eccentric quadriceps femoris identifies functional flexion ratios. Increased muscle activity of the hamstring muscles, as well as coactivity of the quadriceps femoris and hamstring muscles, has been identified as factors for those with knee osteoarthritis.⁴³

During accessory mobility testing of the patella, the knee should be fully extended and the quadriceps femoris muscle completely relaxed, as tension from the quadriceps femoris muscle can restrict passive accessory movement of the patella. Before examining for patellar mobility, the clinician should observe and palpate the resting position of the patella.⁴⁴ Trigger point–induced tension in the vastus medialis muscle can restrict lateral mobility of the patella. Trigger points in the distal portion of the vastus lateralis muscle reduces all normal accessory movement of the patella, including the inferior glide of at least 1 cm that occurs during effective knee flexion.

Sartorius TrPs are typically associated with quadriceps femoris TrPs. Patients with TrPs in the sartorius muscle may report having pain in the anterior and medial thigh and/or about the medial knee area. Trigger points in this muscle typically do not limit movement or cause mechanical dysfunction; therefore, range of motion is not restricted. Weakness and pain on loading the sartorius muscle can be tested with the patient in a seated position with the knee flexed to 90° while asking the patient to perform external rotation of the thigh at the hip against resistance. The pain caused by TrPs in the sartorius muscle is typically vague and more superficial than the pain caused by quadriceps TrPs.

3.4. Trigger Point Examination

Rectus Femoris

In most individuals, a cleft is palpable between the vastus medialis muscle and the medial border of the rectus femoris muscle. The lateral border of the rectus femoris muscle is usually palpable along the length of the anterolateral thigh. Borders of the muscle can be defined by asking the patient to perform a submaximal isometric contraction into knee extension.

Trigger points in the rectus femoris muscle are commonly located proximally in the muscle, close to the anterior inferior iliac spine, and can be identified with cross-fiber flat

palpation (Figure 58-10A). The rectus femoris muscle is distinguished from the sartorius muscle by having the patient perform isometric knee extension without hip flexion. Of these two muscles, only the rectus femoris muscle extends the knee, whereas the sartorius becomes active with knee flexion. Trigger points may also be identified along the distal aspect of the rectus femoris muscle, not less than about 10 cm (4 in) above the superior border of the patella.

Figure 58-10. Cross-fiber flat palpation for trigger points in the quadriceps femoris muscle group. A, Rectus femoris muscle. B, Vastus intermedius muscle. C, Vastus medialis muscle (proximal). D, Vastus medialis muscle (distal).

Vastus Intermedius

It is nearly impossible to palpate the individual taut bands of TrPs in the deep muscle mass of the vastus intermedius muscle, and the entire muscle feels tense deep to the rectus femoris muscle. When it is possible to palpate its TrPs, they are found by first locating the

superior lateral border of the rectus femoris muscle and following it a short distance distally until the fingers feel a space that permits cross-fiber flat palpation very deep, close to the femur (Figure 58-10B). However, it is common that digital pressure on the muscle does not reproduce the TrP referred pain, whereas needle penetration of the TrP does reproduce it. Therefore, the role of these TrPs is easily underestimated. Because of the overlying fascia and muscle, what appear to be TrPs of only slight or moderate tenderness on palpation often prove very painful when penetrated by a filiform needle.

When both the rectus femoris and vastus intermedius muscles contain TrPs, inactivating those in the former makes it easier to locate those in the latter. The vastus intermedius muscle is more likely than the rectus femoris muscle to have TrPs located in the distal part of the muscle.

Vastus Medialis

For examination of the vastus medialis muscle, the patient should lie supine with the thigh of the symptomatic side placed in moderate abduction and the knee supported at about 30° of flexion. A pad or pillow under the knee improves the patient's comfort. Cross-fiber flat palpation is used to identify TrPs that are most commonly found close to the medial border of the muscle (Figure 58-10C). Distal TrPs can be the most troublesome and the ones most likely to cause buckling of the knee (Figure 58-10C). The adductor muscles are commonly involved when distal TrPs in the vastus medialis muscle are present.

A cluster of TrPs may also be located along the medial border of the muscle approximately where the transition to oblique fibers would be expected. The more proximal TrPs are likely to evoke referred pain and not buckling or giving way of the knee. These pain producers are commonly found at about mid-thigh near the medial border of the vastus medialis muscle next to the adductor muscles. Occasionally, a taut band can be palpated close to the linea aspera where the adductor magnus muscle also attaches. During palpation, pressure should be directed toward the femur to locate the taut band and to evoke a pattern of referred pain. Rozenfeld et al⁴⁵ have recently reported that examination of the vastus medialis muscle is reliable for the presence of latent and active TrPs showing kappa values ranging from 0.53 to 0.72.

Vastus Lateralis

For examination of the vastus lateralis muscle, the patient should assume the side-lying position with a pillow placed between the knees to keep the hip in neutral with the knees slightly flexed (Figure 58-11A to D). The vastus lateralis muscle, like the vastus intermedius muscle, usually has multiple TrPs, and many of them lie deep in the muscle. The taut bands of these TrPs can be located by cross-fiber flat palpation directly against the underlying bone (Figure 58-11A-C and E) or with a cross-fiber pincer palpation with the patient in side-lying or ¼ turned toward prone (Figure 58-11D and F). Taut bands of the vastus lateralis muscle are accessible from the anterior and posterior aspect of the iliotibial band (Figure 58-11B and C).

Figure 58-11. Palpation for TrPs in the vastus lateralis muscle. A, Side-lying cross-fiber flat palpation, proximal portion. B, Side-lying cross-fiber flat palpation, mid-portion anterior to iliotibial band (ITB). C, Side-lying cross-fiber flat palpation, distal portion posterior to ITB. D, Side-lying cross-fiber pincer palpation. E, Supine cross-fiber flat palpation mid-thigh. F, Supine $\frac{1}{4}$ turned pincer palpation.

Trigger points in the distal aspect of the muscle can be identified while the patient lies with a relaxed, extended knee. The clinician may also depress the patella inferiorly and medially to palpate the vastus lateralis muscle in line with, and close to, the lateral border of the patella, in an area that the patella had covered before being depressed. Trigger points here often feel like an exquisitely tender hard knot.³⁹

Sartorius

The TrPs of the sartorius muscle are very superficial and easily missed. With the patient in a supine position, TrPs can be identified with cross-fiber flat palpation along the entire length of the muscle (Figure 58-12A and B). Local twitch responses elicited by snapping palpation at the TrP are often visible in this muscle. Confirmation of muscle location can be achieved by asking the patient to perform a gentle isometric hip external rotation and flexion contraction.

Figure 58-12. Cross-fiber flat palpation for TrPs in the sartorius muscle. A, Proximal portion. B, Distal portion. The entire muscle belly should be examined.

4. DIFFERENTIAL DIAGNOSIS

4.1. Activation and Perpetuation of Trigger Points

A posture or activity that activates a TrP, if not corrected, can also perpetuate it. In any part of the quadriceps femoris or sartorius muscles, TrPs may be activated by unaccustomed eccentric loading, eccentric exercise in an unconditioned muscle, or maximal or submaximal concentric loading.⁴⁶ Trigger points may also be activated or aggravated when the muscle is placed in a shortened and/or lengthened position for an extended period of time.

Quadriceps Femoris

The quadriceps femoris group is susceptible to activation of TrPs by an acute overload from a sudden vigorous eccentric contraction, such as stepping into a hole, stepping off the curb, or from stumbling (tripping). Direct trauma by impact against the femur can activate TrPs in any head of the quadriceps femoris muscle, most likely in the vastus lateralis muscle and least likely in the vastus intermedius muscle. Walking in high heel shoes or shoes with wedged-soles can also activate and perpetuate TrPs in the quadriceps femoris muscle group.

Acute or chronic overload can occur in an exercise program that includes deep squats.

This exercise perpetuates quadriceps femoris TrPs, especially those in the vastus intermedius muscle. Another exercise that is likely to perpetuate TrPs in the quadriceps femoris muscle group is an attempt to strengthen the muscle utilizing open chain knee extension with a load at the ankles when TrPs are already present in the muscle. Other activities that can perpetuate TrPs in the quadriceps femoris muscles include skiing, sprinting, ascending/descending stairs, and walking downhill. Sporting activities such as kicking a football or soccer ball can overload the rectus femoris and sartorius muscles.

Immobilization is often an integral part of therapy for orthopedic problems of the lower extremity, such as knee or hip surgery. Often, after such surgeries or when in pain, patients will self-immobilize, holding the limb in a guarded position. Patients should be checked for TrPs before and after immobilization, especially if they are experiencing unexpected pain afterward. Prolonged sitting postures can also exacerbate TrPs of the quadriceps femoris muscles, such as sitting with one foot tucked under the buttock, sitting with a child sitting on the lap, or prolonged kneeling.

Indirectly, any traumatic event into the knee, such as surgery, can also activate TrPs in the quadriceps femoris muscle. In fact, it has been found that patients after a meniscectomy⁴⁷ or after reconstruction of an anterior cruciate ligament (ACL)⁴⁸ develop TrPs.

Sartorius

Sartorius TrPs do not usually occur as a single-muscle syndrome, but rather occur in conjunction with TrP involvement of related muscles especially the iliopsoas, tensor fasciae latae, gluteus medius, gluteus minimus, piriformis, adductors, and quadriceps femoris muscles. Sartorius TrPs usually develop when TrPs in other muscles of its functional unit are present. Occasionally, these TrPs may be initiated by an acute overload strain in a twisting fall or during activities that require the foot to be planted while the leg and trunk are rotated in the opposite direction. More often, TrPs in this muscle are activated from overload that occurs when walking with an excessively pronated foot.

4.2. Associated Trigger Points

Associated TrPs can develop in the referred pain areas caused by TrPs.⁴⁹ Therefore, musculature in the referred pain areas for each muscle should also be considered. Limitation of knee flexion due to TrPs in any one vastus muscle encourages the development of TrPs in the other two vasti muscles as well as the rectus femoris muscle. Shortening of the hamstring muscles due to TrPs, especially in the biceps femoris muscle, overloads the antagonistic quadriceps femoris muscle; when the hamstring muscles have TrPs, usually the quadriceps femoris group will also have associated TrPs. The quadriceps femoris muscle group cannot recover until the hamstring TrPs are alleviated or hamstring length deficits are addressed. The patient may report pain referred from the quadriceps femoris TrPs, not from the hamstring TrPs that are the perpetuating factor. Quadriceps femoris TrPs are also perpetuated by overload resulting from TrPs in the soleus muscle.

Soleus TrPs restrict ankle dorsiflexion, and this limitation can overload the quadriceps femoris muscles, especially when lifting with a sound squat form. Trigger points in the gluteus minimus, tensor fasciae latae, iliopsoas, and adductor muscles can also cause associated TrPs in the quadriceps femoris and sartorius muscles as these muscles lie within their referred pain pattern zone.

Rectus Femoris

Muscles likely to develop TrPs in association with TrPs in the rectus femoris muscle include the three vasti and iliopsoas muscles. The vastus intermedius muscle is the muscle most likely to be involved, and the vastus medialis muscle is the least likely. Proximal TrPs in the sartorius muscle may also appear.

Vastus Intermedius

The rectus femoris and vastus lateralis muscles of the quadriceps femoris group are the agonists most likely also to be involved when the vastus intermedius muscle develops TrPs.

Vastus Medialis

The vastus medialis muscle is the member of the quadriceps femoris muscle group that is most likely to develop TrPs in the absence of TrPs in the other three heads. Such TrPs are often associated with a Morton foot structure that may also lead to the development of TrPs in the peroneus longus and gluteus medius muscles.

Trigger points in the vastus medialis muscle are often associated with TrPs in the hip adductor and tensor fasciae latae muscles.

Vastus Lateralis

Trigger points in the vastus lateralis muscle are often associated with TrPs in the gluteus medius or tensor fasciae latae muscles.

Sartorius

Sartorius TrPs are likely to be observed in conjunction with TrPs in other muscles of the functional unit, such as the rectus femoris and vastus medialis muscles. Sartorius TrPs may also be associated with TrPs in its antagonists, the hip adductor muscles.

4.3. Associated Pathology

Patellofemoral pain syndrome refers to anterior knee pain localized around the patella and has been otherwise identified in previous research as chondromalacia patellae, patellar tracking dysfunction, patellar tendinopathy, and anterior knee pain syndrome. This pathology is characterized by pain around or behind the patella that is aggravated by activities that increase flexion and/or loading of the knee. Patellofemoral pain syndrome is

commonly found in women, sedentary individuals, athletes, and young adults. There are several contributing factors that have been identified in patellofemoral pain syndrome, such as weak quadriceps femoris muscles (especially vastus medialis muscle), weak hip external rotators, hyperpronation or pes planus, increased Q-angle, and anteversion of the femoral head.^{50,51} Some literature identifies weakness and dysfunction of the quadriceps femoris muscles found in patellofemoral pain syndrome and relates these findings to the presence of TrPs that cause muscle inhibition and reduced strength and flexibility.^{52,53} With referred pain patterns similar to those experienced with patellofemoral pain syndrome, TrPs in the quadriceps femoris muscles, particularly those from the vastus medialis muscle, should also be considered as a potential source of the patient's pain and dysfunction.

The clinical features of patellar tendinopathy are pain with quadriceps femoris muscle loading and pain located at the inferior pole of the patella. A thorough clinical examination is required as patients can have a positive MRI indicating patellar tendinopathy and experience no pain. In light of these false positives, the clinical examination and patient reported symptoms are essential for making this diagnosis. This condition is best managed through close monitoring of knee extensor tendon loading, which has a very slow rehabilitation process and may be complicated by lower extremity biomechanical faults and muscle imbalances.⁵⁴

Knee osteoarthritis can lead to early changes in knee extensor muscle function possibly because of TrP activity in the quadriceps femoris muscle group. Kemnitz et al⁵⁵ investigated changes in thigh muscle strength prior to, and concurrent with, symptomatic and radiographic evidence of knee osteoarthritis progression in both men and women. The results of their study revealed a loss of both knee extensor and flexor strength concurrent with the progression of symptoms in women but not in men. This loss of strength that occurs with the progression of knee osteoarthritis seems specific to women.⁵⁵ In this population of patients, it is important to examine for the presence of TrPs in the quadriceps femoris, hip adductors, sartorius, hamstrings, gastrocnemius, soleus, and popliteus muscles. In fact, there is evidence to support the role of active TrPs in pain and disability related to knee osteoarthritis.⁵⁶

Lateral thigh pain characteristic of proximal vastus lateralis TrPs is commonly misdiagnosed as trochanteric bursitis because of referred pain and referred tenderness in the area of the greater trochanter. A similar pain pattern may also be caused by TrPs in the anterior portion of the gluteus minimus muscle or by TrPs in the tensor fasciae latae muscle. Further, the referred pain pattern of vastus lateralis muscle may mimic the pain of iliotibial band dysfunction that commonly occurs at the lateral knee.⁵⁷

Many patients with diabetes mellitus are taught to inject insulin into the lateral aspect or midline of the thigh, and patients can develop TrPs in the rectus femoris or vastus lateralis muscles where they inject themselves. Injection of insulin or other drugs in the region of a latent TrP can activate it. Quadriceps femoris myofibrosis can result from repeated intramuscular injections.⁵⁸

Sartorius

A sartorius TrP can be discovered serendipitously during injection or dry needling of a vastus medialis TrP deep to the sartorius muscle. When the needle encounters superficial sartorius TrPs, the patient reports a sharp or tingling pain felt diffusely over the adjacent thigh. The pain from sartorius TrPs referred to the knee may also be mistaken for pathology of that joint.³⁵

5. CORRECTIVE ACTIONS

In patients with quadriceps femoris TrPs, two guiding principles require attention: to avoid shortening and/or prolonged immobilization of the quadriceps femoris muscle group and to avoid overloading these muscles. Deep squatting should be prohibited for patients with quadriceps femoris TrPs. These maneuvers can cause serious overload of the quadriceps femoris muscles during the initial effort to rise unassisted. In the squatting position, the quadriceps femoris muscle has a poor mechanical advantage. A partial squat, or a partial knee-bend, is relatively safe and recommended.²⁰ Until TrPs and pain in the quadriceps femoris muscle group have resolved, it is important for the patient to avoid overloading these muscles when rising from a seated position. To accomplish this, the patient can use the upper limbs to assist by pushing against an armrest of the chair with one hand and against the distal thigh with the other hand; if no armrests are available, the hands push against both thighs distally. An alternate strategy for sit-to-stand is illustrated in Figure 58-13. The buttocks are first slid forward to the front of the seat. Then the body is turned sideways about 45° and the affected side foot is placed under the front edge of the seat and under the center of gravity of the body. The body is then lifted with the torso slightly flexed forward, so that the load is placed mainly on the gluteus maximus muscle of the forward leg. A push by the hands against the thighs assists the lift if the quadriceps femoris muscles are weak. To return to the seated position, the sequence would be reversed with the use of the hands on the thighs to lower to the chair.

Figure 58-13. Effective technique for rising and returning to a seated position to minimize stress on the quadriceps femoris muscles.

During sitting, one should avoid hip flexion with the knees extended, as occurs in many automobiles with tall seats or when resting feet on an ottoman or in a recliner. Automatic cruise control can be helpful by permitting more flexibility in positioning the right foot on the accelerator pedal during long car trips. Any long trip should be split up by a rest and stretch stop at least every hour. Conversely, habitually sitting with one foot flexed under the other buttock immobilizes the quadriceps femoris and sartorius muscles for long periods. When patients have TrPs in the vastus medialis muscle, they should avoid kneeling on the floor, but rather they should sit on a low bench or box.

To avoid maintaining the quadriceps femoris and sartorius muscles in a shortened position at night, it is important to avoid marked hip flexion with full knee flexion or extension. When in the side-lying position, a pillow should be placed between the knees.

This can reduce pressure on the area of referred tenderness over the knee as well as on the muscle itself when there are TrPs in the vastus medialis or sartorius muscles. This position also avoids putting the vastus lateralis muscle in a stretch position. Patients with vastus lateralis TrPs should avoid sleeping on their affected side because the resulting pressure can be enough to irritate or activate the TrPs. For sleeping on the back, a pillow may be placed under the entire leg, but placing a pillow under the knee alone should be avoided.

The self-pressure release of TrPs in the quadriceps femoris muscles can be achieved with the utilization of a TrP release tool, tennis ball, or a lacrosse ball. To perform TrP self-pressure release with a TrP tool, the patient is seated (Figure 58-14A to E). Finding the sensitive spot with the tool, the patient should apply light pressure (no more than 4/10 pain), hold for 15 to 30 seconds until pain reduces, and repeat five times. This technique can be repeated several times per day. When using a TrP release roller, the patient can work from the top part of the muscle and slowly roll down the muscle until a tender point is felt. When one is encountered, one should stop and slowly rock over the area or pause to wait for it to release prior to moving to the next area. Pressure should be mildly uncomfortable but not overly painful (Figure 58-14A, C, and E).

Figure 58-14. Trigger point self-pressure release with tools. A, Trigger point roller tool on the rectus femoris muscle. B, Lacrosse ball over the vastus intermedius muscle. C, Trigger point roller tool over the vastus medialis muscle. D, Lacrosse ball over the vastus medialis muscle. E, Trigger point roller tool over the vastus lateralis muscle. F, Lacrosse ball over the vastus lateralis muscle in side-lying.

A tennis or lacrosse ball can be used on the vastus lateralis muscle in side-lying with a pillow between the knees and the knees slightly flexed. The patient should roll the ball along the muscles until a tender spot is found, stopping and slowly rocking over the area or pausing to wait for it to release prior to moving to the next area. Pressure should be mildly uncomfortable but not overly painful (Figure 58-14F).

Self-pressure release for TrPs in the sartorius muscle can be performed with a TrP release tool (Figure 58-15A) or manually (Figure 58-15B). Finding the sensitive spot with the tool or thumbs, the patient should apply light pressure (no more than 4/10 pain), hold for 15 to 30 seconds until pain reduces, and repeat five times. This technique can be

repeated several times per day. Trigger points in the sartorius muscle are very superficial; therefore, only light pressure should be applied.

Figure 58-15. Trigger point self-pressure release of the sartorius muscle. A, Trigger point release tool. B, Self-manual release with thumb.

Stretching of the quadriceps femoris muscles may be performed while side-lying or while standing. Effective stretching for the rectus femoris muscle requires the patient to simultaneously extend the thigh while flexing the knee. The side-lying stretch is very useful for patients who are awakened at night by pain arising from rectus femoris TrPs. The patient can grasp the ankle area and pull the leg back and upward toward the buttock, gently stretching the muscle (Figure 58-16A). This stretch will typically allow the patient to return to sleep when awoken with anterior knee or thigh pain due to activation and perpetuation of quadriceps femoris TrPs.

Figure 58-16. Self-stretch of the quadriceps femoris muscle group. A, Side-lying self-stretch for the rectus femoris muscle. The unaffected leg should be placed in hip flexion to stabilize the pelvis. The patient passively brings the heel of the affected leg toward the buttock while maintaining and then increasing hip extension; the hand holds the ankle. B, Standing self-stretch for the quadriceps femoris muscle using a strap around the ankle to assist in maintaining an erect posture.

In the standing position, the patient can grasp the leg just above the ankle and passively bend the knee until a stretch is felt in the front of the thigh. A strap or sheet can be used if the patient is unable to reach the ankle. A chair should be placed in front so it can be used for balance (Figure 58-16B). This exercise emphasizes stretch first the vastus medialis muscle and then the vastus lateralis muscle. The standing self-stretch exercise is most effective if done in a pool of warm water that supports most of the body weight.

An ideal stretch for the sartorius muscle consists of hip adduction, extension, and internal rotation. This combination of movements can be achieved independently in a half-kneeling position, with the affected leg kneeling on the ground and the knee flexed to 90°. The hip should be biased to internal rotation and the patient then asked to shift the body weight into hip extension and adduction (Figure 58-17).

Figure 58-17. Self-stretch of the sartorius muscle in half-kneeling. A, Starting position. B, The hip and thigh are placed in internal rotation and adduction. The patient leans slightly on the affected knee. A stretch should be felt on the front side of the hip.

Adductor Longus, Adductor Brevis, Adductor Magnus, Pectineus, and Gracilis Muscles

“Obvious Problem Makers”

Beth Collier and Joseph M. Donnelly

1. INTRODUCTION

The adductor muscles lie in the medial thigh between the quadriceps femoris muscle group anteriorly and the hamstring muscles posteriorly. The most anterior of the three major adductor muscles is the adductor longus muscle; the adductor brevis muscle is intermediate, and the adductor magnus muscle is the most posterior. The pectineus muscle lies partly anterior and superior to the adductor brevis muscle. The gracilis muscle is the only one of this muscle group that crosses two joints—the hip and the knee. Trigger points (TrPs) in these muscles can present as medial thigh pain, groin pain, pelvic pain, and/or anterior-medial knee pain. Activities that cause the adductor muscles to be overstretched will activate TrPs in this muscle group in addition to activities such as hiking up hill, horseback riding, and gymnastics. Clinicians should consider TrPs in the adductor muscles when suspecting a diagnosis of hip osteoarthritis, inguinal or sports hernia, pubic bone stress injury (osteitis pubis), or a hip labral tear. In treating TrPs in the adductor muscle group, patients may find relief in performing self-pressure release, self-stretch of the involved muscle, and correcting faulty static and dynamic postures that contribute to overuse or shortening of these muscles.

2. ANATOMIC CONSIDERATIONS

Adductor Longus

The adductor longus muscle is the most superficial and prominent of the three major adductor muscles in the anteromedial aspect of the thigh. It attaches proximally by a narrow flat tendon to a relatively small spot on the outer surface of the pelvis between the symphysis pubis and the obturator foramen (Figure 59-1).¹ Its fibers angle inferolaterally and posteriorly to anchor to its insertion at the linea aspera on the middle third of the

femur. The fibers of the adductor longus muscle often blend with those of the vastus medialis muscle distally at their femoral attachment. The adductor longus muscle may unite superiorly with the pectineus muscle, in which case they completely cover the adductor brevis muscle. Superiorly, there appears to be secondary anatomic continuity between the proximal anterior fibers of the adductor longus tendon and the distal attachment of the rectus abdominis muscle as well as the capsule of the pubic symphysis.^{2,3}

Figure 59-1. Attachments of the right adductor muscle group, anterior view. The pectineus muscle is cut and largely removed (light red). The most superficial adductor muscle, the adductor longus muscle, is also light red. The adductor brevis muscle (medium red) extends distally only to the middle section of the femoral attachment of the adductor longus muscle and deep to it. The adductor magnus muscle (dark red) is the deepest (most posterior) and the largest of the adductor muscles.

Adductor Brevis

Viewed from the front, the adductor brevis muscle is partially covered by the pectineus muscle proximally and by the adductor longus muscle distally (Figure 59-2). It is sandwiched between these two adductor muscles anteriorly and the adductor magnus muscle posteriorly. The adductor brevis muscle attaches proximally to the inferior ramus of the pubis and distally to the linea aspera just posterolateral to the adductor longus muscle. Often, the adductor brevis muscle has multiple separate parts or may blend with the adductor magnus muscle.¹

Figure 59-2. Attachments of the right deep adductor muscles, anterior view. The overlying pectineus and adductor longus muscles have been cut and the ends reflected (light red). The adductor brevis muscle (medium red) lies anterior to the larger adductor magnus muscle (dark red). Attachments of the adductor muscles to the posterior aspect of the femur, not in view, are rendered schematically.

Adductor Magnus

The adductor magnus muscle is a large, triangular, and a deeply located muscle that has three parts: the most anterior and superior part, the middle part, and the posteriorly positioned, largely ischiocondylar, third part (Figure 59-3). The most superior of the three parts of the adductor magnus muscle, often known as the adductor minimus muscle, attaches to the inferior pubic ramus of the pelvis, anterior to the attachment of the middle part. Its fibers are the most horizontal as they angle toward its lateral attachment to the femur just inferior to the lesser trochanter of the femur and extending down along the linea aspera. The adductor minimus muscle usually constitutes its own muscle belly.¹

Figure 59-3. Attachments (posterior view) of the right adductor magnus muscle (red) showing the distinctions among its three parts.

The middle part is fan shaped and may overlap the adductor minimus muscle

posteriorly. If so, these intermediate fibers run more diagonally from the ischial ramus to the linea aspera to the tendinous (adductor) hiatus, through which the femoral vessels pass. An upward extension of this hiatus often clearly separates the middle and posterior parts of the adductor magnus muscle.

Proximally, the bulk of the third (most posterior or ischiocondylar) portion attaches to the ischial tuberosity and along the ischial ramus, largely posterior to the other two portions of the muscle. Distally, most of the ischiocondylar part inserts by a thick tendon to the adductor tubercle on the medial condyle of the femur. A few fibers attach to a fibrous expansion that completes the space between the adductor tubercle and the tendinous (adductor) hiatus.¹ This part of the adductor magnus muscle is similar to a hamstring muscle except that it does not cross the knee joint. The vastus medialis muscle attaches medially to all of the adductor muscles, thus covering the lower part of the adductor longus and adductor magnus muscles anteriorly.

The adductor canal (Hunter's canal) is an intermuscular tunnel spanning the distal two-thirds of the medial aspect of the thigh. The adductor hiatus marks the distal (outlet) of the adductor canal that begins proximally at the apex of the femoral triangle. The adductor canal is covered by a fascial layer deep to the sartorius muscle and is bounded anteriorly and laterally by the vastus medialis muscle and posteriorly by the adductor longus and adductor magnus muscles. The canal contains the femoral artery, femoral vein, and the saphenous nerve.¹

Pectineus

The pectineus muscle is a flat, quadrangular muscle that comprises most of the medial floor of the femoral triangle. It attaches proximally to the pectin pubis deep to the inguinal ligament and may be wholly or partially attached to the hip capsule. Its fibers descend posteromedially and then posterolaterally to eventually attach in a line from the lesser trochanter to the linea aspera on the femur. The pectineus muscle covers the proximal fibers of the adductor brevis muscle (Figure 59-4). The pectineus muscle may be bilaminar, consisting of a ventral and dorsal layer that may be separately innervated and may include the pectineus muscle in the anterior compartment of the thigh.¹

Figure 59-4. Attachments (medial view) of the right gracilis muscle (red).

Gracilis

The gracilis muscle is superficial and extends the length of the medial aspect of the thigh, crossing two joints, the hip, and the knee (Figure 59-5). It attaches proximally to the lower rim of the outside of the pelvis at the junction of the body of the pubis and the inferior pubic ramus as well as the adjoining part of the ischial ramus.¹ The gracilis muscle inserts

distal to the medial tibial condyle on the medial surface of the tibia. Here, its tendon joins the sartorius and semitendinosus tendons to form the pes anserinus. The pes anserine bursa lies between these tendons and the tibia. Some fibers from the distal tendon extend and are continuous with the deep fascia of the leg and can blend with the medial head of the gastrocnemius muscle.¹

Figure 59-5. Attachments of the right pectineus muscle (red), anterior and slightly medial

view. The muscle attaches proximally and medially to the superior ramus of the pubis, and distally it inserts into the posterior surface of the femur medial to its midline.

2.1. Innervation and Vascularization

Adductor Longus

The adductor longus muscle is supplied by the anterior division of the obturator nerve from the L2, L3, and L4 spinal nerves. Its vascular supply consists of the “artery to the adductors” of the profunda artery. Additionally, the proximal portion receives a supply from the medial circumflex femoral artery and a distal supply from the femoral artery.¹

Adductor Brevis

The adductor brevis muscle is innervated by the obturator nerve from the L2 and L3 spinal nerves. Its vascular supply is from the obturator artery at the deep surface, the profunda femoris artery distally, and the “artery to the adductors” more proximally. There may be an additional proximal supply from the medial circumflex femoral artery.¹

Adductor Magnus

The superior (adductor minimus muscle) and middle parts of the adductor magnus muscle are supplied by the anterior division of the obturator nerve, and the ischiocondylar part is supplied by the tibial division of the sciatic nerve, both from the L2, L3, and L4 spinal nerves.¹ The vascular supply of the adductor magnus muscle is also divided into anterior and posterior aspects. Anteriorly, the obturator, profunda femoris, and femoral arteries all contribute to the primary supply coming directly from the distal part of the profunda femoris artery. There may also be vascular contributions to the distal aspect of the adductor magnus muscle from the femoral and descending genicular arteries. The medial circumflex femoral, the first and second perforating, and the popliteal arteries supply the adductor magnus muscle posteriorly.¹

Pectineus

The pectineus muscle is innervated by the femoral nerve from L2 and L3 and the accessory obturator nerve, L3. If the pectineus muscle is bilaminar, the dorsal layer may be innervated by the obturator nerve. The pectineus receives its main vascular supply from the medial circumflex femoral artery. There may be minor vascularization from the femoral and obturator arteries.¹

Gracilis

The anterior division of the obturator nerve also supplies the gracilis muscle, but from only the L2 and L3 nerves. The gracilis muscle receives its main vascular supply from the “artery

to the adductors” which is a branch of the profunda femoris artery and a minor proximal supply from the medial circumflex femoral artery.¹

2.2. Function

The adductor muscle group has a primary action of adduction of the hip.¹ The adductor longus and pectineus muscles assist in flexion of the hip, whereas the posterior ischiocondylar portion of the adductor magnus muscle acts as an extensor of the hip.¹ The gracilis muscle is the only muscle of the adductor group to cross both the hip and knee joints. Although its primary action is hip adduction, it also assists in flexion of the knee if the knee is extended, and assists in internal rotation of the tibia when the knee is flexed.^{1,4} All of the adductor muscles are active with either knee flexion or extension, which suggests that they also act as stabilizers. Additionally, the adductors assist in internal rotation of the hip; however, this function is controversial for the pectineus muscle. There has been general disagreement as to whether the pectineus muscle rotates the thigh internally or externally. Based on its anatomy, it could be concluded that the pectineus muscle serves as an external rotator in anatomic position, but may become more involved in internal rotation as the hip is flexed in a more functional position.⁵

The adductor muscle group likely plays several roles during normal gait. According to Ranchos Los Amigos⁶ gait analysis, the adductor longus muscle becomes active around the time of terminal stance and it remains active through pre-swing, initial swing, and the early portion of mid-swing. Its peak action occurs in the latter portion of the terminal stance and is thought to play a significant role in flexion of the femur in transition to pre-swing.^{7,8} The gracilis muscle also peaks in action during initial swing as the limb continues to flex and advance through swing and remains active until loading response. During the earliest part of the stance phase, the gracilis muscle may be functioning to assist the other pes anserinus muscles and the vastus medialis muscle in controlling the valgus angulation of the knee as body weight is shifted onto that foot.⁹ The adductor magnus muscle is active nearly continuously throughout the gait cycle, whereas the ischiocondylar part shows biphasic activity characteristic of the hamstring muscles. During loading response, the adductor magnus muscle peaks in action to assist the hamstrings and gluteus maximus muscles in resisting a flexion torque through the hip joint from ground reaction forces.^{7,8} Further, the anterior rotation of the contralateral pelvis in the swing phase results in a relative internal rotation at the hip of the stance limb. The ischiocondylar portion of the adductor magnus muscle plays a role in the eccentric control of that relative internal rotation of the stance limb.¹⁰ Also, as weight shifts toward and across the midline to the other foot, the adductor longus muscle restrains abduction, controlling the weight shift and adding stability.⁹ The adductor magnus muscle becomes active during ascent of stairs but is inactive during descent.⁸ A patient, who had the entire adductor longus muscle excised, fully compensated by hypertrophy of the remaining adductor muscles and showed no loss of strength or apparent impairment of ambulation on level surfaces, stairs, or jumping.¹¹ Removal of the adductor longus, adductor brevis and adductor magnus muscles resulted in a 70% loss of

adduction strength but only slight or moderate impairment of walking, stair climbing, or jumping.¹¹

With increasing speed of ambulation, the intensity and duration of the peak of electromyography (EMG) activity in the adductor magnus muscle at heel-strike increased,⁷ and activity appeared earlier in the cycle.⁸ Leaning forward while walking markedly increased its EMG activity.⁷ During the more strenuous activities of jogging, running, and sprinting, the adductor longus muscle did not change its basic (walking) pattern of activity but extended its duration a bit.¹²

Electromyographic data of common exercises targeting adductor muscles reveal that the adductor longus muscle demonstrates peak percentage of maximal volitional isometric contraction with side-lying hip adduction, ball squeezes,¹³ and standing adduction with a resistance band.¹⁴ Broer and Houtz¹⁵ found that during right-handed sports activities the EMG activity of the right gracilis muscle, recorded from surface electrodes, is always at least equal to, and usually greater than, that of the contralateral left muscle. The greatest gracilis EMG activity is seen during jumping for a one-foot volleyball spike or for a basketball layup. The activities causing the next greatest EMG response of the gracilis muscle are the tennis serve and batting a ball. These gracilis muscle recordings by surface electrodes may have included considerable adductor magnus EMG activity.

2.3. Functional Unit

The functional unit to which a muscle belongs includes the muscles that reinforce and counter its actions as well as the joints that the muscle crosses. The interdependence of these structures is functionally reflected in the organization and neural connections of the sensory motor cortex. The functional unit is emphasized because the presence of a TrP in one muscle of the unit increases the likelihood that the other muscles of the unit will also develop TrPs. When inactivating TrPs in a muscle, one must be concerned about TrPs that may develop in muscles that are functionally interdependent. Box 59-1 grossly represents the functional unit of the adductor muscles.¹⁶

Box 59-1 Functional unit of the adductor muscles

Action	Synergists	Antagonists
Hip adduction	Quadratus femoris Gluteus maximus (lower portion)	Gluteus medius Gluteus minimus Tensor fascia latae
Hip internal rotation (adductor longus, brevis, magnus)	Gluteus medius (anterior fibers) Tensor fascia latae Semimembranosus Semitendinosus	Gluteus medius (posterior fibers) Gluteus maximus Iliopsoas Piriformis

		Deep hip external rotators
Hip flexion (adductor longus, pectineus)	Adductor longus Pectineus Iliopsoas	Gluteus maximus Hamstrings Adductor magnus-ischiocondylar portion
Hip extension (Adductor magnus-ischiocondylar portion)	Gluteus maximus Hamstrings	Adductor longus Pectineus Psoas major and minor Iliacus
Knee flexion (Gracilis, Adductor magnus)	Hamstrings Gastrocnemius	Quadriceps

The middle part of the adductor magnus muscle and the short head of the biceps femoris muscle have the same fiber direction and a contiguous attachment on the linea aspera along the posterior aspect of the femur. Together, they give the appearance of one muscle except for the dividing line of their common attachment to the femur. As a result, when these two muscles contract at the same time, they function like a single hamstring muscle because of the proximal attachment of the adductor magnus muscle to the ischial tuberosity and the distal attachment of the short head of the biceps femoris muscle to the head of the fibula with an expansion to the lateral condyle of the tibia. They have the advantage of attaching to the femur so that each end of this composite “two-joint” structure can exert force independent of the other. This hip-extensor/knee-flexor function is synergistic with that of the long head of the biceps femoris, semitendinosus, and semimembranosus muscles. During flexion at the knee, the gracilis muscle assists the three hamstring muscles when the knee is straight. It also assists the semimembranosus, semitendinosus, and popliteus muscles with internal rotation of the leg at the knee.

3. CLINICAL PRESENTATION

3.1. Referred Pain Pattern

Adductor Longus and Adductor Brevis

There appears to be no distinction between the patterns of pain and tenderness referred from TrPs in the adductor longus and adductor brevis muscles. These TrPs refer pain both proximally and distally (Figure 59-6). The proximal pattern is consistently present; pain is experienced deep in, and proximal to, the groin and in the anteromedial portion of the upper thigh. Trigger point involvement of the adductor longus muscle is perhaps the most common cause of groin pain.^{17,18} Referral of pain from these TrPs distally, focuses on the upper medial part of the knee with a secondary pattern that extends inferiorly along the tibia.¹⁷⁻¹⁹ The TrPs located in the more proximal part of the muscles usually refer pain

superiorly to the groin, and those located in the more distal part of the muscles tend to refer pain inferiorly to the knee and the tibia.¹⁷

Figure 59-6. Anterior view of the right adductor longus and adductor brevis muscles and the composite pain pattern (dark red) referred from TrPs in these two muscles (light red). The essential pain pattern is solid red; red stippling indicates occasional extension to a spillover pain pattern.

Kelly^{20, 21} reported a tender spot in the adductor longus muscle, near its proximal attachment, as referring pain to the knee and causing stiffness. Long²² characterized

adductor longus syndrome caused by TrPs as producing pain in the medial thigh near the groin, in the vicinity of the medial portion of the inguinal ligament, and superficially along the medial or anterior thigh to the knee.

Kellgren²³ described the pain referred from the adductor longus muscle when it was injected with 0.1 mL of 6% saline solution. Referred pain was noted at the anterior proximal thigh and medial knee but did not extend below the knee.

In children,²⁴ the essential referred pain from adductor longus TrPs was illustrated distal to the inguinal ligament; its secondary pattern covered the anteromedial thigh, medial knee, and upper two-thirds of the medial aspect of the leg. Fine²⁵ reported inguinal pain in a 10-year-old boy caused by TrPs in the adductors muscles of the thigh.

Adductor Magnus

The relatively common TrP location in the mid-muscle belly of the adductor magnus muscle refers pain superiorly into the groin below the inguinal ligament and also inferiorly over the anteromedial aspect of the thigh to the knee (Figure 59-7). This groin pain is described as deep, almost as if it might be in the pelvis, but the patient is unable to identify pain in any specific pelvic structure.

Figure 59-7. Pain pattern (dark red) referred from TrPs in the right adductor magnus muscle (light red). The essential pain pattern is solid red; red stippling locates occasional extension of the referred pain in a spillover pattern. A, Anterior view of the referred pain pattern from

the midhigh region. B, Mid-sagittal view showing the intrapelvic pain pattern. These TrPs are found in the most proximal portion of the ischiocondylar part of the adductor magnus muscle medial to, or deep to, the gluteus maximus muscle. C, Adductor muscles on the right from behind.

Pain referred from TrPs in the more proximal region of the adductor magnus muscle is usually described as a generalized internal pelvic pain but may be identified as including the pubic bone, vagina, rectum, or (less often) the bladder. The pain may also be described as shooting up inside the pelvis and exploding like a firecracker.

Pectineus

Trigger points in the pectineus muscle produce deep-seated aching pain in the groin immediately distal to the inguinal ligament. The pain may also cover the upper part of the anteromedial aspect of the thigh. The deep groin pain may extend medially to the region where the adductor magnus muscle attaches to the pelvis (Figure 59-8).

Figure 59-8. Medial view of the composite pain pattern (dark red) referred from TrPs in the right gracilis muscle (light red). Solid red denotes the essential pain pattern, and red stippling indicates the occasional spillover pain pattern.

Gracilis

The TrPs in the gracilis muscle produce a local, hot, stinging, superficial pain that travels along the medial aspect of the thigh (Figure 59-9).

Figure 59-9. Pattern of pain (bright red) referred from a TrP in the right pectineus muscle (darker red), seen from in front and slightly from the medial side. The *essential* referred pain pattern is solid red, and the occasional spillover pattern is *stippled*.

3.2. Symptoms

Adductor Longus and Adductor Brevis

Patients with TrPs in these two adductor muscles are frequently aware of the pain in the

groin and medial thigh only during vigorous activity or muscular overload, rather than at rest. The reported pain is typically increased by weight bearing and by sudden twists of the hip.²² The patients usually do not recognize that abduction of the thigh is severely restricted, but occasionally, they note restricted external rotation of the thigh.

Adductor Magnus

Patients with TrPs in the proximal end of the adductor magnus muscle may report intrapelvic pain that may be specifically localized to the vagina, penis, or rectum or may be diffuse and described only as somewhere “deep inside.” In some patients, symptoms occur only during sexual intercourse. When TrPs along the mid-muscle belly are active, the patient may report primarily of anteromedial thigh and groin pain.

Patients with adductor magnus TrPs frequently report having difficulty positioning the lower extremity comfortably at night. They usually prefer to lie on the opposite side with a pillow placed between the knees and legs.

Pectineus

Patients with pectineus TrPs report pain locally in the region of the muscle and may also be aware of limited abduction at the hip, especially when seated in the lotus or criss-cross position. Among the muscles that act as adductors, TrPs in the pectineus muscle restrict the range of abduction the least. Clinically, TrPs in the pectineus muscle may present with limited hip flexion range of motion with a springy or muscle guarding end feel.

Gracilis

Patients with active TrPs in the gracilis muscle typically present with a chief report of a superficial, hot, stinging pain in the medial thigh. It may be constant at rest, and changing position or stretching typically does not reduce the pain. Walking, however, tends to relieve it.

3.3. Patient Examination

After a thorough subjective examination the clinician should make a detailed drawing representing the pain pattern that the patient described. This depiction will assist in planning the physical examination and can be useful in monitoring the progression of the patient as symptoms improve or change. The type, quality, and location of the pain should be carefully assessed, and the utilization of standardized outcome tools is imperative when examining patients with lower extremity dysfunctions.

A physical examination should be conducted to rule out lumbar, iliosacral, hip, and knee joint dysfunctions. This includes range-of-motion testing of the lumbar spine, hip, and knee; passive accessory motion testing of the hip, iliosacral joint, knee, and/or lumbar spine; strength testing of the adductor muscles and other hip muscles; and any appropriate neurologic testing or orthopedic special tests. A careful assessment should be made to rule

out referral into the medial thigh from other muscles, joints, or neural tissues that can refer to the same region.

It is important to perform a postural examination in standing to identify a structural or functional scoliosis, the presence of a hemipelvis, iliac upslip, anterior innominate rotation or pubic symphysis dysfunction,²⁶ and leg length discrepancy. A leg length discrepancy will be identified as a frontal plane asymmetry of the pelvis with one side of the pelvis elevated and the opposite side depressed. This pelvic deviation could cause TrPs in the adductor muscle on either or both sides from muscle overload. Functional activities such as sit to stand, single leg stance, and double- and single-leg squat (see Figure 55-3A) should be examined. The clinician should take note of any frontal plane deviations noted in the pelvis, hip and/or knee, and any excessive transverse plane motion at the ankle and foot (see Figure 55-3B). A deviation in the frontal plane as described may lead to overload in the adductor muscles because of an increase in the adductor moment secondary to hip abductor muscle weakness. This relative adducted position of the femur can also lead to compressive loading of the greater trochanter of the femur because of tensile loading of the gluteal muscles and may lead to abnormal compressive loading of the trochanteric bursa. The presence of hip adductor TrPs or length and strength deficits may lead to inhibition/weakness of the hip abductor muscles. The hip adductors should be examined carefully for length and strength deficits as it is vital that the hip adductors and abductors work together during weight-bearing activities such as gait to stabilize the lower extremity.²⁷

Because of regional interdependence of the hip and lumbosacral spine and hip and knee, specific testing should be carried out to identify interactive impairments. Patients with adductor TrPs typically do not exhibit an abnormal gait pattern unless the pain from the TrPs is so severe that it causes an antalgic gait with a reduced duration of stance phase on the affected side. However, observed gait deviations could contribute to the activation and perpetuation of TrPs in the adductor muscles.

Trigger points in the adductor longus and adductor brevis muscles restrict abduction of the thigh to a greater degree than do TrPs in the pectineus muscle. Trigger points in the adductor magnus muscle can also restrict flexion of the hip, especially in the abducted position. These restrictions are readily tested in a Flexion Abduction External Rotation test position. With this technique, the thigh is flexed, abducted, and somewhat externally rotated, which simultaneously tests all three of the major adductors for shortening (Figure 59-10). Moving the heel of the limb being tested farther proximally against the other thigh will cause pain and be limited by the presence of TrPs in the vastus medialis muscle, which is prone to involvement with the adductor muscle group.

Figure 59-10. Flexion Abduction External Rotation test to assess muscle length of the adductor muscle group. The clinician's hand stabilizes the contralateral pelvis at the anterior superior iliac spine (ASIS) while gently pressing the knee down toward the table. The thigh can be further flexed by moving the foot up the thigh to allow for testing of the ischiocondylar part of the adductor magnus muscle.

An alternate procedure first tests the stretch range of the ischiocondylar part of the adductor magnus muscle by partially flexing the thigh of the supine patient and then tests the stretch range of all three adductor muscles by further abduction of the flexed thigh. Gradual lowering of the abducted thigh toward the floor reveals tightness of the adductor longus, adductor brevis, and gracilis muscles (Figure 59-11).

Figure 59-11. Adductor muscle length testing. A, Adductor muscle length testing of the adductor longus, adductor brevis, and adductor magnus muscles. B, The gracilis muscle length is assessed with knee extended.

Tenderness of the tendinous attachment of the adductor magnus muscle is elicited by pressure on the posteromedial aspect of the medial femoral condyle. Tenderness is usually present there when the adductor magnus muscle has TrPs. Pectineus TrPs primarily cause pain with little weakness or restriction of motion. Patients with active TrPs in the pectineus muscle may present with limited combined hip flexion and adduction range of motion with groin pain reported at the end range.

3.4. Trigger Point Examination

Adductor Longus and Adductor Brevis

To examine for TrPs in the adductor longus and adductor brevis muscles, the patient is placed in a supine position with the thigh and knee partially flexed and the thigh abducted to place the adductor longus muscle on moderate stretch. The one-third of the adductor longus muscle that is closest to the pelvis is best examined by cross-fiber pincer palpation. The distal two-thirds is usually best examined for TrPs by cross-fiber flat palpation against the underlying femur (Figure 59-12A).

Figure 59-12. Palpation for TrPs in the adductor muscles. A, Cross-fiber pincer palpation of the adductor longus and adductor brevis muscles. B, Cross-fiber pincer palpation of the proximal adductor magnus muscle. C, Cross-fiber flat palpation of the distal adductor magnus muscle. D, Cross-fiber flat palpation of the gracilis muscle. E, Cross-fiber flat palpation of the pectineus muscle.

Because the adductor brevis muscle underlies the adductor longus muscle, it is reached only by deep cross-fiber flat palpation or by needle penetration, and its TrPs are located primarily by the patient's pain referral pattern and symptoms. The adductor longus muscle rarely produces noteworthy local twitch responses to palpation, and the adductor brevis muscle is practically inaccessible to snapping palpation; however, needle penetration into TrPs will elicit a local twitch response.

Adductor Magnus

Posteriorly, in the proximal third of the thigh, the adductor magnus muscle is covered by the gluteus maximus, biceps femoris, semitendinosus, and semimembranosus muscles. Only in the proximal portion of the posteromedial aspect of the thigh is a triangle of the muscle accessible to subcutaneous palpation. This narrow triangle is bordered by the ischial tuberosity and pubis proximally, the semimembranosus and semitendinosus muscles behind, and the gracilis muscle anteriorly. This “window of palpation” may extend the length of the upper one-third of the thigh and may be several centimeters (an inch or more) across at its widest, just below the pelvis. The gracilis muscle covers the ischiocondylar part of the adductor magnus muscle over most of its length. Therefore, TrPs in the proximal aspect of the most medial portion of the ischiocondylar part of the adductor magnus muscle are usually best located by cross-fiber pincer palpation that reaches around and deep to the gracilis muscle (Figure 59-12B). Trigger points in the diagonal fibers (middle portion) of the adductor magnus muscle in the mid-muscle belly region and in the proximal aspect in some patients can be reached only by cross-fiber flat palpation posterior

to the gracilis muscle (Figure 59-12C and D). Each TrP region can produce a distinctive referred pain pattern. Tenderness may be caused by TrPs in the adductor magnus muscle or by TrPs in the overlying musculature, especially the gracilis muscle. Because so much of the adductor magnus muscle lies deep to other sizeable muscles, it is often difficult to detect and locate its TrPs accurately, and hence, they are readily overlooked.

Pectineus

With the patient in a supine hook-lying position, the proximal aspect of the pectineus muscle can be palpated just lateral to the pubic tubercle. Taut bands may be palpable when strumming parallel to the pubic ramus just distal to the muscle's insertion (Figure 59-12E). The distal end of the muscle is deep to the femoral neurovascular bundle and difficult to palpate; however, it is readily accessible by needle penetration.

Gracilis

Trigger points in the gracilis muscle may be located by cross-fiber pincer palpation in patients who are thin or have relatively loose skin, but examination often requires superficial cross-fiber flat palpation (Figure 59-12D).

4. DIFFERENTIAL DIAGNOSIS

4.1. Activation and Perpetuation of Trigger Points

A posture or activity that activates a TrP, if not corrected, can also perpetuate it. In any part of the adductor muscles, TrPs may be activated by unaccustomed eccentric loading, eccentric exercise in an unconditioned muscle, or maximal or submaximal concentric loading.²⁸ Trigger points may also be activated or aggravated when the muscle is placed in a shortened and/or lengthened position for an extended period of time.

Trigger points in the adductor muscle group are likely to be activated by sudden overload, as when someone slips on ice and resists spreading the legs apart while trying to recover balance. Adductor TrPs may also be activated by osteoarthritis of the hip or after hip surgery.

Adductor magnus TrPs are often activated by skiing or by taking a long bicycle trip. Running uphill or downhill may also perpetuate adductor TrPs. Patients with TrPs from the larger adductor muscles are more likely to identify the onset of symptoms with a specific event than are patients with pectineus TrPs. Adductor TrPs may also be perpetuated by sitting in a fixed position while riding in a car or plane or while sitting for long periods in a chair with the hips acutely flexed and one thigh or leg crossed over the opposite knee.

4.2. Associated Trigger Points

Associated TrPs can develop in the referred pain areas caused by TrPs.²⁹ Therefore, musculature in the referred pain areas for each muscle should also be considered. Trigger

points in the adductor longus and adductor brevis muscles may be associated with TrPs in the adductor magnus muscle and occasionally with TrPs in the pectineus muscle. Involvement of the adductor longus and adductor magnus muscles may be associated with TrPs in the most medial fibers of the vastus medialis muscle. Anatomically, they are literally fused. The fascial coverings of these muscles form a thick bridge between them above the knee that helps establish a medial pull on the patella that counters the lateral pull of the vastus lateralis muscle.

Pectineus TrPs are frequently discovered in association with TrPs in the iliopsoas muscle group, the three adductors, and the gracilis muscles. If the pectineus muscle has TrPs, the other adductor muscles almost always will as well; therefore, they need to be addressed first. When these associated TrPs have been inactivated, a search for the cause of the residual tenderness and deep groin pain reveals the pectineus muscle TrPs. For this reason, it is important to always check for residual pain-producing TrPs in the pectineus muscle after eliminating any TrPs in the iliopsoas and adductor muscles.

Surprisingly, TrPs in the gracilis muscle are rarely associated with TrPs in the primary adductors, but these may be associated with TrPs in the lower end of the sartorius muscle.

4.3. Associated Pathology

In patients with persistent chronic pain, one must expect that multiple etiologies are responsible. Ekberg and associates³⁰ employed a multidisciplinary approach to manage long-standing unexplained groin pain in 21 male athletes. The diagnostic medical team evaluated the athletes for inguinal hernia, neuralgia, adductor tenoperiostitis, symphysisitis, and prostatitis. The evaluation included radiographs of the pelvis and radioisotope studies of the pubic symphysis. Only two patients had just one condition, namely, symphysisitis. Ten patients had two conditions, six patients had three conditions, and three patients had four conditions. The authors did not explore the additional possibility of myofascial pain caused by TrPs. Holmich³¹ proposed diagnostic categorization of groin pain based on five clinical entities: adductor-related pain, iliopsoas-related pain, abdominal wall-related/hernia, hip joint pathology, and pubic bone stress injury (formerly osteitis pubis).

Typical signs of adductor-related pain include pain with palpation of adductor muscle origin and pain with passive stretch.³²

Pain of iliopsoas muscle origin is typically provoked with palpation of the muscle as well as resisted hip flexion. During a modified Thomas test, pain will likely be reproduced during a hip extension stretch.³² In a review of 894 patient cases, iliopsoas pathology was most commonly seen in female patients. Women with ligamentous laxity tend to demonstrate excessive use of and myofascial tightness in the iliopsoas muscle.³² Iliopsoas muscle pain is also prevalent among runners. The iliopsoas muscle plays an important role in running as a hip flexor and, as such, is at risk for being overused.³³

A sports hernia is a deficiency of the posterior wall of the inguinal canal secondary to dysfunction of the conjoint tendon. Patients typically report pain in the lower abdomen or groin.³⁴ Pain is typically exacerbated with palpation of the rectus abdominis muscle and the

conjoint tendon. Pain is further provoked during a resisted situp. A femoral or inguinal hernia may be visible upon inspection or display a cough impulse.³²

Intra-articular dysfunction is characterized by pain and restriction reproduced during hip range of motion.³² Multiple sources^{22,35} warn that the referred pain from adductor longus TrPs may be mistaken for the pain of osteoarthritis of the hip. It is easy to attribute all the pain to osteoarthritis and not consider the potential role of hip adductor TrPs. Inactivating the adductor TrPs provides satisfactory pain relief to some patients with osteoarthritis of the hip joint.¹⁷ Clinically, the pain of osteoarthritis is usually deeper in the groin and is more likely to be referred laterally rather than medially.²²

The concept that part of the disability associated with osteoarthritis of the hip is of muscular origin was substantiated by a study³⁶ in which patients with osteoarthritis of the hip were given stretching exercises for the adductor musculature. The mean increase of 8.3° in the range of hip abduction and the increase in the cross-sectional area of type 1 and type 2 fibers in the adductor muscles was significant.³⁶

Rold and Rold³⁷ emphasized that pubic stress symphysitis of athletes must be distinguished from adductor tendon avulsion at the pelvis, from fractures of the pubic or ischial rami, and from local septic conditions. Pubic stress symphysitis usually has a gradual insidious onset of groin or lower abdominal pain with acute exacerbation during stressful sports activity.³⁸ Examination reveals focal tenderness of the pubic symphysis bilaterally and pain on abduction and extension of the thighs.^{37,39} Symphysitis sometimes is accompanied by adductor TrPs. In this situation, abduction and extension are more restricted on the side of the TrPs. The most anterior adductor muscles, the pectineus and adductor longus muscles, are the most likely to be involved. This situation is understandable because these two adductor muscles have the most effective leverage for putting asymmetric stress on the pubic symphysis. Radiographic evidence of sclerosis and irregularity of the pubic bones at the symphysis, as well as scintigraphic evidence of increased radionuclide uptake at the symphysis, are confirmatory findings.^{37,40} The tendency for the pelvis to seesaw up and down is aggravated by tension of the adductor muscles.⁴⁰ Further, the tension of the adductor muscles may lead to disruption of the fibrocartilaginous symphyseal disc.⁴¹

The obturator and genitofemoral nerves may cause pain or tingling in the groin or in the medial thigh when they become entrapped. The genitofemoral nerve may be involved by TrPs or shortness in the iliopsoas muscle group.

About half of the patients who have an obturator hernia (usually elderly women) develop symptoms of entrapment of the obturator nerve including pain and paresthesias down the medial surface of the thigh to the knee (Howship-Romberg sign).⁴²⁻⁴⁶ Extension of the thigh increases the pain,⁴³ and the adductor deep tendon reflex is diminished or absent. (This reflex is elicited with a reflex hammer by tapping a finger placed across the musculotendinous junction of the adductor magnus muscle about 5 cm [2 in] above the medial epicondyle).⁴²

Entrapment of the genitofemoral nerve is often caused by excessively tight clothing over

the inguinal ligament. Patients with entrapment of this nerve experience pain and/or numbness in an elliptic area on the anterior aspect of the thigh immediately below the middle of the inguinal ligament. This area also shows reduced perception of pinprick and touch. Appendectomy, psoas muscle infection, and local trauma are predisposing factors.⁴⁷

Although tension due to TrPs in the adductor longus, adductor brevis, and gracilis muscles are not known to cause nerve entrapment, TrPs in the adductor magnus muscle can lead to compression of vascular structures. A taut adductor magnus muscle can compress the femoral vessels at their exit through the adductor (tendinous) hiatus. Sometimes, the middle and posterior parts of the adductor magnus muscle are fused, which greatly reduces the size of the hiatus. A patient who lacks a palpable dorsalis pedis pulse can experience a return of the pulse immediately after inactivation of a TrP in the adductor magnus muscle. This unusual result may be due to an atypical anatomic structure that facilitated compression of the femoral artery combined with a taut band of adductor magnus fibers at the adductor hiatus.

Three cases of thrombosis of the superficial femoral artery at the outlet of the adductor canal were reported in association with athletic activities.⁴⁸ The arterial injury and thrombosis were attributed in two cases to a scissor-like compression by the vastus medialis and adductor magnus tendons at this location and, in another case, to compression by a constricting tendinous band extending across the femoral artery from the adductor magnus muscle to the vastus medialis tendon at the level of the adductor canal outlet. These observations suggest that, in some adductor canal configurations, taut-band tension on the tendons forming the margins of the canal might cause at least venous compression at this site.

When adductor longus TrPs develop bilaterally, as may occur with strenuous horseback riding, the symmetric distribution of referred pain can simulate a mid-lumbar spinal dysfunction.¹⁸

5. CORRECTIVE ACTIONS

Patients with TrPs in the adductor muscles should limit the time they spend sitting with one knee crossed over the other. If patients feel the need to cross their legs, they should opt for crossing the affected leg's ankle over the other ankle. Crossing the legs at the ankle will leave the thigh and adductor muscles in a better resting position. Taking intermittent breaks during long periods of sitting to walk and stretch are also encouraged. For all the hip adductor muscles, it is important to avoid leaving the muscle in a shortened position for a long period of time. This shortened position is avoided when the patient is sleeping on one side by placing a pillow between the knees and legs. Excessive prolonged hip flexion should also be avoided.

Self-treatment of the adductor muscles can be achieved with the utilization of a TrP self-pressure release tool or with manual (hands-on) release. To perform TrP self-pressure release with a tool or manually, the patient is seated or side-lying (Figure 59-13A to D). Finding the sensitive spot with the tool, by pincer grasp, or with digital pressure, the

patient applies light force (no more than 4/10 pain), holds for 15 to 30 seconds until pain reduces, and repeats five times. This release can be repeated several times per day. Pressure should be mildly uncomfortable but not overly painful.

Figure 59-13. Self-pressure release of TrPs in the adductor muscles. A, TrP release tool for TrPs in the adductor longus and adductor brevis muscles. B, Manual release using pincer grasp. C, Using a small tool. D, Side-lying manual release of the gracilis and adductor magnus muscles.

Patients with a strong upper body can utilize a foam roller along the adductor muscles. In a side-lying position, the bottom leg should be placed in maximal hip flexion so that the medial aspect of the affected leg can rest on the foam roller. The patient can roll along the foam roller until identifying the tender TrP, at which point the patient should hold constant isolated pressure for up to 90 seconds or until the tenderness reduces. For patients who are unable to attain this position, a similar technique may be utilized in sitting using a hand-held roller.

Following pressure release, a self-stretch of the adductor muscles should be performed as long as the stretch does not increase symptoms. A clinician should instruct the patient in a home-stretch program to maintain full adductor muscle length.

The patient can perform bent-knee fallouts with post-isometric relaxation to reduce the activity of TrPs in the adductor muscles. The patient lies on the back with the hips and knees flexed (Figure 59-14). For TrPs that are irritable, the patient supports the affected leg with the hand on the outside of the knee (Figure 59-14A). The patient keeps the opposite lower extremity in this position while slowly lowering the affected knee down toward the bed until a slight stretch is felt on the inner thigh (Figure 59-14B). Once the stretch is felt, the patient can take a deep breath that causes a slight contraction in the adductor muscles, holding the breath for 6 to 10 seconds and then breathing slowly out. At the end of the exhalation, the patient relaxes the adductor muscle until a stretch is felt again on the inner thigh. This cycle can be repeated three to five times as long as there is no increase in pain or symptoms. To enhance the stretch and achieve balance in the adductor muscle length, this can be performed on both sides at the same time (Figure 59-14C).

Figure 59-14. Bent-knee fall out. A, Starting position. B, With manual support to control the stretch in the adductor muscles for irritable TrPs. C, Bilateral bent-knee fall out to increase stretch and to maintain symmetry between both hip adductor muscle groups.

Patients can also stretch the adductor muscles by sitting with their back against a wall with both hips flexed, externally rotated, and abducted using a pillow under the outside of

the knees and thighs to support this position (Figure 59-15A). Patients can also be instructed in a contract-relax technique to stretch the adductor muscles (Figure 59-15B). Möller and associates⁴⁹ found that the contract-relax adductor muscle stretch was one of the most effective (Figure 59-15B). The stretch techniques described for the adductor muscle group do not stretch the gracilis muscle because bending the knee shortens the gracilis muscle. A stretch of the gracilis muscle can be accomplished with the assistance of a stretch strap (Figure 59-15C).

Figure 59-15. Self-stretch of the adductor muscles. A, Gravity assisted stretch of the adductors if TrPs are irritable. B, Gentle overpressure to enhance the stretch. C, Yoga strap–assisted stretch for stretch of the gracilis muscle.

Hamstring Muscles: Semitendinosus, Semimembranosus, and Biceps Femoris

“Chair Seat Victims”

Beth Collier

1. INTRODUCTION

The muscles of the posterior compartment of the thigh are informally termed the “hamstrings” when discussed as a group. Individually, this group includes the true hamstring muscles, the semitendinosus, semimembranosus, and the long head of the biceps femoris muscles. The true hamstring muscles cross the hip and knee joint and contribute to both hip extension and knee flexion. The short head of the biceps femoris muscle acts only in knee flexion. Trigger points (TrPs) in these muscles refer pain as widespread posterior thigh and/or knee pain and often mimic knee joint pathology. They can be activated by inactivity, especially by prolonged sitting with the hips and knees flexed or from an ill-fitting chair. Sporting activities such as football, basketball, and soccer can overload the hamstring muscles because of the combined hip flexion and knee extension that is required. Differential diagnosis should include hamstring muscle strain, proximal hamstring tendinopathy, lumbosacral radicular pain or radiculopathy, ischial bursitis, and pes anserine bursitis. Corrective actions should include techniques to improve sitting posture, gait mechanics, self-pressure release, and self-stretching techniques.

2. ANATOMIC CONSIDERATIONS

Semitendinosus

The semitendinosus muscle originates proximally from the posterior aspect of the ischial tuberosity by a common tendon with the long head of the biceps femoris muscle.¹ The belly of the semitendinosus muscle becomes tendinous below mid-thigh and travels distally, superficial to the semimembranosus muscle. Its tendon curves around the posteromedial aspect of the medial condyle of the tibia passes superficial to the tibial collateral ligament and inserts into the medial aspect of the tibia (Figure 60-1). Of the three tendons that

insert together at this site, called the “pes anserinus,” the semitendinosus tendon inserts most distally. The sartorius and gracilis muscles also attach at the pes anserinus. The pes anserine bursa separates the three tendons of the pes anserinus from the underlying tibial collateral ligament of the knee joint. This distal tendon attachment is considerably farther from the axis of rotation of the knee joint than is that of the other hamstring muscles. This gives the semitendinosus strong leverage to flex the knee after the knee is partially bent. This leverage becomes apparent when one bends the knee to a right angle, contracts the hamstring muscles, and palpates the relative prominence of the semitendinosus tendon. Furthermore, at the distal attachment, there is a blending with the tendon of the gracilis muscle, the deep fascia of the leg, and the medial head of the gastrocnemius muscle. These multiple extra fascial connections with the semitendinosus muscle can cause difficulty when harvesting the tendon surgically for a graft, but it increases its functional influence at the knee.

Figure 60-1. Attachments of the right superficial hamstring muscles, posterior view. The semitendinosus and long head of the biceps femoris muscles are light red. The underlying semimembranosus and short head of the biceps femoris muscles are dark red.

The division of the semitendinosus muscle into two tandem segments by the tendinous inscription across the midline of the muscle is apparently related to its phylogenetic origin. Two distinct end plate bands are found in the semitendinosus muscle, one above and one below the inscription (Figure 60-1).

Semimembranosus

The relatively broad semimembranosus muscle originates proximally on the posterior aspect

of the ischial tuberosity and lateral and deep to the common tendon of the semitendinosus and biceps femoris muscles. This anatomic arrangement places the semimembranosus muscle deep to the semitendinosus muscle on the medial aspect of the posterior compartment of the thigh (Figure 60-2). In fact, the semimembranosus muscle has the longest proximal tendon and the greatest muscle-tendon interface area of all the hamstring muscles.² Pérez-Bellmunt et al³ have recently described an annular connective tissue structure, a retinaculum, covering and adapting to the attachment of the hamstring muscles on the ischial tuberosity. In addition, this retinaculum receives expansions of the anterior epimysium of the gluteus maximus muscle.³

Figure 60-2. Attachments of the deep layer of right hamstring muscles, posterior view. The semimembranosus and short head of the biceps femoris muscles are dark red. The cut ends of the superficial layer of hamstring muscles are light red.

The oblique semimembranosus muscle fibers form a short, thick muscle belly mostly in the distal half of the thigh. Distally, the medial aponeurosis of the semimembranosus muscle becomes tendinous and divides into multiple components at the level of the knee. The main insertion terminates onto the posteromedial surface of the medial condyle of the tibia, just below the joint capsule and close to the axis of rotation of the knee joint (Figure 60-3). Other attachment sites include multiple fascial slips to the medial aspect of the tibia immediately deep to the tibial collateral ligament; a fibrous expansion to the fascia of the popliteus muscle; and a strong fascial expansion that passes obliquely superior to the femoral intercondylar line and lateral femoral condyle forming much of the oblique popliteal ligament of the knee.¹ Some authors describe an intimate attachment of the semimembranosus tendon to the posterior capsule of the knee and the medial or lateral meniscus.⁴⁻⁷ An important bursa lies between the semimembranosus and the medial head of the gastrocnemius muscles, and a secondary bursa exists to separate the semimembranosus muscle from the knee joint.¹

Figure 60-3. Attachments of the right hamstring muscles, medial view. The superficial semitendinosus muscle is light red, and the deeper semimembranosus muscle is dark red. The two heads of the biceps femoris muscle are intermediate red.

Biceps Femoris

The biceps femoris muscle, in the posterolateral compartment of the thigh, is comprised of a long head and a short head. The long head crosses both the hip and knee joints, but the short head crosses only the knee joint.

The long head of the biceps femoris muscle originates proximally at the posterior aspect of the ischial tuberosity from a common tendon with the semitendinosus muscle and at the

inferior portion of the sacrotuberous ligament⁸ (Figure 60-1). Frequently, the superior bursa of the biceps femoris muscle separates this common tendon from the deeper tendon of the semimembranosus muscle. The short head of the biceps femoris muscle originates proximally from the lateral lip of the linea aspera, between the adductor magnus and vastus lateralis muscles, extending from approximately the gluteus maximus muscle distally along the lateral supracondylar line to just superior to the lateral femoral condyle. Distally, the short head joins the long head in a common tendon that inserts into the posterolateral aspect of the head of the fibula (Figure 60-2). The biceps femoris muscle also has attachments to the fibular collateral ligament and the lateral tibial condyle.¹ Tosovic et al⁹ have recently described a nonuniform architecture of the muscle in which the distal portion of the long head of the biceps femoris muscle has significantly shorter fascicles and larger pennation angles than its proximal sites.

There are several anatomic variations of the hamstring muscles. For instance, the long head of the biceps femoris and the semimembranosus muscles can have hemipennate architecture, and their fiber length can be shorter than that of semitendinosus and short head of biceps femoris muscles.¹⁰ On some occasions, the short head of biceps femoris muscle may be absent. Also, additional attachment sites may include the ischial tuberosity, linea aspera, or medial supracondylar line.

Throughout the posterior thigh, the sciatic nerve lies deep to a hamstring muscle. In the upper thigh, it lies deep to the gluteus maximus muscle and the lateral side of the long head of the biceps femoris muscle, resting on the adductor magnus muscle. As it descends through the upper half of the thigh, the nerve crosses deep to the long head of the biceps femoris muscle from its lateral side to its medial side. At mid-thigh, the nerve lies deep to the biceps femoris muscle and between it and the semimembranosus muscle, still resting on the adductor magnus muscle. In the distal thigh, the tibial and peroneal branches of the sciatic nerve lie deep in the space between the semimembranosus muscle and the tendon of the long head of the biceps femoris muscle, lateral to the popliteal vessels.¹

2.1. Innervation and Vascularization

The semitendinosus, semimembranosus, and long head of the biceps femoris muscles are supplied by branches from the tibial portion of the sciatic nerve containing fibers of the L5, S1, S2 nerve roots. The short head of the biceps femoris muscle is supplied by branches of the common fibular division of the sciatic nerve, which also receives fibers from the L5, S1, S2 nerves.¹ Additionally, it has been observed that the hamstring muscles demonstrate an intramuscular arborization innervation.¹¹

The hamstring muscles receive their vascularization from the perforating arteries. The semitendinosus and biceps femoris muscles are also supplied superiorly by the medial circumflex femoral artery. Each hamstring muscle may receive some accessory vascularization from the inferior gluteal artery at the ischial tuberosity. Distally, at the tibial attachment, there may be an accessory vascularization from the superior lateral and medial genicular or popliteal arteries.¹

2.2. Function

The three true hamstring muscles (semitendinosus, semimembranosus, and long head of the biceps femoris) act primarily as hip extensors and knee flexors when the thigh and leg are free to move. The hamstring muscles provide between 30% and 50% of hip extensor strength.¹² During standing and forward bending, they control flexion at the hip. All the hamstring muscles are involved in knee flexion. The medial hamstring muscles (semitendinosus and semimembranosus) assist with internal rotation of the thigh at the hip, and the long head of the biceps femoris muscle assists external rotation of the thigh at the hip when the hip is extended. When the knee is flexed, the semitendinosus and semimembranosus muscles also internally rotate the leg, and both heads of the biceps femoris muscle externally rotate it. The short head of the biceps femoris muscle is primarily a flexor of the knee joint.

All three of the true hamstring muscles are electromyographically quiescent during static standing, as is the case with the quadriceps femoris, adductor magnus, and gluteus maximus muscles. However, in contrast to the gluteus maximus muscle, any action that takes the center of gravity in front of a medial-lateral axis at the hip joint, such as reaching or bending forward, is accompanied by a vigorous eccentric contraction of the hamstring muscles. As the forward trunk lean increases, the hip extensor moment arm of the hamstring muscles increases, whereas the hip extensor moment arm of the gluteus maximus muscle decreases.¹³ Because of the increased moment arm of the hamstring muscles, their activation in the forward trunk lean provides an important contribution to the lumbopelvic rhythm in forward flexion of the trunk.¹⁴

In gait, the hamstrings muscles function indirectly to keep the trunk erect during stance (directly restraining the tendency toward hip flexion that is produced by body weight) and to decelerate the forward-moving limb at terminal swing, regardless of speed.^{15,16} During the last half of swing, the hamstring musculature is active, lengthened, and absorbing energy from decelerating the limb in preparation for foot contact.^{16,17} The biceps femoris muscle experiences the greatest musculotendinous muscle stretch during terminal swing, which may contribute to its greater likelihood to be strained when compared with the other two hamstring muscles.¹⁸ Additionally, significant differences in the activation patterns between the biceps femoris and semitendinosus muscles were observed. With higher running speed, the biceps femoris muscle was more activated during the late-swing phase, whereas the semitendinosus muscle was significantly more activated during the middle-swing phase.¹⁹ The hamstring muscles also help extend the hip during late-stance to pre-swing phase of gait. The individual hamstring muscles do not act consistently in flexing the knee during gait, though the short head of the biceps femoris muscle is active in knee flexion for toe clearance.

Ericson²⁰ calculated that, together, all of the hip extensor muscles produce 27% of the total positive mechanical work during ergometer cycling. An average of surface electrode activity through 25 cycles of pedaling in 11 subjects²¹ showed that the electromyographic (EMG) activity of the biceps femoris muscle peaked at the beginning of the backward

motion of the pedal. In contrast, the combination of semitendinosus and semimembranosus muscles EMG activity peaked near the end of this period. Activity of the biceps femoris muscle increased with increased pedaling rate and with increased seat height.²¹

The hamstring muscles also provide dynamic stability for the knee joint because of their distal medial and lateral attachments at the knee. This function is supported by the anatomy of the popliteus muscle and the presence of a three-layered retinaculum acting as kinematic sustentation for the hamstring muscles.²² The hamstring muscles also lend active resistance to the anterior glide of the tibia on the femur, providing the anterior cruciate ligament with dynamic support.¹²

2.3. Functional Unit

The functional unit to which a muscle belongs includes the muscles that reinforce and counter its actions as well as the joints that the muscle crosses. The interdependence of these structures is functionally reflected in the organization and neural connections of the sensory motor cortex. The functional unit is emphasized because the presence of a TrP in one muscle of the unit increases the likelihood that the other muscles of the unit will also develop TrPs. When inactivating TrPs in a muscle, one must be concerned about TrPs that may develop in muscles that are functionally interdependent. Box 60-1 grossly represents the functional unit of the hamstring muscle group.²³

Box 60-1 Functional unit of the hamstring muscle group

Action	Synergists	Antagonists
Hip extension	Gluteus maximus Adductor magnus (ischiocondylar portion)	Iliopsoas Tensor fascia latae Rectus femoris Sartorius
Knee flexion	Sartorius Gracilis Gastrocnemius Plantaris	Quadriceps femoris

3. CLINICAL PRESENTATION

3.1. Referred Pain Pattern

The referred pain pattern of TrPs in the semitendinosus and semimembranosus muscles usually projects upward to the ischial tuberosity and gluteal fold. Referred pain can also extend inferiorly to the medial posterior thigh, posterior knee, and occasionally to the

medial calf, often with a sharpness that is less commonly felt from the other hamstring muscles (Figure 60-4A).

Figure 60-4. Composite pain patterns (dark red) referred from TrPs in the hamstring muscles. Solid red denotes the essential pain distribution referred from these TrPs. Red stippling locates the occasional extension of the pattern in some patients. A, Semitendinosus and semimembranosus muscles. B, Long and short heads of the biceps femoris muscle.

The pain pattern referred from TrPs in either or both heads of the biceps femoris muscle often projects distally to the posterior lateral knee. Chan et al²⁴ described a case report where a calcific tendinitis of the biceps femoris muscle was a cause of acute knee pain. The referred pain can also spread inferiorly below the knee into the calf and may also extend upward in the posterior thigh as high as the gluteal fold (Figure 60-4B).

3.2. Symptoms

Patients with TrPs in the hamstring muscles will report pain in the buttock near the gluteal fold and ischial tuberosity, posterior thigh and/or knee, especially with walking or running. Some authors called these symptoms the “hamstring syndrome.”²⁵ Patients can also report pain in the buttock, upper thigh, and back of the knee when sitting due to pressure on the TrPs, especially when sitting on hard surfaces. They may also report increased pain upon

rising from a seated position especially if they have been sitting with their knees crossed. They may tend to push themselves up out of the chair with their arms because of pain.

The patient may also report a disturbed or interrupted sleep pattern that is commonly due to TrPs in the biceps femoris muscle. Pain and symptoms from the biceps femoris muscle are typically located in the posterolateral aspect of the knee, and pain can be focused around the head of the fibula at its attachment.

Patients can also experience a wide distribution of symptoms and pain in the posterior thigh that may lead to a diagnosis of “sciatica.” Even when the patient may have experienced a traumatic injury resulting in a hamstring muscle strain, examination for TrPs is necessary to help control painful symptoms caused by the associated TrPs.

3.3. Patient Examination

After a thorough subjective examination the clinician should make a detailed drawing representing the pain pattern that the patient has described. This depiction will assist in planning the physical examination and can be useful in monitoring the progression of the patient as symptoms improve or change. In assessing posture, persons with short or stiff hamstring muscles may present with a posterior pelvic tilt and a reduced lumbar lordosis. A typical swayback posture, as could be seen in this population, would also include a forward head posture. The importance of a thorough examination, even when all muscular symptoms are limited to one half of the body, cannot be overemphasized.

For proper examination of the hamstring muscles, the clinician should observe sitting and standing postures. In sitting, posture and environmental setup should also be assessed. The clinician should watch for potential compression of the posterior thighs by the front of a chair seat that may occur if the patient’s legs are not long enough to rest fully on the floor. A tendency for the patient to cross the knees in sitting could also contribute to the presence of TrPs in the hamstring muscles. Further, when the patient is seated, he or she may lean forward to reduce the load on the ischial tuberosities, thus placing an increased load in the mid-thigh region of the hamstring muscles.

Physical examination should be conducted to rule out lumbar, sacroiliac, hip, or knee joint pathology. This evaluation may include range of motion testing of the lumbar spine, hip, and knee; passive accessory motion testing of the hip, sacroiliac joint, or knee; strength testing of the hip (especially in extension, adduction, and knee flexion) and other associated muscles or movement; and any appropriate neurologic testing or orthopedic special tests. A careful assessment should be made to rule out pain or symptom referral into the buttock or posterior thigh from other muscles, joints, or neural tissues that can also refer pain to the same region.

It is also important to observe the patient’s gait pattern with close attention to terminal swing phase and early-stance phase as this is when the hamstring muscles are most active during the gait pattern. The knee may be held in a flexed position throughout the stance phase due to pain in the hamstring region from TrPs. Gluteus maximus muscle weakness may also lead to overload of the hamstring musculature during gait, and observation of the

lumbar spine and innominate positions during the stance phase is warranted.

The regional interdependence of the lumbosacral spine and hip, as well as the hip and knee joints, makes it necessary to examine these relationships in a closed and open kinetic chain. A functional activity that should be assessed in standing is the double-leg squat, which should be observed from a sagittal perspective (see Figure 54-3A). The clinician should note any excessive movement in the lumbosacral region or hip joint. During a proper squat, the patient should be able to demonstrate a good range of hip flexion without an excessive anterior pelvic tilt, excessive lumbar hyperextension, or a major shift of the knee in front of the foot in the sagittal plane (see Figure 54-3B). Movement from a standing to sitting position should be observed to examine gluteus maximus and hamstring muscle control during sitting along with hip and knee flexion range of motion.

Hip and knee range of motion, muscle strength, and activation patterns should be assessed in all planes. Muscle length assessment of one and two joint hip flexor muscles should be performed (see Figure 54-7). Hip extension muscle activation patterns should be assessed in the prone position. Janda described a muscle activation pattern during hip extension that includes the following muscle firing sequence: hamstrings, gluteus maximus, and contralateral paraspinal muscles, followed by ipsilateral paraspinal muscles. The lumbar spine should be maintained in a neutral position and the knee in extension; any deviation would be indicative of movement impairment.²⁶ Hamstring muscle strength should be tested both for its role in hip extension and knee flexion.

Muscle length assessment should be differentiated from the altered neurodynamics of the sciatic nerve. Hamstring muscle tightness or stiffness is the most frequent reason why an individual may have limited forward bending or excessive lumbar flexion when attempting to touch one's toes with the knees extended,²⁷ though the tightness does not restrict flexion at the hip when the knees are bent. Hamstring extensibility can be assessed utilizing the 90/90 test, in which the hip is flexed to 90° and the knee is passively moved from 90° of knee flexion toward full extension (Figure 60-5).

Figure 60-5. Hamstring muscle length test using 90-90 position. A, Starting position. B, End position demonstrating hamstring muscle length deficit.

Trigger points in the hamstring muscles markedly limit motion during the Straight Leg Raise Test (Figure 60-6). The pain that TrPs cause at the limit of hip flexion may be felt in

the lower buttock, the back of the thigh, or behind the knee. Structural differentiation with ankle dorsiflexion would still be necessary to determine the relative contributions of neural tension and myofascial tension. The addition of dorsiflexion at the end of their range of motion during the straight leg test should not further provoke TrPs in the hamstring muscles, and thus no change in pain in the buttock or posterior thigh should increase with this differentiating maneuver. In some muscles, active TrPs cause pain when the muscle is maximally shortened, so that they restrict both the shortened range of motion and the stretch range of motion. Active TrPs in the hamstring muscles may slightly restrict the combination of active extension at the hip with combined flexion at the knee, giving the impression that a tight rectus femoris muscle is responsible. In this situation, inactivation of the hamstring TrPs restores active range of motion. However, this hypothesis is not supported by two studies showing that dry needling combined with stretching of hamstring muscles was not more effective than stretching alone for improving their length.^{28,29}

Figure 60-6. Hamstring muscle length assessment using the straight leg raise. A, Starting position. B, End position demonstrating hamstring muscle length deficit.

3.4. Trigger Point Examination

The semitendinosus muscle is easily identified by locating its prominent tendon behind the medial aspect of the knee when the knee is flexed against resistance and then by following the tendon superiorly into the thigh. The semimembranosus muscle lies deep to the semitendinosus muscle and is muscular in the distal thigh. Its muscle fibers can be palpated on each side of the semitendinosus tendon. The semimembranosus muscle forms the medial border of the hamstrings and is adjacent to the gracilis muscle in the lower half of the thigh.

To palpate TrPs in the semitendinosus or semimembranosus muscles, the patient can lie prone, side-lying, or supine, though prone is preferred. To locate TrPs in the semitendinosus or semimembranosus muscles, the patient lies in the prone position, with the involved thigh in a slightly abducted position and the knee slightly flexed with the ankle resting on a pillow. Cross-fiber flat palpation can be used for examination of the distal medial hamstring muscles (Figure 60-7A) by applying direct pressure on the muscle against the underlying femur. Cross-fiber flat palpation can also be used to palpate TrPs in

the proximal portion of the medial hamstring muscles (Figure 60-7B). With the patient side-lying with the affected side down, cross-fiber pincer palpation can be used to identify TrPs in the semitendinosus muscle (Figure 60-7C). While the patient is lying supine with the hip slightly flexed, abducted, and externally rotated and a pillow placed under the knee and upper lower leg, cross-fiber pincer palpation can be used to identify TrPs in the semitendinosus and semimembranosus muscles (Figure 60-7D).

Figure 60-7. Palpation for TrPs in the medial hamstring muscles. A, Cross-fiber flat palpation of distal medial hamstring muscles. B, Cross-fiber flat palpation proximal medial hamstring muscles. C, Side-lying cross-fiber pincer palpation. D, Supine cross-fiber pincer palpation.

When examining the biceps femoris muscle for TrPs, it is best to approach it from the posterior and lateral aspect of the thigh. The short head of the biceps femoris muscle lies deep to the long head in the distal half of the thigh. The two heads can be distinguished by palpation as the long head becomes tense when the patient tries to extend the hip, whereas the short head does not change tension. Cross-fiber flat palpation is utilized to identify TrPs in the short head of the biceps femoris muscle (Figure 60-8A). To palpate for TrPs in the long head of the biceps femoris muscle, cross-fiber flat palpation should be used by applying direct pressure on the muscle against the underlying femur with the patient in

prone with a pillow placed under the ankle to place the knee in slight flexion (Figure 60-7B). Trigger points can also be located in side-lying utilizing cross-fiber flat palpation (Figure 60-7C).

Figure 60-8. Palpation for TrPs in the lateral hamstring muscles. A, Cross-fiber flat palpation of the short head of the biceps femoris muscle in prone. B, Cross-fiber flat palpation of the long head of biceps femoris muscle in prone. C, Cross-fiber flat palpation side-lying.

4. DIFFERENTIAL DIAGNOSIS

4.1. Activation and Perpetuation of Trigger Points

Any posture or activity that activates a TrP, if not corrected, can also perpetuate it. In any part of the hamstring muscles, TrPs may be activated by unaccustomed eccentric loading, eccentric exercise in an unconditioned muscle, or maximal or submaximal concentric loading.³⁰ Trigger points may also be activated or aggravated when the muscle is placed in a shortened and/or lengthened position for an extended period of time.

Hamstring TrPs are often activated and perpetuated by a sedentary lifestyle or by immobility where the knees and hips are frequently kept in a flexed position for a prolonged period of time. Under-thigh compression by an ill-fitting chair can both activate and perpetuate TrPs in the hamstring muscles. Short-statured individuals with hamstring TrPs who sit in customary chairs, or patients of average stature who sit in chairs with a high seat, can experience aggravation of pain due to excess pressure on hamstring TrPs as a result of the weight of the dangling legs. In addition, they may experience the tingling and numbness of neurapraxia due to pressure on the sciatic nerve. To address this problem of under-thigh compression by the chair seat, the seat should be lowered to allow the feet to rest on the ground if possible, or the patient can utilize a footstool that supports the heels and lifts the thighs. As seen in the younger population, many school chairs present this same problem because chairs of one size are used for children of widely different heights.

Sporting activities such as football, basketball, and soccer can result in hamstring muscle injuries, especially in unconditioned or poorly trained athletes. Kicking motions often require simultaneous flexion at the hip and extension at the knee placing the muscle in a passively insufficient position while performing an eccentric contraction to decelerate the leg. This scenario can easily overload the hamstring muscles. Other exercise activities such as swimming or cycling may also lead to an overload of the hamstring muscles. Gymnastic activities such as the splits can activate and perpetuate TrPs, especially in the semimembranosus and semitendinosus muscles, due to the severe lengthening of these muscles.

A patient's presenting thigh condition may result from quadriceps femoris TrPs, and a clinician can easily overlook the hamstring muscles. Because the quadriceps muscles are part of the hamstring muscle functional unit, if TrPs are present in the quadriceps muscles, the dysfunction could actually originate in the hamstring muscles.

4.2. Associated Trigger Points

Associated TrPs can develop in the referred pain areas caused by other TrPs.³¹ Therefore, musculature in the referred pain areas for each muscle should also be considered.

In association with TrPs in the hamstring muscles, TrPs are likely to develop in the posterior (ischiocondylar) part of the adductor magnus muscle, which helps extend the hip as part of the hamstring muscle functional unit. The gastrocnemius muscle also tends to

develop TrPs in association with hamstring TrPs. The vastus lateralis muscle is prone to developing TrPs when TrPs exist in the long head of the biceps femoris muscle.

Antagonists to the hamstrings may also develop associated TrPs, especially the iliopsoas muscle and the quadriceps femoris muscles. The patient may only report symptoms of quadriceps femoris TrPs even when there is dysfunction in the hamstring muscles. Shortening of the hamstring muscles caused by TrPs is likely to overload the quadriceps femoris muscles. This overload can activate TrPs in the quadriceps femoris muscles. In this case, the quadriceps femoris muscle symptoms will not resolve until the TrPs in the hamstring muscles have been eliminated.

Hamstring muscle length deficits or tension caused by TrPs produces a posterior tilt of the pelvis that causes associated flattening of the lumbar spine that can result in thoracic kyphosis and a forward head position. This postural dysfunction imposes compensatory overload on a number of muscles of the trunk, including the periscapular and neck muscles, thoracic paraspinal muscles, and quadratus lumborum and rectus abdominis muscles. Hamstring muscle tension caused by TrPs and/or muscle length deficits is often a key to low back pain of myofascial origin. Clinically, starting treatment by releasing the hamstring muscles, even though the iliopsoas or quadratus lumborum muscles seem to be involved, will provide improved results as TrPs in the proximal muscles are typically associated with the TrPs in the hamstring muscles.

Several other muscles whose pain referral patterns overlap those of the hamstring muscles and could have associated TrPs include the obturator internus, piriformis, gluteus medius, gluteus minimus, vastus lateralis, popliteus, and gastrocnemius muscles.

4.3. Associated Pathology

A hamstring muscle strain is defined as posterior thigh pain where direct contact to the area is excluded as the mechanism of injury. Detection of hyperintense signals on magnetic resonance imaging (MRI) within the hamstring muscles is indicative of a hamstring muscle strain.³² Hamstring muscle strains commonly occur in athletes who employ high-speed kicking and sprinting, such as football and soccer.³³ Athletes may describe an audible pop as part of the mechanism of injury when the proximal hamstring tendon is involved and are likely not able to continue with sport activity immediately after the injury.³⁴ With proximal tendon involvement, the patient may report pain while sitting on the ischial tuberosity,³⁵ swelling, weakness, and a loss of range of motion at the hip and at the knee.³⁶ Clinically, palpation typically reveals local area tenderness and a possible apparent defect in the affected muscle.³⁶ However, it is important to consider that pathology of the hamstring muscles is also prevalent in asymptomatic people. Thompson et al³⁷ demonstrated that 15% of individuals without symptoms had bilateral partial tears, and 2% had bilateral complete tears of hamstring muscle insertion, with the semimembranosus muscle most often affected.

Puranen and Orava³⁸ were the first to describe “hamstring syndrome” as pain in the lower gluteal area that radiated down the posterior thigh to the popliteal space.

Contemporary medicine refers to this diagnosis as “proximal hamstring tendinopathy” or, in lay terms, “high hamstring” tendinopathy. This pathology is characterized by pain as described previously that is easily aggravated during sports activities, specifically running at a faster pace. Often, the pain can be so intense that the athlete is not able to sprint at all. Pain can also be exacerbated with prolonged sitting and made worse with continued exercise and stretching of the hamstring muscles. Because of the complex nature of diagnosing pain in the gluteal region and posterior thigh, MRI is often used to confirm or negate the diagnosis of hamstring tendinopathy and exclude other potential sources of pain.³⁹

Proximal hamstring tendinopathy is an insertional disease that can affect athletic and nonathletic populations. Pain is typically reported as deep buttock pain about the ischial tuberosity and common hamstring tendon. The onset of pain may occur from training errors, especially in runners introducing sprinting, lunging, hurdles, and/or hill training; prolonged static stretch positions, as may occur in participation in yoga or Pilates; or compressive loading from prolonged sitting, particularly on a firm surface.⁴⁰ Proximal hamstring tendinopathy is assessed by adding compressive or tensile load to the common hamstring attachment at the ischial tuberosity. Tensile loading assessment from a 90/90 hamstring muscle length test or straight leg raise may provoke local pain symptoms (Lasegue sign). Compressive loading can be assessed by asking the patient to perform active hamstring muscles exercises, such as a low-level bridge and gradually increasing load on the hamstring muscles up to a single-leg deadlift.⁴⁰

Proximal hamstring tendinopathy and hamstring TrPs present very similarly. In both cases, pain is exacerbated by sitting postures, hamstring muscle length is decreased, and taut bands can be palpated. The thickening or fibrosing of the common proximal hamstring tendon that occurs with tendinopathy produces a taut band with palpation. Trigger points and tendinopathy can occur together. Two case reports of runners with proximal hamstring tendinopathy showed improved pain reports with TrP dry needling to the hamstrings and adductor magnus muscles. The authors propose that release of the involved TrPs may reduce tension on the tendinous insertion to the ischial tuberosity.⁴¹ After TrP dry needling, treatment progressed to eccentric training of the hamstring muscles following recommendations for achilles tendinopathy rehabilitation.

Typical MRI findings of hamstring tendinopathy include increased tendon girth, intrasubstance signal heterogeneity, and asymmetric involvement of hamstring tendons (in unilateral cases).⁴² Martin et al²⁵ proposed that diagnosis in a patient with posterior hip pain should differentiate deep gluteal syndrome, hamstrings syndrome, and ischiofemoral impingement. Clinically, the fibrotic bands of hamstring tendinopathy should be distinguished from taut bands of TrPs by the fact that they are connective and not muscle tissue, and should not produce local twitch responses on snapping palpation.

Ischial or ischiogluteal bursitis is an inflammation of the ischiogluteal bursae due to excessive or ineffective form with physical activity such as running, jumping, kicking, or prolonged sitting.⁴³ Patients with ischiogluteal bursitis typically present with buttock pain that is exacerbated by any activity that recruits the hamstring muscles, that stretches the

hamstring muscles, or that requires sitting on the ischial tuberosity. Pain and tenderness is typically identified with palpation over the ischial tuberosity.⁴⁴ Ischial bursitis is rare and an infrequently recognized pathology that requires diagnostic imaging to differentiate from other soft tissue pathologies and local area tumors.⁴⁵ Ultrasound and MRI are best for visualization of the ischial bursae.⁴⁶

Distally, the pes anserine refers to the tendons of the sartorius, gracilis, and semitendinosus muscles along the insertions into the proximal medial aspect of the tibia. In pes anserine bursitis, the bursa separating these three tendons becomes inflamed and causes pain. Patients experiencing pes anserine bursitis may report of vague medial knee pain and may experience swelling and tenderness along the medial proximal tibia. Pes anserine bursitis is commonly associated with degenerative joint disease, obesity, genu valgum, pes planus, and sport activities.^{47, 48}

5. CORRECTIVE ACTIONS

Patients with TrPs in the hamstring muscles should limit the duration of time spent sitting. If they are employed in a desk job where the majority of the day is spent sitting, assessment and education for proper ergonomics and sitting postures would be beneficial. Taking short breaks to stand, utilizing a standing desk, or improving postural support will assist in reducing symptoms. A timer placed across the room can remind the patient to get up, walk across the room, reset the device, and return to the chair with minimal distraction from thought. The design of the chair that the individual uses and the materials that the seat are made of change the amount of pressure, contact area, and tissue perfusion.⁴⁹ Under-thigh compression can be avoided by selecting or adjusting chairs to match the leg length of the individual, or by propping the feet up on a footrest placed a short distance in front of the chair.

When selecting a chair for home, one should ensure that the front edge of its seat is rounded and well-padded. When driving on long automobile trips, prolonged immobilization and excessive pressure on the hamstring muscles can be alleviated by using automatic cruise control. This function permits alteration in the leg position and allows frequent “stretch” breaks. Sleeping on the side with a pillow between the legs to keep the hip in a neutral position and knees closer to being fully straightened may assist in addressing hamstring TrP activation and perpetuation especially in the biceps femoris muscle. Patients should avoid placing a pillow under the knee while sleeping on their back, as this will keep the hamstring muscles in a prolonged shortened position that can activate and perpetuate TrPs in the hamstring muscles.

Hamstring TrPs can be self-treated with self-pressure release techniques utilizing a TrP release tool, tennis or lacrosse ball, or a foam roller based on personal preference and abilities. Utilizing a TrP release tool, the patient lies on the unaffected side and the tool is placed on a tender point in the hamstring muscle (Figure 60-9A). The patient can also use a pincer grasp while seated to perform self-release by finding the most tender spot and applying a light pressure to the area (Figure 60-9B). A ball can be used by placing it under

the thigh for pressure on the tender area (Figure 60-9C). In all pressure-release techniques, pressure should be held for 15 to 30 seconds and repeated six times. This sequence can be repeated every 2 to 3 hours as long as relief of symptoms is achieved. Too much pressure (no more than 4/10 pain scale) on the TrPs should be avoided, as excessive pressure can actually cause activation and perpetuation of the TrPs.

Figure 60-9. Trigger point self-pressure release. A, Lateral hamstring muscles. B, Manual self-release medial hamstring muscles. C, Tennis ball under hamstring muscles.

Foam rolling can be utilized to help release TrPs in the hamstring muscles and is commonly used by athletes. In a long sitting position, the unaffected leg should be placed in knee flexion with the foot planted on the floor and the posterior aspect of the affected leg resting on the foam roller. The patient can roll along the foam roller until identifying the tender TrP, at which point the patient should hold constant isolated pressure for 15 to 30 seconds or until the tenderness reduces, as instructed earlier.

Assuming that patients have no neural tension (no numbness, tingling with stretch), a basic stretch that those with hamstring TrPs should perform at home is the single-leg long-sit stretch. The patient should sit at the edge of a table with one leg on the table with the knee extended and the ankle in a neutral relaxed position (Figure 60-10A). The opposite limb should be firmly planted on the ground to provide stability during the stretch. Ensuring a neutral or slight anterior tilt of the pelvis and neutral lumbar spine, the patient should flex forward in an attempt to touch the belly button to the thigh (Figure 60-10B). The stretch should be maintained for a 30-second hold followed by relaxation and repeated four times as long as the symptoms are resolving. This sequence can be repeated two to three times per day.

Figure 60-10. Hamstring muscles self-stretch. A, Start position in erect posture with neutral lumbar spine. B, Leaning forward maintaining neutral lumbar spine until a stretch is felt behind the thigh. C, Starting position for supine 90-90 stretch. D, Actively straightening the knee until a gentle stretch is felt behind the thigh.

If the patient has neural tension with hamstring TrPs (numbness, tingling), he or she can perform a supine active hamstring muscle stretch from the 90/90 position (Figure 60-10C), in which the patient stabilizes the thigh at 90° of hip flexion with the hands placed behind the thigh and actively extends the knee to the point of stretch behind the thigh and knee but prior to the onset of pain of neural provocation (Figure 60-10D).

When the patient or athlete requires a prolonged stretch, the doorway stretch can be utilized (Figure 60-11). The patient lies on the floor with the unaffected leg through the doorway and the affected side up on the door jamb. The patient should not start with the hip at greater than a 45° angle. A slight stretch should be felt in the back of the thigh and knee; no numbness or tingling should be experienced in the back of the thigh, calf, or foot. This stretch is commonly used for true muscle length deficits and performed following the elimination of TrPs.

Figure 60-11. Hamstring stretch in the doorway.

A yoga strap can be used to assist and augment a hamstring muscle stretch through a full range of hip motions (Figure 60-12). The yoga strap should be secured around the foot just below the bottom of the heel of the foot. The leg is then placed out to the side, and the stretch should be felt along the inner thigh and behind the knee (Figure 60-12A). Using the hands and arms, the leg is pulled up into hip flexion while slightly out to the side and

held in the position of a firm stretch (Figure 60-12B). The leg is positioned so that it is aligned with the trunk (Figure 60-12C) and then placed across midline (Figure 60-12D). Each stretch position should be held for 15 to 30 seconds with a minimum of four stops through the range. The patient should not experience numbness or tingling in the leg or foot at any time. If these sensations are felt, the stretch should be stopped immediately.

Popliteus Muscle

“Bent Knee Troublemaker”

Orlando Mayoral del Moral, Óscar Sánchez Méndez, María Torres-Lacomba, and Michelle Finnegan

1. INTRODUCTION

The popliteus muscle is a deeply located triangular muscle that attaches proximally to the lateral condyle of the femur and distally to the posterior aspect of the medial tibia. The main function of the popliteus muscle appears to be to “unlock” the knee at the start of weight bearing by externally rotating the femur on a fixed tibia. Activity of this muscle prevents forward displacement of the femur on the tibia when a person squats, and places weight on the bent knee. The pain referred from trigger points (TrPs) in the popliteus muscle normally concentrates in the back of the knee proximal to the location of the TrP. It can also include the posteromedial and medial sides of the tibia, projecting to the pes anserine area. Symptoms mainly appear when squatting, running, walking downhill, when going downstairs, as well as standing up after prolonged sitting. Popliteus myofascial pain syndrome can readily be misdiagnosed as popliteus tendinopathy. Other diagnoses that can appear confusingly similar include a Baker cyst, anteromedial and posterolateral instability of the knee joint, and avulsion of the popliteus tendon. For TrP examination, the popliteus muscle is most accessible close to the lower (medial) and upper (lateral) ends of its muscle belly. Trigger points in the popliteus muscle may be activated while the person plays soccer or football, runs, twists, or slides and can be perpetuated by knee joint conditions; by associated TrPs in biceps femoris, gastrocnemius, and vastus lateralis muscles; by prolonged immobilization; or by excessive pronation of the foot. Corrective actions for the treatment of TrPs in the popliteus muscle include dynamic and static postural education, self-pressure release, and self-stretching exercises.

2. ANATOMIC CONSIDERATIONS

The popliteus is a thin, flat muscle with the shape of an obtuse triangle that forms the

lower part of the popliteal fossa behind the knee (Figure 61-1).^{1,2} It originates proximally and laterally by a strong tendon that is inserted in a depression on the outer side of the lateral condyle of the femur (Figure 61-2). This tendinous attachment lies anteroinferior to the proximal attachment of the lateral collateral ligament on the lateral epicondyle of the femur.² Some variations of the proximal attachments of the popliteus muscle have been reported. These include attachments to the lateral femoral condyle (100%), posterior horn of the lateral meniscus (63%), or fibular head (52.1%).³ The popliteus muscle is the only muscle that attaches posteriorly within the joint capsule of the knee. The popliteus tendon crosses the knee joint in a posteroinferior direction beneath the lateral collateral ligament and the tendon of biceps femoris muscle.⁴ It then passes through the popliteal hiatus and is joined by collagenous fibers arising from the arcuate popliteal ligament, the fibrous capsule adjacent to the lateral meniscus, and the outer margin of the meniscus.¹ In the posterolateral part of the knee, the popliteus muscle has another important attachment to the fibula by a short and strong structure named the popliteofibular ligament (PFL).^{1,5} It is one of the strongest lateral stabilizers of the knee joint.² The PFL has the shape of an inverted Y; the anterior limb originates from the anterior aspect of the fibular head, and the posterior limb arises from the posterosuperior aspect of the fibular head. Both insert proximally into the musculotendinous junction of the popliteus muscle and into the popliteomeniscal fascicle.^{5,6}

Figure 61-1. Attachments of the right popliteus muscle (red), from a posterior view. Its attachment to the femur is shown in Figure 61-2. Not shown in this figure because of the complexity of the popliteus muscle attachments: popliteofibular ligament, popliteal meniscal ligament, and fabellofibular ligament.^{5, 6, 13}

Figure 61-2. Proximal attachment of the right popliteus muscle (red) to the femur, from the lateral view.

Fleshy fibers expand from the inferior limit of the tendon to form a triangular muscle that descends distally and medially to insert into the medial two-thirds of the triangular area above the soleal line on the posterior surface of the tibia and into the tendinous expansion that covers its surface (Figure 61-1).¹

The PFL is the single most important stabilizer of the posterolateral corner of the knee. It prevents posterior translation, varus angulation, and external rotation of the tibia on the femur.^{1,6,7} Murthy⁸ found the attachment to the fibular head to be missing bilaterally in 4 out of 30 cadavers. Other studies have shown that the PFL is present in 100% of the population.^{6,7,9,10} The most plausible explanation for these criteria differences among the authors is that the shallow layer of the PFL is close to the arcuate ligament in terms of its

direction and position making its identification in prior studies inconsistent.¹⁰

Regarding the meniscus, different authors have found, clearly delineated but highly variable, three popliteomeniscal fascicles attaching into the lateral meniscus.^{5, 11–14} Tria et al¹⁵ found no strong connection in 45% of subjects. Only 17.5% of subjects had that strong connection to the lateral meniscus as described by others. Unquestionably, this meniscal attachment is of importance in some, and possibly many, individuals.

The popliteal bursa is an extra-articular extension of the synovial membrane of the knee joint. The course of the bursa extends from the popliteal hiatus along the proximal part of the popliteus tendon in order to separate this tendon from the lateral condyle of the femur above the head of the fibula.²

The popliteus muscle is analogous to the deep portion of the pronator teres muscle in the forearm and is rarely absent.¹⁶ There are several anatomic variants for the popliteus complex, such as variations of the medial portion and on the aponeurotic extension of the muscle.^{17, 18} Morphologic alterations of the popliteus tendon have also been described, such as the possibility of bifurcation^{19, 20} or a three-bundle form.²¹ Benthien and Brunner²² reported a case of posterolateral knee pain caused by the presence of a sesamoid bone named cyamella located between the popliteal tendon and the femur. Also, the sesamoid bone has been found as a proximal attachment to an accessory muscle.²³ Occasionally, two other muscles may be found deep in the posterior aspect of the knee: the popliteus minor muscle, a small muscle situated above the popliteus muscle that runs from the posterior surface of the lateral tibial condyle, medial to the plantaris muscle, to the oblique popliteal ligament, and the peroneotibialis muscle, located deeper than the popliteus muscle and running from the medial side of the fibular head to the upper end of the soleal line.¹

2.1. Innervation and Vascularization

The popliteus muscle is innervated by two to three parallel branches of the tibial nerve that arise from the L4, L5, and S1 spinal nerves.^{1, 24} These branches descend obliquely across the popliteal vessels, wind around the distal border of the muscle, and enter through its anterior surface. The nerve entry point is approximately 3 cm below the fibular head.²⁴ These nerve branches further separate into the left, right, and anterior branches so as to innervate different parts of the muscle.²⁴

Vascularization to the popliteus muscle is supplied by the inferior medial and lateral genicular arteries, two branches that originate from the popliteal artery deep to the gastrocnemius muscle. The course of the lateral inferior genicular artery is on the surface of, through, or underneath the arcuate ligament.¹⁰ It is possible that the muscle has additional supplies from the nutrient artery of the tibia, the proximal part of the posterior tibial artery, and the posterior tibial recurrent artery.¹

2.2. Function

The popliteus muscle rotates the tibia internally on the femur when the thigh is fixed and

the leg is free to move, as when sitting erect.^{1,25} When the tibia is fixed, as happens in a standing position, the popliteus muscle is capable of rotating the femur externally on the tibia, thus “unlocking” the knee joint at the beginning of the flexion movement.^{1,26,27} This muscle also acts as a dynamic stabilizer of the knee.^{2,12,28,29} Its role as a stabilizer can be related to the presence of the high density of Ruffini endings at its tendon.³⁰

Basmajian and Lovejoy³¹ studied this muscle electromyographically using fine-wire electrodes in 20 subjects. These investigators found that, with the leg free to move, the popliteus muscle was activated by voluntary effort to produce internal rotation of the leg at various knee angles between knee straight and 90° of flexion in the sitting and prone positions.³¹

Several authors^{31–34} have reported that, when the person stood in semicrouched bent-knee position between 30° and 50° of knee flexion, the popliteus muscle showed continuous motor unit activity. In this typical “ready” position, normally adopted in sport activities that involve sudden stopping, such as running with directional changes,³⁵ the noncontractile tissue structures are relaxed and the body weight tends to slide the femur downward and forward on the slope of the tibia. This contraction of the popliteus and quadriceps femoris muscles assists the posterior cruciate ligament in preventing forward dislocation of the femur³³ on the knee and acts as a dynamic knee joint guidance.

Basmajian and Lovejoy³¹ reported that during walking, the greatest electromyography occurs during initial contact and mid-stance. Mann and Hagy²⁵ found that the highest activity of the muscle develops at the early part of the stance phase. Perry³⁶ reported that popliteus muscle activity occurs during all the gait phases, except on initial swing and mid-swing, with great variability between subjects. Davis et al³⁷ reported a strong activation of the popliteus muscle during downhill walking at the mid-stance gait phase. Nevertheless, the muscle is inactive when the person quietly stands erect.³⁸

According to Amonoo-Kuofi,³⁹ human fetal popliteus muscles contained many muscle spindles arranged in complex and tandem forms. The author concluded that these spindles could provide a major part of the kinesthesia needed to monitor locking and unlocking of the human knee joint.³⁸

2.3. Functional Unit

The functional unit to which a muscle belongs includes the muscles that reinforce and counter its actions as well as the joints that the muscle crosses. The interdependence of these structures is functionally reflected in the organization and neural connections of the sensory motor cortex. The functional unit is emphasized because the presence of a TrP in one muscle of the unit increases the likelihood that the other muscles of the unit will also develop TrPs. When inactivating TrPs in a muscle, one must be concerned about TrPs that may develop in muscles that are functionally interdependent. Box 61-1 grossly represents the functional unit of the popliteus muscle.⁴⁰

Box 61-1 Functional unit of the popliteus muscle

Action	Synergist	Antagonist
Internal rotation of the leg	Semimembranosus Semitendinosus Sartorius Gracilis	Biceps femoris

3. CLINICAL PRESENTATION

3.1. Referred Pain Pattern

Trigger points in the popliteus muscle refer pain primarily to the back of the knee joint (Figure 61-3). Mayoral et al⁴¹ has clinically observed a variant in this pain pattern including the posteromedial and medial sides of the tibia and, projecting to the pes anserinus area.

Patients rarely report pain in the knee solely due to TrPs in the popliteus muscle. Initially, the source of knee pain is identified as coming from TrPs in other muscles, such as the gastrocnemius or biceps femoris muscles. On first examination, the latter appears to account for the patient's report of pain; however, after the TrPs in these other muscles have been inactivated, the patient becomes more aware of back-of-the-knee pain that examination then identifies as originating in the popliteus muscle. Deep pain felt within the posterior area of the knee joint can alert the clinician to examine for TrPs in the popliteus muscle from the outset.

Figure 61-3. Referred pain pattern (dark red) of a TrP in the right popliteus muscle (light red) seen in posterior view. The essential pain pattern is solid red. Red stippling indicates occasional spillover of the essential pattern.

3.2. Symptoms

The chief report of pain in patients with TrPs in the popliteus muscle is pain in the back of the knee when crouching, running, or walking, especially while going downstairs, downhill, or wearing high heels. Trigger points in the popliteus muscle may produce stiffness that could make it painful and difficult to extend the knee when getting out of bed in the morning or standing up following a long period of sitting.⁴¹ Patients with popliteal TrPs rarely report of knee pain at night and are frequently not aware of their relatively slight decrease in range of motion at the knee or weakness of internal rotation of the tibia.

3.3. Patient Examination

If the popliteus muscle has TrPs, the knee is painful when the patient attempts to fully extend or flex it. The tibial attachment and tendon of the popliteus muscle should be examined for tenderness. The position described and illustrated to examine the knee for popliteus tendinitis^{25, 42} may also be used for examining the femoral end of the muscle and

its tendon. The seated patient places the leg of the affected limb on the opposite knee, leaving the foot to hang relaxed. The proximal attachment of the popliteus tendon on the lateral side of the femoral condyle is examined for tenderness, and the tendon is palpated along the 2-cm distance proximal to the point where it passes posteriorly deep to the fibular collateral ligament that is a well-defined landmark (Figure 61-2).²⁵ The TrP tightness of the popliteus muscle restricts the range of passive external rotation and weakens the active internal rotation of the leg with the knee flexed nearly 90°. To assess the popliteus muscle with an active functional test, the patient lies in the supine position with 90° of hip and knee flexion and is asked to resist the examiner's external rotation force on the tibia. If the maneuver reproduces the posterolateral pain of the patient, the test is considered positive suggesting popliteus tendinopathy⁴³ (Figure 61-4).

Figure 61-4. Popliteus tendinopathy assessment. The clinician, while palpating the popliteus muscle, provides an external rotation force to the tibia while the patient attempts to resist the movement. Production of symptoms in the posterolateral aspect of the knee may be indicative of popliteus tendinopathy.

The relatively small restriction of full knee extension (usually only 5°, possibly 10°) is often not clearly appreciated until retesting after treatment. Only then is the full range of normal extension for that patient's knee identified.

3.4. Trigger Point Examination

The popliteus muscle is palpated for TrPs with the patient lying on the affected side and the knee slightly flexed (Figure 61-5A) or with the patient positioned in hook-lying with the knee supported by the clinician (Figure 61-5B). Alternatively, the patient can lie supine with the hip in flexion and external rotation and the knee flexed comfortably. The slight

flexion of the knee slackens the overlying gastrocnemius muscle, whereas a plantar-flexed foot further slackens the gastrocnemius and plantaris muscles, and the external rotation of the leg places the popliteus muscle on a slight stretch that can be adjusted to increase tenderness of the popliteus TrPs for examination.

Figure 61-5. Palpation for TrPs in the lower medial part of the right popliteus muscle. The circle marks the medial condyle of the tibia. The patient lies on the affected side with the knee flexed, and the foot plantar is flexed at the ankle to place the gastrocnemius and plantaris muscles on slack. A, Cross-fiber flat palpation of the tibial attachment of the popliteus muscle is performed in a superior to inferior direction. The clinician also applies anterior pressure against the posterior surface of the tibia. B, Hook-lying cross-fiber flat palpation for TrPs in the popliteus muscle, as described in A. This position allows gravitational pull of the gastrocnemius muscle away from the tibia.

The medial side of the mid-part of the muscle is approachable between the semitendinosus tendon and the medial head of the gastrocnemius muscle along its attachment to the tibia.¹ The most distal portion of the tibial attachment of the popliteus muscle is covered by the soleus muscle¹ that can usually be displaced laterally to partially uncover the popliteus muscle. This medial, distal end of the popliteus muscle is examined for TrPs, as illustrated in Figure 61-5. It is important to displace the overlying muscles laterally as part of the examination.

In the popliteal space, the upper lateral end of the popliteus muscle is covered by the plantaris muscle and the lateral head of the gastrocnemius muscle. However, as the popliteus muscle crosses the leg diagonally just above the head of the fibula (Figure 61-2), it can be reached by palpating between the tendon of the biceps femoris muscle laterally and the lateral head of the gastrocnemius muscle and the plantaris muscle medially.⁴⁴ With the patient in one of the positions of Figure 61-5, these overlying muscles can be displaced to the side with one hand while palpating for TrPs with the other as needed. If the popliteus muscle has active TrPs, this spot will be painful, and pressure on it will cause diffuse pain referred throughout the back of the knee. The region of attachment of the popliteus tendon onto the tibia will also be painful.

If popliteus TrPs are sufficiently irritable, pain may be elicited by pressure exerted straight into the belly of the popliteus muscle through the overlying soleus muscle. The

proximal end of the soleus muscle runs nearly parallel with the popliteus muscle fibers and covers the distal half of them.⁴⁵ It is difficult to distinguish TrPs unambiguously in the intermediate portions of the popliteus muscle from TrPs in the intervening musculature.

4. DIFFERENTIAL DIAGNOSIS

4.1. Activation and Perpetuation of Trigger Points

A posture or activity that activates a TrP, if not corrected, can also perpetuate it. In the popliteus muscle, TrPs may be activated by unaccustomed eccentric loading, eccentric exercise in an unconditioned muscle, or maximal or submaximal concentric loading.⁴⁶ Specifically, TrPs may be activated in the popliteus muscle due to an overload produced by an eccentric contraction that takes place when there is internal rotation of the femur on the tibia in a closed kinematic chain,⁴¹ for example, when an individual plays soccer or football, runs, twists, slides, and especially, runs or skis downhill. This muscle is also specifically overloaded by breaking the forward motion of the femur on the tibia during a twisting turn with the body weight on a slightly bent knee of the side toward which the body is turning. Overload that causes a tear of the plantaris muscle may also activate TrPs in the popliteus muscle.

A trauma or strain that tears the posterior cruciate ligament of the knee can also overload and strain the popliteus muscle,^{47,48} which can then lead to the development of TrPs in the muscle.

Knee joint conditions such as meniscus tears, osteoarthritis, or hydrarthrosis can also activate and perpetuate TrPs in the popliteus muscle.⁴¹

Brody⁴² reported an association between an excessively pronated foot during weight-bearing activities and aggravation of popliteus tendinitis symptoms. The added stress from excessive pronation could also perpetuate TrPs in the popliteus muscle.

4.2. Associated Trigger Points

Associated TrPs can develop in the referred pain areas caused by TrPs.⁴⁹ Therefore, musculature in the referred pain areas for each muscle should also be considered. The TrPs in the proximal portion of either or both heads of the gastrocnemius muscle are the ones most commonly associated with TrPs in the popliteus muscle. Other muscles associated with TrPs in the popliteus muscle are the biceps femoris and vastus lateralis muscles.⁴¹ In a few patients, popliteus TrPs have been associated with a tear of the plantaris muscle and may have been activated when the plantaris muscle was torn.

With the foot dorsiflexed, the degree of pain in the popliteal fossa and restriction of motion at the knee caused by TrPs in the lateral head of the gastrocnemius muscle is comparable to that caused by TrPs in the popliteus muscle.

4.3. Associated Pathology

Popliteus TrPs are easily overlooked when a diagnosis of popliteus tendinitis or

tenosynovitis is the focus of attention. Other conditions to consider in the differential diagnosis of posterior knee pain include Baker cyst, thrombosis of the popliteal vein, anteromedial and posterolateral instability of the knee, avulsion of the popliteus tendon, and tear of a meniscus or of the posterior capsule of the knee joint.

One should be wary of blaming pain in the back of the knee on a torn plantaris muscle months or years after injury. In that case, the muscle should have healed. Such residual pain is more likely to be caused by TrPs in the popliteus muscle.

Popliteus tendinopathy and popliteus tenosynovitis are closely associated with activities that would overload an inadequately conditioned popliteus muscle. Mayfield⁵⁰ reported on 30 patients seen with the diagnosis of tenosynovitis in a 5-year period. The findings leading to this diagnosis are apparently more common than is generally appreciated.^{50,51} The characteristic symptom is pain in the lateral aspect of the knee on weight bearing with the knee flexed 15° to 30°, as when running or walking downhill.⁵⁰ Anterolateral knee pain has also been reported,⁵¹ as well as pain in the lateral knee after a direct hit to the knee in 90° of flexion, causing intermittent pain with running and short-distance walking.⁵¹ Backpacking enthusiasts reportedly spent days ascending into the mountains without symptoms until the end of the journey, but during a rapid descent out of the mountains, the symptoms developed.⁵⁰ Sometimes, pain is also experienced during the early part of the swing phase of gait and on attempting to rise from the cross-legged sitting position.⁵⁰ Brody⁴² also noted that symptoms were aggravated more readily when the patient walked on a slanted surface or performed some other activity that excessively pronated the foot during weight bearing.

The visualization of tenosynovitis through the use of ultrasonography has been well-documented.⁵² Ultrasound characterizations of this condition include increased size of the tendon, loss of homogeneity, and a hypoechogenic area surrounding the tendon due to inflammatory fluid.

Calcific tendonitis of the popliteus tendon is another condition that can present with lateral knee pain,⁵³⁻⁵⁶ mimicking popliteal tendinopathy or popliteal TrPs. It can also mimic symptoms of tear of the lateral meniscus.⁵⁵ The calcifications can be visualized with radiographs,^{53,54,56} ultrasound,⁵³ or magnetic resonance imaging (MRI).^{53,54}

In one study,⁵⁷ MRI of the normal popliteus tendon was sometimes mistaken for a tear in the posterior horn of the lateral meniscus. In another study of 200 knees,⁵⁸ the bursa of the popliteus tendon simulated a tear of the posterior horn of the lateral meniscus in 27.5% of the knees studied by MRI. This bursa can also be confused with a tear of the popliteus tendon or of the posterior capsule.²

Trigger points in the popliteus muscle can mimic the symptoms of a popliteal (Baker) cyst that produces pain in much of the same posterior region of the knee joint. The cyst produces a swelling, often painful, in the popliteal space that is caused by an enlargement of the bursa that lies deep to the medial head of the gastrocnemius muscle and/or an enlargement of the semimembranosus bursa, both of which normally communicate with the synovial cavity of the knee joint. The swelling may be more prominent in the standing

patient than in the recumbent one. Flexion of the knee increases discomfort. The swelling (effusion) is usually due to disease or injury of the knee joint, such as rheumatoid arthritis or a meniscal tear in adults, but not in children. If appropriate treatment does not relieve the swelling and pain, surgery may be considered directed to the intra-articular cause of the joint fluid production, not to the popliteal cyst, unless it is unduly large and highly symptomatic.⁵⁹ Although TrPs in the popliteus muscle may elicit deep tenderness in much the same region as a Baker cyst, the TrPs do not produce visible or palpable swelling. For differential diagnosis, MRI is the gold standard as it allows differentiation from other conditions. Ultrasound is also an option for diagnosis as its ability to detect Baker cyst is nearly 100%, although it lacks the specificity for differentiating it from other conditions.⁵⁹

Rupture of a Baker cyst may closely simulate thrombophlebitis. If the rupture of the Baker cyst is thought to be very likely, further imaging with a venogram, ultrasound, or arthrogram clearly shows the entry of dye from the knee joint into the region of the calf muscles should be considered before placement of antithrombotics.⁵⁹

The popliteus muscle is a major contributor to rotational stability of the knee joint. Together, the popliteus tendon and PFL are the primary stabilizers for external rotation of the knee at both 60° and 90° of flexion.^{60–62} These two structures can contribute to varus stability at 30° of knee flexion and also have a role of providing static stabilization of the knee in extension.⁶² Because of the important stabilizing function at the knee, tears in the popliteus tendon or other structures of the posterolateral corner of the knee can contribute to instability.⁶³

Surgical treatment typically has positive outcomes for the improvement of stability.⁶³ In cadavers, structures of the posterolateral corner have been resected, thereby demonstrating increased instability of the knee and altered kinematics. After reconstruction, kinematics improved.

Surgically shortening the popliteus muscle-tendon unit that was elongated or torn in eight patients, resulted in static and dynamic stability and return to full function in seven of them. None of the eight experienced any loss of power in the popliteus muscle.⁶⁴ Depending on which ligaments are lax or torn, excessive internal rotation of the femur on the tibia produces either rotary anteromedial instability⁶⁴ or rotary posterolateral instability.^{65,66} In either condition, surgical relocation of the tibial attachment of the popliteus muscle in order to shorten it increases its tension, improves its dynamic function, and corrects the problem.

Several cases of avulsion or rupture of the popliteus tendon have been reported.⁶⁷ Radiographs are commonly used initially, frequently showing the avulsion.^{68,69} However, in one case, it was reportedly normal.⁶⁷ As a result, MRI is better to evaluate the nature of the knee injury.^{67–69} The diagnosis can also be confirmed by an arthroscopic examination.⁶⁷

This injury may be treated conservatively or surgically by repairing the rupture and/or fixating the bone avulsion.⁶⁷ Satisfactory outcomes have been reported for both the surgical treatment^{70,71} and the nonsurgical treatment^{68,71}; however, the latter type of treatment

was not as successful in one subject.⁷¹

5. CORRECTIVE ACTIONS

The patient may wear a properly fitted, elastic sleeve brace (knee support) with an opening in front for the patella that extends from above the knee to below it. This device is consistently helpful and worth using as long as symptoms persist. It applies counter pressure over the region of the TrPs, reducing their sensitivity, and it reminds the patient that the knee should be protected.

Splinting or immobilizing the knee and leg with a stiff brace or cast tends to aggravate popliteus TrPs. When popliteus TrPs present a problem, immobilization should be avoided, or the period of immobilization be minimized, to prevent worsening of symptoms.⁷²

Before the patient can get back to participation in sports, it is best to gradually condition the muscle, starting with nonweight-bearing exercises and moving on to dynamic weight-bearing exercises.¹²

Individuals prone to popliteus TrPs should avoid a sudden increase in the amount of downhill running or walking because this change in activity could overload the muscle.⁵⁰ Additionally, high heels should be avoided, as wearing them is tantamount to continuously walking downhill.

Effort should be made to limit walking or running on laterally sloped surfaces, such as on the sides of paved roads designed for water drainage (the grade of which increases pronation of the foot and the effect of a longer lower extremity on the high side). Running can be performed on a track, on the crown of an empty road, or on the same side of the road for both directions of the trip. Appropriate shoe inserts should be utilized if indicated.

Trigger point self-pressure release may be performed in the seated position, as demonstrated in Figure 61-6. A patient should locate the popliteus muscle on the inside of the leg, just under the knee, by shifting the bulk of the calf muscle toward the outside of the knee and placing either a thumb, or two fingers along the backside of the shin to find a tender point. The patient should be careful not to place pressure on the popliteal vessels by gently feeling for a pulse behind the knee and avoiding it when locating the popliteus muscle. Firm pressure may be held on a TrP of the popliteus muscle for up to 30 seconds or until a decrease in tenderness is felt. This technique may be repeated several times until an adequate release is obtained.

Figure 61-6. Self-pressure release of the popliteus muscle. The patient sits with the foot of the leg to be treated resting on the floor. The thumbs or the fingers may be used to locate the popliteus muscle on the inside of the calf underneath the bulk of the gastrocnemius muscle.

Self-stretch of the popliteus muscle may be very difficult for a patient to perform independently without specific instructions and observation of the technique by a proper professional. The self-stretch is performed in the prone or seated position. In each position,

the knee is flexed 15° to 20°. If no one is available to be instructed as an assistant at home, reciprocal inhibition can be used instead of a passive stretch.

For the prone position, the patient lies on his or her stomach with enough blanket roll or pillow under the distal leg to flex the knee 15° to 20° (Figure 61-7A,B). The patient tries to rotate the leg externally for several seconds (reciprocally inhibiting the popliteus) and then relaxes fully. The cycle is repeated a few times. The advantage of this position is that the thigh is stabilized so that the leg, rather than the thigh, rotates. If the blanket roll or pillow touches the foot, friction may help maintain external rotation during relaxation. Otherwise, gravity pulls the foot and leg back into neutral position.

Figure 61-7. Self-stretch of the popliteus muscle. A, Prone starting position with pillow under the ankle to place the knee in slight flexion. B, Prone turning foot out to stretch the popliteus muscle. C, Sitting start position with the knee in slight flexion and weight of the leg is resting on the floor. D, Sitting foot turned outward to stretch the popliteus muscle. The hand above the knee ensures the thigh does not move.

For relaxation of the popliteus muscle in the sitting position, the seated patient places the leg forward with the heel on the floor and the knee flexed 15° to 20° (Figure 61-7C,D). A low-seated bench or chair may be required. As thigh rotation is often substituted for leg

rotation in this position, special care must be taken to ensure that the patient knows the difference and achieves external rotation of the leg at the knee. After a maximal external rotation effort for several seconds, the patient relaxes fully while gravity tends to maintain the external rotation. This cycle is repeated at least three times with a pause between each cycle.

Each stretching session is completed with a full active range of motion through internal and external rotation of the leg and then through knee flexion and extension.

Clinical Considerations of Hip, Thigh, and Knee Pain

César Fernández de las Peñas and N. Beth Collier

1. HIP OSTEOARTHRITIS

1.1. Overview

Osteoarthritis (OA) of the hip is a common cause of hip pain and dysfunction in older adults. Hip and knee OA was ranked as the 11th highest contributor to global disability and 38th highest in affecting quality of life.¹ Dagenais et al² reported an overall prevalence for hip OA ranging from 0.9% to 27%. Prevalence data on lower extremity OA is variable depending on the utilization of radiographic changes as a criterion for a diagnosis of OA.³ The American College of Rheumatology (ACR) has established criteria that are commonly used for the diagnosis of hip OA in clinical practice.⁴ However, because clinical criteria are usually combined with radiologic findings of hip degeneration, it is important to consider that there is little correlation between the presence of hip pain and radiologic evidence of degenerative changes. Patients with hip pain do not always exhibit radiographic changes associated with hip OA.⁵

Osteoarthritis is a metabolically active, dynamic process that involves all synovial joint tissues (cartilage, bone, synovium/capsule, ligaments, and muscles) and is characterized mainly by focal areas of loss of articular cartilage within the synovial joints associated with hypertrophy of the bone (osteophytes and subchondral bone sclerosis) and thickening of the joint capsule. Hip OA can result in hip capsular changes, cartilage degeneration, osteophyte formation, sclerosis of subchondral bone, and muscle weakness.⁶

Hip OA is considered to be a multifactorial condition where genetic, constitutional, and biomechanical factors occur at the same time. Among the constitutional factors, age is probably the most common predisposing factor for hip OA because this condition affects mainly individuals over 60 years of age.^{4,7} Other risk factors associated with the development of hip OA include a history of hip dysplasia,^{8,9} a previous hip injury,¹⁰ and an increased body mass index.¹¹

Individuals with hip OA usually experience debilitating pain. In fact, some people with

minimal radiographic changes exhibit severe symptoms, whereas other people with radiographic evidence of advanced joint degeneration have minimal symptoms.⁵ This inconsistency between symptoms and imaging findings should lead the clinician to consider the presence of nociceptive sensitization mechanisms in patients with hip OA. Although symptoms of pain in patients with hip OA can have mainly musculoskeletal origins, a recent systematic review has reported a prevalence of 23% of neuropathic pain in patients with knee or hip OA.¹² In fact, several studies have confirmed that individuals with hip OA exhibit central sensitization,^{13, 14} and when the nociceptive afferent input was removed (hip replacement), this process reversed.¹⁵ A recent study has reported that central sensitization may be a determinant of how much patients with hip or knee OA benefit from joint replacement, but the effect varies by the severity of structural changes in the joint.¹⁶ Therefore, current evidence supports the role of periarticular tissues surrounding the hip (eg, muscles) as a source of neuroplastic changes.

Most international clinical practice guidelines on hip and knee OA advocate for nonpharmacologic treatments as the first line of management, followed by pharmacologic treatment, and finally (if needed) surgery. The recommendations of the OA Research Society International include education, exercise, acupuncture, and weight reduction as nonpharmacologic therapies that are effective for hip OA.¹⁷ The European League Against Rheumatism produced an evidence-based clinical guideline for nonpharmacologic management of people with hip or knee OA that suggests a combined treatment approach including¹⁸ (1) education regarding OA, (2) regular individualized exercise programs, and (3) addressing weight loss if overweight or obese. Further, the UK clinical guidelines for management of hip OA also recommend the inclusion of manual therapy,¹⁹ although its effectiveness is questioned by others.²⁰ Similarly, the clinical practice guideline proposed by the ACR recommends the use of multimodal treatment, including manual therapy, for the management of hip and knee OA.²¹

1.2. Initial Evaluation of a Patient With Hip Osteoarthritis

The clinical presentation of hip OA is characterized by pain, stiffness, reduced movement or function, and variable degrees of local inflammation. A clinical diagnosis of hip OA is confirmed when patients present with one of the following clusters of clinical findings: (1) hip pain, hip flexion less than 115°, and hip internal rotation less than 15°; or (2) pain with hip internal rotation, duration of morning stiffness of the hip less than or equal to 60 minutes, and age over 50 years.⁴ These clinical criteria have shown a sensitivity of 86% and a specificity of 75%.⁴ A radiographic diagnosis of hip OA is made by viewing a narrowed joint space, osteophyte formation, or subchondral sclerosis on plain film radiographs.^{4, 22, 23} Sutlive et al²⁴ identified five possible clinical predictors for a diagnosis of hip OA, as defined by a Kellgren and Lawrence score of ≥2: pain with squatting, a positive scour test, pain with active hip flexion, pain with active hip extension, and passive range of motion of hip internal rotation less than 25°. The presence of symptoms potentially associated with hip OA diagnosis should alert the clinician to perform a thorough examination.

The clinician must perform a thorough subjective and physical examination that includes motor and sensory testing to establish whether the patient is appropriate for manual therapy or has any red flags indicating the need for referral to a physician. A human body pain drawing is beneficial to establish the location and area of the reported pain or symptoms. A pain drawing helps determine whether the reported pain is located mainly in the anterior, lateral, or posterior part of the hip or extends into the lower extremity. This drawing can be useful in monitoring the progression of the patient as symptoms improve and/or change. In addition, a report of the quality of the pain can help incriminate the main tissue responsible for the symptoms or pain referral.

Hip OA can lead to activity limitations, participation restrictions, or disabilities associated with walking, climbing stairs, getting in and out of a car, cycling, putting on shoes, and social participation. Therefore, it is essential that the clinical physical examination include the entire lower extremity, the pelvis, and the lumbar spine (see Chapter 53). The physical examination should include observation of posture, gait, active and passive range of motion testing, muscle length testing, muscle weakness, passive physiologic or accessory motion testing, palpation, and special tests to rule in or rule out OA and other conditions. All planes of motion of the hip should be assessed with active and passive movement testing. A patient with hip OA will present with restricted and painful hip range of motion, particularly in internal rotation and flexion.²⁵ Of particular interest is limitation of hip internal rotation because it is a predictive factor for the development of low back pain (LBP) in patients with hip OA.²⁶ The Flexion Abduction External Rotation (FABER) and scour tests can be used to further support a diagnosis of hip OA,^{25,27} although it should be recognized that the sensitivity and specificity of these tests are low.

Patients with hip OA exhibit a generalized muscle strength deficit of 20% in the affected lower extremity.²⁸ Of particular interest is gluteus medius muscle weakness. Patients with hip OA also demonstrate limited ranges of coordinated motion of the pelvis, femur, and hip joint, especially in deeply flexed and rotated positions.²⁹ Therefore, a comprehensive examination of the soft tissue surrounding the hip is essential, including the examination for trigger points (TrPs) in the tensor fasciae latae, gluteus medius, gluteus minimus, gluteus maximus, piriformis, pectineus, adductor longus, adductor brevis, adductor magnus, quadriceps femoris group, quadratus lumborum, iliopsoas, and other lumbopelvic muscles as indicated.

1.3. Trigger Points in Hip Osteoarthritis

The pain of hip OA is perceived as deep in the hip and/or groin area, and it is more likely to refer laterally than medially. Several muscles can refer pain to this area, mimicking symptoms of hip OA; however, most studies investigating TrPs in the hip musculature, eg, gluteus medius muscle, have been conducted in patients with LBP³⁰ or patellofemoral pain.³¹ Clinically, patients with hip OA present with weakness of the hip abductor muscles compared to the unaffected side and to healthy controls,²⁸ although the muscle

morphology is significantly different.³² Trigger points within the gluteus medius muscle can lead to inhibition weakness with no changes in the muscle cross-sectional area.

Older publications suggested that the referred pain from adductor longus TrPs may be mistaken for the pain of hip OA.^{33,34} Inactivation of the adductor longus TrPs provides satisfactory pain relief to some patients with hip OA.³⁵ Nevertheless, a more recent experimentally induced pain study has observed that hypertonic saline injection of the adductor longus caused regionalized pain distribution with pain in the groin.³⁶

Functionally, hip flexion and abduction range of motion, as seen in the FABER test position, can result from TrPs in the adductor muscles. Similarly, internal rotation of the hip can be limited by the presence of TrPs in the hip external rotation muscles, particularly the piriformis muscle. In fact, Izumi et al³⁶ found that hypertonic saline injections into the hip muscles led to a positive FABER test, suggesting that the test can be positive because of muscle pain and not just hip OA. Finally, the role of TrPs in hip OA is supported by the goals of the therapeutic management of hip OA because the objective is to increase the hip range of motion and strengthen both the hip and the knee musculature to reduce the excess load absorbed by the joint when hip/knee musculature is weak.

2. NONARTHRITIC HIP PAIN

2.1. Overview

Femoral Acetabular Impingement

Femoral acetabular impingement (FAI) is caused by repetitive approximation of an abnormally shaped femoral head and/or acetabulum at the end range of hip motion.³⁷ This process eventually leads to damage to the acetabular labrum and acetabular cartilage.³⁷ Osseous deformity of the femoral head/neck, or cam impingement, is most commonly seen in men aged 20 to 30 years and is the most common form of isolated FAI; osseous deformity of the acetabulum, or pincer impingement, is most commonly seen in women aged 30 to 40 years.³⁸⁻⁴⁰ However, the most common form of FAI is a combined impingement that has components of both cam and pincer impingement.³⁸ Ejler and Hogervorst⁴¹ have recently hypothesized that migration of the femoral head occurring in patients with cam or pincer impingement can lead to hip OA. These authors suggest that the impingement caused by femoral head migration can lead to hip joint cartilage damage.

Labral Tear

Acetabular labral tear is the most common intra-articular hip disorder and is commonly associated with other hip pathologies that may contribute to a patient's symptoms, such as FAI.⁴² It is commonly found in an athletic population because acetabular labral tears are often the result of repetitive microtraumas.⁴³ Patients with a symptomatic labral tear report anterior groin pain that may radiate medially, laterally, or posteriorly in the hip.⁴⁴ The patient may report clicking or "locking" of the hip, and symptoms are exacerbated with

activity.⁴² There is also a clinical overlap between symptoms from FAI and labral tears.

Athletic Pubalgia (Groin Pain)

Historically referred to as “sports hernia,” athletic pubalgia is defined as lower abdominal or groin pain without the presence of a hernia.⁴⁵ Other terms used to describe this condition include footballer hernia, inguinal insufficiency, conjoined tendon tear, hockey player’s groin, or Gilmore groin.⁴⁶ Typically experienced while performing athletic sport activities involving hyperextension or rotation, athletic pubalgia is thought to occur when the adductor longus muscle pulls on its insertion in the pubic symphysis in an unopposed fashion, as would occur with a weak or inhibited rectus abdominis muscle.⁴⁵ This pathogenic mechanism may explain why osteitis pubis and adductor tenoperiostitis coexist in these patients. Muscular imbalances and decreased hip range of motion may increase the risk of injury in the groin area.⁴⁷ Athletic pubalgia is more common in men because of the narrower and less stable nature of the male pelvis.⁴⁸ Proper management of athletic pubalgia includes strengthening exercises for the adductor and abdominal muscles.⁴⁹ Therefore, a careful examination of soft tissues surrounding the hip seems to be crucial in all these nonarthritic conditions.

2.2. Initial Evaluation of a Patient With Nonarthritic Hip Pain

The clinician must perform a thorough subjective and physical examination that includes motor and sensory testing to establish whether the patient is appropriate for manual therapy or has any red flags indicating the need for referral to a physician. A human body pain drawing is beneficial to establish the location and area of the reported pain or symptoms. A pain drawing helps determine whether the reported pain is located mainly in the anterior, lateral, or posterior part of the hip or extends into the lower extremity. This drawing can be useful in monitoring the progression of the patient as symptoms improve and/or change. In addition, a report of the quality of the pain can help incriminate the main tissue responsible for the symptoms or pain referral.

In FAI, symptoms are more common in the anterior area of the hip and sometimes spread to the medial area (groin pain). In labral tears, the groin and greater trochanter areas are the most common locations of referred pain.⁴⁴ Patients with athletic pubalgia report unilateral deep groin pain, lower abdominal pain, or pubic pain that are more proximal and deeper than a hip flexor or adductor muscle strain.⁵⁰

Westermann et al⁵¹ have recently observed that patient factors, including mental health, activity level, gender, and smoking, were more predictive of hip pain and function than were intra-articular findings during hip arthroscopy in subjects with FAI; therefore, a thorough clinical examination is crucial for these patients. The physical examination of a patient with nonarthritic hip pain should include observation of hip and pelvic posture and gait, active and passive hip range of motion, muscle length testing, muscle strength testing, passive physiologic or accessory motion testing, palpation, as well as special tests to rule in

or rule out FAI, labral tear, or other conditions. All planes of motion of the hip should be assessed with active and passive movements. The flexion, adduction, and internal rotation (FADIR) test, also called the impingement test, has been used for assessment of intra-articular pathologies such as labral tears and FAI. The meta-analysis conducted by Reiman et al⁵² found that the FADIR and the flexion-internal rotation tests accurately screen for diagnosis of FAI or labral tears. Similarly, subjects with athletic pubalgia and those who had recurrent symptoms compared with those who had recovered from their groin pain episode also exhibit reduction of internal and external hip range of motion.⁵³ Typically, a patient with nonarthritic hip pain will present with less than 20° of hip internal rotation measured at 90° of hip flexion; this clinical finding is also common in patients with hip OA and patients with LBP. Further diagnostic imaging may be indicated and should include radiography or magnetic resonance arthrography to visualize bony structures, joint integrity, and other surrounding soft tissue structures.⁵⁴

Patients with nonarthritic hip pain also exhibit weakness of the surrounding musculature, particularly the gluteal and adductor muscles. Therefore, a comprehensive examination of the following muscles should be performed for TrPs: gluteus medius, gluteus minimus, gluteus maximus, piriformis, adductors, pectineus, rectus abdominis, rectus femoris, and iliopsoas muscles.

2.3. Trigger Points and Nonarthritic Hip Pain

Similar to hip OA, as described previously, there is no study investigating the prevalence of TrPs in patients with FAI, labral tear, or athletic pubalgia. The patient's pain and symptom reports should dictate which muscles need to be examined for the presence of TrPs and their contribution to the patient's clinical presentation. For instance, in a patient with FAI, the pectineus, iliopsoas, and tensor fasciae latae muscles can be more relevant; whereas in a patient with athletic pubalgia, the rectus abdominis or adductor longus muscles might be more relevant.

3. GREATER TROCHANTERIC PAIN SYNDROME

3.1. Overview

Greater trochanteric pain syndrome (GTPS) refers to pain originating from any of the multiple structures that relate to the greater trochanter of the femur, including tendons and bursae. The tendons of gluteus medius, gluteus minimus, piriformis, obturator internus, obturator externus, and superior and inferior gemelli muscles all insert in some capacity to the greater trochanter and thus may cause pain if in an inflammatory state.⁵⁵ There are also multiple bursae in the area that lie between each layer of muscle in the region. Pathology of these bursae has historically been called trochanteric bursitis; however, recent diagnostic testing has revealed that the presence of inflammation in the bursa may be much less common than once believed.^{56,57} The incidence peaks between the fourth and sixth decades of life, with women more affected than men.

Gluteal tendinopathy, which encompasses overuse injuries to the gluteus medius or gluteus minimus tendons, commonly causes pain in the greater trochanteric area.⁵⁸ Muscle imbalances caused by weakness or abnormal tightness throughout the hip can predispose the tendons that attach to the greater trochanter to overload and thereby cause injury. A commonly observed muscle imbalance or altered muscle activation pattern in those patients with GTPS is an overcompensation by the tensor fasciae latae muscle in hip abduction leading to weakness and atrophy of the posterior portion of the gluteus medius muscle.⁵⁹ Therefore, conservative management of GTPS includes rest during the acute phase, followed by physical therapy, corticosteroid injections, and other analgesic modalities.^{60, 61}

3.2. Initial Evaluation of a Patient With Greater Trochanteric Pain Syndrome

The clinician must perform a thorough subjective and physical examination that includes motor and sensory testing to establish whether the patient is appropriate for manual therapy or has any red flags indicating the need for referral to a physician. A human body pain drawing is beneficial to establish the location and area of the reported pain or symptoms. A pain drawing helps determine whether the reported pain is located mainly in the anterior, lateral, or posterior part of the hip or whether it extends into the lower extremity. This drawing can be useful in monitoring the progression of the patient as symptoms improve and/or change. In addition, a report of the quality of the pain can help incriminate the main tissue responsible for the symptoms or pain referral.

Patients with GTPS may report pain with lying on the affected side, walking, and bearing weight on the affected leg. Pain is typically reported along the lateral hip and sometimes along the lateral thigh; the pain rarely spreads below the knee area.⁵⁶

The hip should be inspected for local visible signs of inflammation, particularly around the greater trochanter. Careful palpation should be performed in an attempt to identify anatomical structures responsible for the patient's clinical presentation.⁵⁶ In fact, palpation of the greater trochanter has been reported to be the most provocative test included in clinical exam for lateral hip pain.⁶² In the presence of gluteus medius tendinopathy, pain will be reproduced with resisted hip abduction and external or internal rotation, and the patient may exhibit a positive Trendelenburg sign. Lequesne et al⁶³ found that if single-leg stance can be held for less than 30 seconds, it has a sensitivity and specificity of 100% and 97.3%, respectively, for the diagnosis of gluteus medius tendinopathy.

Other factors that have been linked to lateral hip pain in the athlete include a wide pelvis, leg length discrepancy, excessive foot pronation, and poor running surfaces. Therefore, a thorough examination of the entire lower extremity should be carried out. Active hip range of motion, muscle length and strength testing, and passive physiologic or accessory motion testing should be conducted. Passive external rotation of the hip with the hip in 90° of flexion is typically the only painful provocative movement for patients with GTPS during hip range of motion assessment.⁶³

3.3. Trigger Points and Greater Trochanteric Pain Syndrome

There are several muscles that may refer pain to the greater trochanteric area when dysfunctional, including the following muscles: tensor fasciae latae, vastus lateralis, gluteus medius, gluteus minimus, gluteus maximus, piriformis, gemelli, and quadratus lumborum muscles. Differential diagnosis of specific source tissues can be difficult in GTPS, and palpation to implicate a bursa may be specific only with an acute inflammatory presentation of trochanteric bursitis. A recent randomized control trial reported that patients with GTPS who received either cortisone injection to the trochanteric bursae or deep dry needling to surrounding musculature obtained similar results in pain reduction and functional outcome measures.⁶⁴ Similarly, Jacobson et al⁶⁵ found that the application of tendon fenestration, a technique similar to dry needling, was equally effective as platelet-rich plasma injection for patients with GTPS. These studies would suggest that regardless of identifying the specific anatomical source of symptoms, treatment of TrPs in the surrounding area in a patient with suspected GTPS may be sufficient to relieve pain.

4. PIRIFORMIS SYNDROME

4.1. Overview

Piriformis syndrome describes a neuromuscular disorder in which the piriformis muscle compresses the sciatic nerve, inducing sciatic-type pain, paresthesias, and numbness in the buttocks and along the sciatic nerve pathway down to the lower thigh and into the leg. Patients with piriformis syndrome typically report pain deep in the buttock that may or may not have correlating symptoms of radiating pain down the leg and dysesthesias associated with the sciatic nerve. Onset of piriformis syndrome is most common in the fourth or fifth decade of life and can be associated with both sedentary and active lifestyles.⁶⁶ However, sometimes the piriformis muscle is not involved at all.⁶⁷

4.2. Initial Evaluation of a Patient With Piriformis Syndrome

It has been recently reported that the four most common symptoms of piriformis syndrome include buttock pain, pain aggravated on sitting, external tenderness near the greater sciatic notch, pain with any maneuver that increases piriformis muscle tension, and limitation in straight leg raising.⁶⁸ The patient may also report a loss in his or her hip range of motion or flexibility into internal rotation and adduction. Fishman et al⁶⁹ investigated the diagnostic utility of the flexion adduction internal rotation test (FAIR) to identify an operational definition of piriformis syndrome and found it to have a sensitivity of 0.81 and a specificity of 0.83. Therefore, a careful examination of the hip and pelvic regions should be conducted. Because the tissue source of symptoms in piriformis syndrome can be difficult to discern (muscle or sciatic nerve), neurodynamic tests can be used for assessing mechanical nerve sensitivity. The slump test is sensitive for diagnosing neuropathic pain in the lower extremity.⁷⁰ The entire lower extremity should be examined when a patient presents with symptoms consistent with piriformis syndrome because other conditions can also mimic these symptoms, as previously discussed.

4.3. Trigger Points and Piriformis Syndrome

All symptoms associated with piriformis syndrome can be directly related to the presence of TrPs in the piriformis muscle; however, there is no study that has explicitly investigated this association. Differentiating symptoms from compression of the sciatic nerve caused by a tight piriformis muscle, or sensory symptoms elicited by the pain referral associated with piriformis TrPs, is extremely difficult. Manual palpation of the muscle and exclusion of contribution from neural components by utilizing neurodynamic tests are key for differential diagnosis.

5. PATELLOFEMORAL PAIN SYNDROME

5.1. Overview

Patellofemoral pain syndrome (PFPS) is a condition causing pain at the anterior and/or medial knee during activities that load or compress the patella, such as prolonged sitting and climbing stairs. Importantly, PFPS is an “umbrella” term to describe pain in and around the patella in the absence of other pathologies. Although the prevalence of PFPS has been estimated to be as high as 40%, the annual incidence and prevalence of this condition are unknown.⁷¹ The pathophysiology of PFPS is not well understood, and the general consensus is that the etiology is multifactorial, including repeated knee microtrauma, muscle imbalances of the knee extensors, biomechanical dysfunctions in the lower extremity, and changes in nociceptive pain processing.^{72,73} For instance, biomechanical factors involved in PFPS include muscle strength imbalance between the activity of the vastus medialis muscle in relation to the vastus lateralis muscle, reduced flexibility, patellar tracking, altered quadriceps angle, and altered patellofemoral joint morphology.⁷⁴ In their review, Lankhorst et al⁷⁵ identified the following variables associated with PFPS: larger Q-angle, sulcus angle, patellar tilt, reduced hip abduction strength, weaker hip external rotation, and reduced knee extension peak torque. Pain from PFPS is also influenced by confounding psychosocial factors, such as fear-avoidance behaviors.⁷⁶

There is a plethora of treatments proposed for the management of PFPS. Barton et al⁷⁷ concluded that the treatment of PFPS should include gluteal and quadriceps femoris muscle strengthening, patellar taping, neuromuscular control exercises, education, and activity modification. The review conducted by Cochrane concluded that there is consistent, but low-quality, evidence regarding the effectiveness of exercise for patients with PFPS, but no data exists to determine the best form of exercise.⁷⁸ Historical therapeutic strategies for PFPS targeted the knee muscles, but research supports focus on the hip abductors and external rotators.⁷⁹ It would be reasonable to consider a potential role of TrPs as part of a rehabilitation plan of care.

5.2. Initial Evaluation of a Patient With Patellofemoral Pain Syndrome

Symptoms of PFPS usually include pain around the patella or surrounding areas (most

commonly in the anterior or medial areas), swelling, crepitus, and catching of the knee. Symptom behavior often includes aggravation with loading of the joint during activities such as climbing stairs, squatting (especially beyond 20°–30° of knee flexion), and sitting with knee flexion for a prolonged period of time. Hallmark clinical features of PFPS include quadriceps femoris and hip muscle strength deficit, particularly in the vastus medialis,⁸⁰ hip abductor, and hip external rotator muscles.⁷⁹ Patients with PFPS also exhibit quadriceps femoris muscle atrophy, which may primarily affect vastus medialis⁸¹ or the vastus lateralis muscles, or it may impact all the quadriceps femoris muscles.⁸²

Clinical assessment of a patient with PFPS should include provocative tests for pain from surrounding structures, assessment of kinetic chain influences, functional tests, and assessment of patellar mobility and palpatory tests.⁸³ A comprehensive manual exploration should be performed of the lower extremity musculature, including the following muscles: gluteus medius,³¹ gluteus minimus, piriformis, iliopsoas, pectineus, rectus femoris, vastus medialis, vastus lateralis, hamstrings, and gastrocnemius muscles. Additionally, the patient should undergo a thorough biomechanical analysis of weight-bearing activities, such as gait, running, and jumping, as pain allows. Patients with PFPS usually display excessive hip adduction and internal rotation, as well as contralateral pelvic drop during single-limb tasks when compared with healthy individuals.⁸⁴ If these impairments are identified, evaluation of hip and foot function and structure should be conducted to determine the source of biomechanical inefficiencies.

5.3. Trigger Points and Patellofemoral Pain Syndrome

Knee extensor musculature weakness with PFPS may be a result of inhibition of quadriceps femoris muscles or altered timing of muscle activation during functional activities caused by the presence of TrPs.⁸⁵ Referral pain patterns from several muscles (vastus medialis, rectus femoris, vastus lateralis, or vastus intermedius) can mimic the symptoms experienced by patients with PFPS; however, there is no epidemiologic study investigating the prevalence of TrPs in this population. Roach et al³¹ reported the presence of latent TrPs in the hip muscles (gluteus medius and quadratum lumborum) in patients with PFPS. In this study, reduced hip abduction strength was associated with the presence of latent TrPs. There is preliminary evidence suggesting that manual compression of TrPs surrounding the knee area, mostly applied to the vastus medialis muscle, is effective in the short and medium term for reducing symptoms in patients with PFPS.^{86, 87}

6. KNEE OSTEOARTHRITIS

6.1. Overview

Knee OA is a multifactorial degenerative disease influenced by age, genetics, and history of repetitive microtrauma of the knee. Hip and knee OA were ranked together as the 11th highest contributor to global disability and 38th highest in affecting quality of life.¹ The clinical diagnosis of knee OA is typically made using the ACR clinical criteria developed by

Altman that has been found to be 89% sensitive and 88% specific.⁸⁸ These criteria are age older than 50 years, less than 30 minutes of morning stiffness, crepitus on active motion, bony tenderness, and bony enlargement and/or no palpable warmth of synovium.⁸⁸ Clinical criteria are usually combined with radiologic findings of degeneration, although as with hip OA, pain in knee OA is highly individual, and no radiologic changes have demonstrated a robust correlation with pain manifestation.

Many structural features of the joint have been suggested to be involved in knee OA related-pain, including, but not limited to, the presence of osteophytes in the knee, focal or diffuse cartilaginous abnormalities, subchondral cysts, bone marrow edema, subluxation of the meniscus, meniscal tears, or Baker cysts.⁸⁹ The fact that no association exists between degenerative changes and symptoms has inspired researchers to investigate the presence of sensitization pain mechanisms in knee OA.^{90,91} Therefore, multimodal management of individuals with knee OA should include manual therapy, exercises, cognitive-behavioral therapy, neuroscience education, and pharmacologic drugs.⁹² The clinical practice guideline proposed by the ACR strongly recommends nonpharmacologic interventions for individuals with knee OA, including aerobic, aquatic, and/or resistance exercise as well as weight loss for individuals who are overweight.²¹ It has also been demonstrated that the addition of manual therapy and/or exercise can improve the cost-effectiveness of the management of patients with knee OA.⁹³

An important feature in knee OA is arthrogenic muscle inhibition caused mainly by a change in the discharge of articular sensory receptors arising from factors such as swelling, inflammation, joint laxity, and damage to joint afferents.⁹⁴ Interestingly, the presence of symptomatic, radiographic changes is not associated with deficits in the temporal recruitment of the vastus medialis and vastus lateralis muscles during stair climbing in subjects with knee OA.⁹⁵ This supports the notion that arthrogenic muscle inhibition is not the main cause of muscle pain and inhibition in this population.

6.2. Initial Evaluation of a Patient With Knee Osteoarthritis

The main clinical features in patients with knee OA are joint pain, stiffness in the morning or after rest, limited joint motion, night pain, and/or joint deformity. Although pain symptoms are located mainly in the knee area, the presence of diffuse pain distribution has also been found in this population as a result of sensitization mechanisms.⁹² Therefore, a thorough clinical examination and the use of pain-body diagrams can be helpful in determining the pain pattern in a patient with knee OA.

Abnormal knee loading is a key factor in OA progression⁹⁶; therefore, a comprehensive examination of the lower extremity is required. Biomechanically, knee OA is influenced by body weight, knee range of motion, and excessive varus or valgus moments during gait.^{96,97} Clinicians should explore the pelvis, hip, knee, and ankle joints for identification of dysfunctions that could contribute to increased loading in the knee. Active and passive range of motion (with and without overpressure), mobility tests, and muscle length in the lower extremity should be assessed.

Assessment of muscle strength and endurance is a key component of the clinical examination in patients with knee OA and should guide the rehabilitation program. In fact, quadriceps femoris muscle power⁹⁸ and strength⁹⁹ are predictive factors of radiographic and symptomatic knee OA. In this scenario, identification of active and latent TrPs in the musculature of the lower extremity should precede a therapeutic exercise program. Muscles that should be examined are gluteus medius, gluteus minimus, piriformis, iliopsoas, rectus femoris, vastus medialis, vastus lateralis, adductors, hamstrings, tibialis anterior, and gastrocnemius muscles.

6.3. Trigger Points and Knee Osteoarthritis

Evidence supports the role of myofascial pain and of TrPs in individuals with knee OA.¹⁰⁰ Studies describe patients with painful knee OA who also had active TrPs in the muscles surrounding the knee that reproduced the patient's symptoms.^{101–104} In these studies, the number of active TrPs was associated with the intensity of persistent pain, and the intensity of knee pain was inversely related to the physical function of the patients, meaning that patients with more intense pain experienced reduced physical function. Alburquerque-García et al¹⁰¹ found that the vastus medialis, vastus lateralis, and gastrocnemius muscles were the most affected by active TrPs. Bajaj et al¹⁰⁴ found that the rectus femoris, gastrocnemius, and vastus medialis muscles were the most affected. And Itoh et al¹⁰³ found that the quadriceps femoris, the iliopsoas, sartorius, hip adductors, and hamstring muscles were the most affected. In addition, referred pain areas evoked by intramuscular injection of hypertonic saline were also significantly larger in patients with knee OA.¹⁰⁴ Henry et al¹⁰² observed that patients with painful knee OA who were waitlisted for total knee arthroplasty surgery had active TrPs in the quadriceps femoris, hamstrings, and gastrocnemius muscles and experienced a significant reduction in pain reports 8 weeks after TrP treatment. Similarly, treatment of TrPs by different electrotherapy and manual therapy modalities has also been found to be effective in addressing pain in patients with knee OA.¹⁰⁵

When patients with knee OA undergo a total knee arthroplasty procedure, increased pain is typically experienced within the first month postsurgery, and TrPs have been found in patients following total knee arthroplasty. In a study of 40 subjects undergoing total knee arthroplasty as a knee OA intervention, Mayoral et al¹⁰⁶ investigated the effect of TrP dry needling on postoperative pain. Dry needling was performed after administration of anesthesia in the group assigned to treatment. Postoperative pain levels were compared between the group that received dry needling prior to surgery and the group that did not. Results showed reduced pain in the treatment group immediately after surgery and 1 month postsurgery, but no difference was found at 3 and 6 months postsurgery. This study demonstrates that in patients with knee OA who undergo total knee arthroplasty, TrPs likely play a role in a patient's pain experienced postoperatively.¹⁰⁶ Núñez-Cortés et al¹⁰⁷ described a case series of patients with pain following total knee arthroplasty in whom dry needling combined with therapeutic exercise was effective for improving pain, range of

motion, and function; however, the lack of a control group limits the extrapolation of the results. Nguyen¹⁰⁸ has proposed a hypothetical pain model where TrPs in the knee muscles can provoke muscle tightness, pain, and weakness leading to early pathologic neuromuscular changes including knee instability and, consequently, falls in older adults. In this model, long-term TrPs may promote knee instability and can facilitate degenerative changes in the knee joint, which will in turn, cause arthrogenous muscle inhibition typical of knee OA.¹⁰⁸ There is no study supporting this hypothesis, so further studies are warranted.

7. ILIOTIBIAL BAND SYNDROME

7.1. Overview

Iliotibial Band Syndrome (ITBS) typically presents with an insidious onset of lateral knee pain from functional overuse and is commonly seen in athletes, particularly runners.¹⁰⁹ The mechanism underlying ITBS is questioned in the scientific literature. The historically accepted theory of ITBS described friction occurring between the distal iliotibial band (IT band) and the lateral femoral epicondyle during repetitive knee flexion and extension activities.¹¹⁰ More recent research shows that the distal end of the IT band actually compresses against the lateral femoral epicondyle at 30° of knee flexion and is likely not flexible enough to move over the lateral femoral epicondyle as the friction theory suggests.¹¹¹ This conclusion may be related to the fact that the IT band is a thickening of the fasciae latae system of the thigh and is firmly connected to the linea aspera of the femur rather than being a separate, mobile band.¹¹²

Factors contributing to ITBS include downhill running, wearing worn-out or old shoes, leg length discrepancy, repetitive running on the same side of a road, excessive pronation of the foot, weakness of the gluteus medius muscle, and an increased Q-angle.¹⁰⁹

7.2. Initial Evaluation of a Patient With Iliotibial Band Syndrome

A body pain drawing is beneficial to establish a pattern and location of the pain. A pain drawing helps determine whether the pain is located mainly in the anterior, lateral, or posterior aspect of the knee or if the distribution of symptoms radiates to the leg. Patients affected by ITBS often report sharp and occasionally burning pain localized to the lateral aspect of the knee. These symptoms are exacerbated mostly by physical activity, particularly running, hiking, or jumping. A thorough examination of the lower extremity should be carried out to identify contributing factors such as pes planus that can contribute to the development of ITBS from increasing strain on the IT band caused by increased internal rotation of the leg during walking and running gait.¹¹⁰ The physical examination should include observation of the lower extremity during gait; active motion testing of the knee, hips, and ankle; manual palpation of muscles and structures; muscle length and strength assessment; passive physiologic or accessory motion testing; and any indicated orthopedic special tests. Symptoms may be provoked with the Noble Compression test that compresses

the IT band at the lateral femoral condyle as the patient performs active knee extension from an initial position of 90° of flexion.¹¹³ The Ober test or Modified Ober test may be used to assess for IT band length;¹¹⁴ however, this test may actually be assessing muscle length deficits of the tensor fasciae latae, gluteus maximus, and gluteus medius muscles, given the extensive attachments of these muscles to the IT band. The Thomas test may also be used to identify muscle length deficits of the iliopsoas, rectus femoris, and/or the tensor fasciae latae muscles. Of particular relevance would be the examination of myofascial restrictions or TrPs in the vastus lateralis, tensor fasciae latae, gluteus maximus, gluteus medius, piriformis, and distal biceps femoris muscles.

Because runners with ITBS show reduced hip abductor muscle strength in their affected lower extremity as compared with their nonaffected lower extremity and as compared with a control group,¹¹⁵ a functional assessment of muscle strength of the hip musculature is also crucial. Additionally, some patients with ITBS may also exhibit imbalances between the posterior fibers of the gluteus medius and tensor fasciae latae and/or the gluteus maximus and hamstring muscles.¹¹⁴ Therefore, assessment of hip function and strength is vital in order to design a comprehensive rehabilitation program for individuals with ITBS.

7.3. Trigger Points and Iliotibial Band Syndrome

Treatment of ITBS includes flexibility exercises targeting muscles that have an attachment to the IT band and strengthening exercises that avoid exacerbation of symptoms.^{110, 114} However, the strengthening phase should be initiated only once myofascial restrictions and/or TrPs have been addressed and normal flexibility has been established.^{113, 114} Therefore, identification and inactivation of TrPs is crucial for the proper management of patients with ITBS. However, the literature on this topic is scant. Pavkovich¹¹⁶ described a case report of a patient with a diagnosis of ITBS in whom the application of dry needling to the vastus lateralis and other thigh muscles was effective for reducing pain and improving function.

Clinically, it has been noted that TrPs in the vastus lateralis and tensor fasciae latae muscles directly refer pain in a pattern similar to that of ITBS. Dysfunction of these muscles, typically from overuse or sometimes direct trauma (in the case of the vastus lateralis muscle), can be the source of lateral knee pain symptoms. Given the anatomical relationship between the vastus lateralis muscle and the IT band, a hypertrophied or tonic vastus lateralis muscle will result in increased approximation to the overlying IT band, potentially resulting in a general lack of mobility and perhaps increased compression on the lateral aspect of the knee.

Additionally, the imbalance between the gluteus maximus, the posterior fibers of the gluteus medius, and the tensor fasciae latae muscles present in many patients with ITBS¹¹⁴ can also be related to the presence of TrPs in these muscles. Treating TrPs inhibiting the gluteus medius and minimus muscles could help improve stability to the pelvis during single limb-stance activity, as is required in running. Treatment aimed at TrPs and

neuromuscular retraining of the tensor fasciae latae muscle and inhibition of the gluteus maximus muscle, both of which share an attachment to the IT band, can restore normal biomechanical function of the IT band.

8. INJURIES OF THE KNEE

8.1. Overview

Articular structures of the knee, including ligaments and menisci, are commonly damaged during knee joint trauma. The anterior cruciate ligament (ACL) and the menisci are the structures most commonly affected, although injury or tears on the collateral ligaments are also highly prevalent. Globally, the annual incidence of ACL injuries is estimated to be 0.01% to 0.05%¹¹⁷, although these rates are higher in athletes.¹¹⁸ Medial collateral ligament injury is usually associated with an injury in the ACL and has an annual incidence of 0.24 per 1000 people roughly.¹¹⁹ Nevertheless, meniscal injuries are the most common intra-articular knee lesions and are the most frequent cause of orthopedic surgery.¹²⁰ Meniscal tears occur more frequently in the firmly attached medial meniscus but can also occur in the lateral meniscus.¹²¹ Injuries to the knee typically occur when a patient performs an abrupt or uncontrolled twisting maneuver with the foot planted, commonly referred to as a “noncontact injury.” The patient may report a “tearing” sensation or an audible “pop” at the time of injury, with later complaints of “locking” or “catching” in the knee in the case of meniscal damage or instability in the case of ACL injury. The patient typically presents with delayed effusion at the knee joint 6 to 24 hours after injury; immediate onset of a joint effusion is indicative of multistructural injury.

Different risk factors have been associated with knee injuries. In a meta-analysis, Snoeker et al¹²² reported strong evidence that age over 60 years, male gender, work-related kneeling or squatting, and climbing stairs were risk factors for degenerative meniscal tears. Additionally, strong evidence for associated acute meniscal injuries in soccer and rugby players was reported. This meta-analysis also concluded that waiting longer than 12 months between an ACL injury and a reconstructive surgery was a strong risk factor for a medial, but not lateral, meniscal tear.¹²²

Knee injuries, including ACL and meniscal tears, can be managed with conservative or surgical treatment, and the data is inconclusive on the best therapeutic options following ACL or meniscus injury. The Cochrane review concluded that there is insufficient evidence from randomized clinical trials to determine whether surgery or conservative management is best following ACL injury at 2 and 5 years postinjury.¹²³ Further, the incidence of radiologic knee OA is similar between patients treated conservatively and those who underwent surgical treatment and is also independent of the preoperative grade of laxity and the functional status of the patients.¹²⁴ Nevertheless, some authors suggest that the menisci should be repaired in patients with residual laxity on clinical assessment after ACL reconstruction because of a potential risk of failure of the ACL reconstruction.¹²⁵

Most clinicians support the implementation of exercise programs for management and also for prevention of knee injuries. This suggestion is based on the fact that scientific and

clinical research notes that the knee musculature demonstrates deleterious effects following a knee injury. A recent meta-analysis found that both the quadriceps femoris and hamstring muscles demonstrated reduced strength in patients with an ACL tear, but the reduction in quadriceps femoris strength was 3-fold greater than that in the hamstrings.¹²⁶ In fact, there is also evidence that neuromuscular and proprioceptive training reduces knee injury in general and ACL injury in particular, confirming the role of the dynamic knee stabilizer muscles in traumatic knee events.¹²⁷ Swart et al¹²⁸ concluded that exercise and meniscectomy yielded comparable results on pain and function; however, there is no evidence supporting one form of exercise over another.¹²⁹ In fact, quadriceps femoris muscle strengthening is an important milestone in the rehabilitation of knee injuries and is achieved through a combination of open and closed kinetic chain exercises. The clinical practice guidelines on ACL injury from the Dutch Orthopaedic Association and from the Orthopaedic Section of the American Physical Therapy Association (APTA) have found moderate to strong evidence that open and closed chain strength training had a positive effect on the strength of both the quadriceps femoris and hamstring muscles along with functional recovery in patients following knee injury.^{130, 131}

8.2. Initial Evaluation of a Patient after an Injury of the Knee

In any patient with a history of knee injury, clinicians must perform a thorough subjective and physical examination to establish whether the patient is appropriate for manual therapy or has any red flags indicating serious structural damage. In fact, current recommendations suggest the use of diagnostic imaging only when fracture is suspected based on the Ottawa Knee rules or when the physical examination is positive for meniscal or ligamentous knee damage.¹³² These guidelines are confirmed by the American College of Radiology Appropriateness Criteria for acute knee injury.¹³³

Patients with a meniscal tear typically experience joint line pain on the medial or lateral aspect of the knee, usually with maximum passive knee flexion and/or extension range of motion. Furthermore, these patients can also report the presence of “locking or blocking events,” mostly in maximum knee flexion. Patients with an ACL tear can experience deep pain inside the knee or sometimes pain at the insertion of the ligament; however, the main clinical symptom of an ACL tear is an anterior-to-posterior instability. Clinical assessment should include provocative tests of knee structures, active and passive range of motion, functional testing, assessment of patellar mobility, and palpatory examination of knee structures and associated musculature. Of particular interest is identification of aberrant knee joint movement, including hypo- or hypermobility. Several tests can be used to identify ACL tear (the Lachman test is the most sensitive [87.1%], whereas the pivot shift test is the most specific [97.5%])¹³⁴ and meniscus tear (McMurray test: sensitivity 61%, specificity 84%; joint interline pain tenderness: sensitivity 83%, specificity 83%; Thessaly test: sensitivity 75%, specificity 87%).¹³⁵

Altered quadriceps femoris and hamstring muscle activation patterns may change anterior shear forces and knee extensor moments, making the individual more susceptible

to an ACL injury. Hewett et al¹³⁶ reported altered quadriceps femoris and lowered hamstring muscle activation strategies, along with lowered hamstring muscle to quadriceps femoris torque ratios after ACL rupture. Therefore, examination of knee injuries should include muscle strength, power, endurance, and flexibility assessment. All musculature of the lower extremity should be examined, including gluteus medius, gluteus minimus, hip external rotator, hip adductor, rectus femoris, vastus medialis, vastus lateralis, hamstrings, and gastrocnemius muscles. Other factors, including psychosocial elements, such as hypervigilance, catastrophization, and fear avoidance behaviors should also be identified.

8.3. Trigger Points and Injuries of the Knee

Although research is lacking on the relationship between ACL or meniscal tears and TrPs, it is commonly seen in clinical practice that pain referral from the vastus medialis, vastus lateralis, rectus femoris, sartorius, adductor longus, and adductor brevis muscles can mimic similar symptoms of a medial or lateral meniscal tear, and therefore, they should be considered in the differential diagnosis of a patient presenting with knee pain after an injury. Similarly, active TrPs in the knee musculature can be activated after a knee injury, with or without an associated ACL injury. Torres-Chica et al¹³⁷ found a higher number of active TrPs in the quadriceps femoris muscle, but particularly within the vastus medialis muscle, in individuals experiencing pain following a meniscectomy. Additionally, the number of active TrPs was associated with the intensity of knee pain after surgery. These authors hypothesize that TrPs could have developed from dynamic mobility changes that commonly occur after a meniscal tear or from the physiologic changes produced by the surgery itself.¹³⁷ Velázquez-Saornil et al¹³⁸ have recently observed that the inclusion of dry needling of active TrPs in the vastus medialis muscle into a rehabilitation protocol was effective for increasing range of motion and function in patients after surgical reconstruction of complete ACL rupture. Because the vastus medialis muscle is the main stabilizing muscle of the medial aspect of the knee, it seems that this muscle is the most affected by TrPs in patients after they experience a knee injury. Therefore, the presence of active TrPs in the knee muscles could be related to deficits in muscle strength (inhibition weakness) and proprioception.

9. HIP AND KNEE NERVE ENTRAPMENTS

9.1. Overview

Radicular pain typically extends from the lumbar spine into the lower extremity and generally distal to the knee in the case of lumbar or sacral nerve root compression or inflammation. Pain that extends beyond the gluteal region and into the leg is often a result of nerve irritation. Symptoms can include referral to the lower thoracic or upper lumbar region, abdomen, flanks, groin, genitals, thighs, knees, calves, ankles, feet, and toes. Lumbar radicular pain is considered a subclassification of LBP and is often characterized by a radiating pain in one or more lumbar dermatomes that may or may not be accompanied

by other radicular irritation symptoms.^{139,140} Symptoms of radiculopathy may include numbness, motor loss, muscle wasting, weakness, and loss of reflexes. Prognostic indicators of successful recovery in cases of radicular pain or radiculopathy include patients with higher education levels, working full-time, and with low fear avoidance; predictors of nonsuccess include higher patient age and the presence of reflex impairments.¹⁴¹

In a systematic review, Hahne et al¹⁴² found moderate evidence that stabilization exercises are better than no treatment at short-term follow-up and that manipulation is better than sham manipulation at short-term and intermediate-term follow-up for people with acute lumbar disc herniation and radicular symptoms who had an intact annulus.

9.2. Initial Evaluation of a Patient with Nerve Entrapment

The presence of discogenic pain has also been discussed in Chapter 53 of this textbook. Therefore, in this chapter, we will focus on diagnosis differentiation with other hip and thigh conditions that cause pain or other symptoms in this region. Symptoms associated with radicular pain or nerve entrapment include pain in dermatomal patterns. The most common affected nerves are the femoral (anterior hip or thigh pain) and sciatic (posterior thigh, knee, or leg pain) nerves. Therefore, proper examination should differentiate between radicular, peripheral nerve, and myofascial pain symptoms. The presence of urinary retention, saddle anesthesia, or bilateral neurologic symptoms represents potential red flags, and the patient should be referred to a physician.

In common nerve entrapment clinical presentations, the LBP clinical practice guideline from the Academy of Orthopaedic Physical Therapy, of the APTA classifies patient presentations as LBP with radiating pain.¹⁴³ Initial evaluation of patients within this clinical classification should include movement testing to assess for specific directional movements of lumbar active range of motion that may provoke or relieve symptoms; nerve mobility testing such as a straight leg raise and/or slump test; and neurologic testing, including sensory, motor, and reflex testing.¹⁴³ Forward trunk flexion is usually accompanied by peripheralization of pain symptoms toward the legs or buttocks. Repeated movement into flexion often worsens the nature of the symptoms. The straight leg raise is a common provocation test used when differentially diagnosing lumbar radicular pain or radiculopathy from other neurogenic causes. Other neurodynamic tests that can be used are the slump test or the femoral nerve slump test.¹⁴⁴ Once radicular pain or other nerve involvement has been excluded or identified, TrPs should be investigated.

9.3. Trigger Points and Hip and Knee Nerve Entrapment

Referred pain from TrPs can be easily mistaken for common reports of radicular pain. In addition, TrPs can also be activated on account of nerve root irritation. In fact, the presence of gluteal TrPs showed a high specificity (91.4%) of predicting lumbar radiculopathy, as confirmed with diagnostic magnetic resonance imaging.¹⁴⁵ Active TrPs in the gluteal muscles were significantly correlated with the same side as reported radiating

pain.¹⁴⁶ Therefore, examination of those muscles innervated by the nerve root affected (eg, gastrocnemius with L5, S1 nerve root involvement, rectus femoris with L2, L3 nerve root involvement) is crucial because active TrPs could be the source of, or a contributing factor to, the patient's symptoms. Additionally, patients who failed spinal surgery for lumbar nerve root decompression have been found, on multiple occasions, to present with active TrPs in the piriformis and other muscles of the back and hip, suggesting that TrPs in associated muscles can serve as persistent pain generators, even after decompression of nervous tissue in this patient population.¹⁴⁷

Leg, Ankle, and Foot Pain

Tibialis Anterior Muscle

“Foot Drop Muscle”

Wesley J. Wedewer

1. INTRODUCTION

As the strongest dorsiflexor of the ankle, the tibialis anterior muscle is one of the main muscles of ambulation. It commonly develops trigger points (TrPs) and produces pain over the anteromedial ankle and the dorsal and medial surfaces of the great toe. On occasion, pain may refer to the anterior leg and dorsal ankle. This muscle is important for force absorption and foot clearance during ambulation and plays a key role in dynamic standing balance. Trigger points in the tibialis anterior muscle can be caused by strenuous walking, running, and climbing. Walking down hill, or on rough or uneven terrain can also activate TrPs in the tibialis anterior muscle. The differential diagnosis should include L5 radicular pain and/or radiculopathy, chronic exertional compartment syndrome, shin splints, and herniation of the tibialis anterior muscle. Corrective actions are self-pressure release, self-stretching tight antagonist gastrocnemius-soleus muscles and the tibialis anterior muscle, and activity modification to reduce recurrent overload of the muscle.

2. ANATOMIC CONSIDERATIONS

The tibialis anterior muscle is subcutaneous just lateral to the anterior sharp edge of the tibia. It is thick and fleshy at its upper portion and becomes tendinous in the lower third of the leg (Figure 63-1). It originates proximally from the lateral condyle of the tibia, the superior half or two-thirds of the lateral surface of the tibia, the deep surface of the deep fascia, the adjacent interosseous membrane, and the intermuscular septum between itself and the extensor digitorum longus muscle.¹ The fibers of the tibialis anterior muscle converge on their aponeurosis and tendon in circumpennate form, like the spokes of a wheel, and insert into an internal axial tendon that extends the length of the muscle.^{2,3} The tendon descends and crosses in front of the tibia to the medial side of the foot where it inserts distally on the medial and plantar surfaces of the medial cuneiform and the base of

the 1st metatarsal.^{1,4} Brenner⁴ found variations in the attachment of the tibialis anterior muscle in the dissection of 156 feet. In the typical presentation, 96.2% inserted on both the 1st metatarsal and medial cuneiform, 1.9% had a single insertion at the 1st metatarsal base, and 1.3% had an insertion at the medial cuneiform. A subtendinous bursa was detected in 17.3% of cases. In a separate cadaveric study, the majority of specimens showed a larger overall area of the tendon footprint (3:2) at the medial cuneiform compared with the 1st metatarsal. Additional tendon slips were observed in 4.8% of specimens; inserting at the proximal 1st metatarsal shaft and at the distal metatarsal shaft.⁵

Figure 63-1. Attachments of the right tibialis anterior muscle (red), anterior view. The foot is turned outward to show the distal attachments to the medial cuneiform and 1st metatarsal bones.

The distribution of motor endplates was studied by staining longitudinal cryosections of whole tibialis anterior muscles for cholinesterase. The neuromuscular junctions were diffusely distributed, with the greatest concentration found toward the periphery and toward the proximal end of the muscle.⁶

A cross-section at the lower part of the middle third of the leg (Figure 63-2) shows the unyielding fascial structures and bones that form the anterior compartment. The tibialis anterior muscle shares this relatively small compartment with the extensor digitorum longus, extensor hallucis longus, and fibularis tertius muscles, the deep fibular nerve, and the anterior tibial artery and vein. The deep fibular nerve and anterior tibial vessels lie on the interosseous membrane deep to the tibialis anterior muscle.¹

Figure 63-2. Cross-section outlining the compartments of the middle third of the right leg, viewed from above. The anterior compartment is located anterior to the interosseous membrane, medial to the shaft of the fibula, and lateral to the shaft of the tibia, and it is bound anteriorly by the deep fascia of the leg. (After Figure 4-72 in Anderson JE. *Grant's Atlas of Anatomy*. 8th ed. Baltimore, MA: Williams and Wilkins; 1983 [p. 107]).

2.1. Innervation and Vascularization

The deep fibular nerve supplies the tibialis anterior muscle with fibers from ventral rami of the L4 and L5 spinal nerves^{1,7} and sometimes⁷ the S1 spinal nerve of the sacral plexus.

The vascularization of the inextensible anterior compartment of the leg is supplied by a series of medial and anterior branches of the anterior tibial artery. Proximally, there is an accessory supply from the anterior tibial recurrent artery. The tibialis anterior tendon is supplied by the anterior medial malleolar artery, dorsalis pedis artery, medial tarsal arteries, and by the medial malleolar and calcaneal branches of the posterior tibial artery.^{1,8}

2.2. Function

The tibialis anterior muscle has important functions in posture and gait. It maintains standing balance by controlling excessive posterior postural sway and assists in keeping the leg vertical over the fixed foot.^{9–12} The tibialis anterior muscle functions eccentrically in gait for force absorption to control lowering of the foot following initial contact^{13–16} and functions concentrically for foot clearance in the swing phase of gait.^{14,15}

In the nonweight-bearing limb, the tibialis anterior muscle dorsiflexes the foot at the talocrural joint and supinates (inverts and adducts) the foot at the subtalar and transverse tarsal joints^{1,17}; however, it is not active as an invertor during plantar flexion.¹⁸ In standing, the tibialis anterior muscle becomes more active with leaning backward, and activity ceases when leaning forward, at any rate of movement.^{9,10} The further one leans back, and the closer the center of pressure moved toward the heel, the greater the electromyographic (EMG) activity of the tibialis anterior muscle.¹¹ Additionally, this muscle contributes to lateral sway control for narrower stances, such as feet together and tandem stance.¹⁹ Di Giulio et al¹² identified the deep compartment of the tibialis anterior muscle as the best mechanical source of proprioceptive information among the ankle muscles in maintaining human upright posture.

The potential active role of the tibialis anterior muscle during standing has relevant implications for fall prevention in the elderly. Middle-aged adults exhibit impaired mediolateral postural control at the ankle compared with young adults.²⁰ Reduced ankle strength and rate of torque development of ankle dorsiflexor muscles have been suggested as key factors that distinguish those individuals who fall from those who do not.²¹

The primary peak of EMG activity in the tibialis anterior muscle occurs at initial contact^{14,15,22} during all speeds of ambulation.²³ More specifically, the ankle dorsiflexors (tibialis anterior and long extensor muscles of the toes) prevent foot slap just after initial contact; they undergo a lengthening contraction as they control the descent of the foot to the floor. The secondary peak, during walking, appears at terminal stance^{14,15,22} at all speeds of ambulation.²³ Dragging of the toes at the beginning of the swing phase is commonly due to inadequate hip and knee flexion; later in swing, as the limb moves forward, toe dragging results from inadequate dorsiflexion.²⁴

In healthy children, aged 6 to 11 years old, a third of the activation pattern is present during mid-stance, likely due to the tibialis anterior muscle controlling balance during single limb support.²⁵ In a similar study of healthy children, greater than 80% of the gait

cycle resulted in cocontractions of the gastrocnemius muscle lateral head and tibialis anterior muscle. This increased complexity in muscle recruitment strategy beyond pure activation suggests that cocontractions are likely functional to further physiologic tasks such as balance improvement and joint stability.²⁶

In comparison with level and upslope walking, downslope treadmill walking imposes increased demands on the tibialis anterior muscle. For instance, during downslope walking, there is increased displacement of the center of mass anteriorly and increased foot deceleration moments at initial contact.²⁷ The deceleration moment is produced by a significant eccentric tibialis anterior muscle contraction to control the lowering of the foot from initial contact to the loading response.²⁸ This eccentric effort leads to delayed onset muscle soreness that is unique to downslope walking,²⁹ and it may also contribute to the formation of TrPs in the tibialis anterior muscle.

The pattern of EMG activity of the tibialis anterior muscle changes between jogging, running, and sprinting. During jogging and running, activity begins just after terminal stance and continues throughout the remainder of the swing phase and the first half of the support (stance) phase. However, during sprinting, EMG activity ceases briefly at mid-swing when plantar flexion of the foot begins.³⁰ Muscle activity varies between runners who strike on the rearfoot versus the forefoot. Runners who strike with the rearfoot land with greater dorsiflexion than those who land with the forefoot, and there is greater tibialis anterior muscle activity before foot contact. In contrast, runners striking primarily on the forefoot have greater gastrocnemius muscle activity than those who strike on the rearfoot.^{31, 32}

This muscle is moderately to vigorously active during most sports activities.^{33, 34} Its type 1 (slow-twitch) fibers that predominate, whereas type 2 (fast-twitch) fibers compose, at most, only one-third of the muscle. The type 2 oxidative muscle fibers, with an inherent resistance to fatigue, support the muscle's primary function for long-duration aerobic activities.³⁵⁻³⁷

2.3. Functional Unit

The functional unit to which a muscle belongs includes the muscles that reinforce and counter its actions as well as the joints that the muscle crosses. The interdependence of these structures is reflected functionally in the organization and neural connections of the sensory motor cortex. The functional unit is emphasized because the presence of a TrP in one muscle of the unit increases the likelihood that the other muscles of the unit will also develop TrPs. When inactivating TrPs in a muscle, one must be concerned about TrPs that may develop in muscles that are functionally interdependent. Box 63-1 grossly represents the functional unit of the tibialis anterior muscle.³⁸

Box 63-1 Functional unit of the tibialis anterior muscle

Action	Synergists	Antagonists
Dorsiflexion of the foot	Extensor digitorum longus Extensor hallucis longus Fibularis tertius	Gastrocnemius Soleus Fibularis longus and brevis Long flexors of the toes Tibialis posterior
Inversion of the foot	Tibialis posterior Extensor hallucis longus	Fibularis longus and brevis Fibularis tertius Extensor digitorum longus

3. CLINICAL PRESENTATION

3.1. Referred Pain Pattern

The tibialis anterior muscle can exhibit TrPs in any part of the muscle. Commonly, TrPs found in the upper third of the muscle refer pain and tenderness primarily to the anteromedial aspect of the ankle and over the dorsal and medial surfaces of the great toe (Figure 63-3).^{39,40} In addition, sometimes, the pain may extend downward over the shin to the ankle and foot anteromedially.^{39,41,42} Other authors reported that tibialis anterior TrPs referred pain to the anterior leg and dorsal ankle^{43,44}; dorsal ankle and dorsal region of the great toe⁴⁵; to the leg, ankle, and foot; or specifically, to the dorsal surface of the great toe.^{46,47} Occasionally, a taut band with spot tenderness occurs distally along the lower half of the muscle near the musculotendinous junction. The referral pattern in the latter case is severe burning pain in the foot and knee that is exacerbated with long periods of standing.⁴⁸ Tibialis anterior TrPs are occasionally the source of the chief report of pain in children. The referred pain pattern is similar to that seen in adults.⁴⁹

Figure 63-3. Pain pattern (dark red) referred from a TrP in the right tibialis anterior muscle (light red), as seen in the anterior view with the foot slightly abducted. The essential pain pattern is solid red; the red stippling indicates occasional extension of the essential pattern.

In 15 subjects, Rubin and colleagues⁵⁰ injected the tibialis anterior muscle with 0.5 mL of 5% hypertonic saline solution. The injection caused a deep, dull ache in the muscle belly, and often referred pain to the front of the ankle and dorsum of the medial foot. Several subjects had pain only referred to the ankle, whereas others had pain only in the leg. Additionally, one subject reported pain internal to the medial and dorsal surface of the knee, another reported pain in the medial gastrocnemius muscle, and a third reported pain

proximal to the ankle joint. After injection of lignocaine, pain disappeared in all but two subjects, where the mean total pain intensity of primary and referred pain declined in parallel by 74%, suggesting that referred muscle pain usually depends on ongoing noxious inputs from the site of primary pain.⁵⁰

The typical referral outlined earlier is similar to the pattern Kellgren described.⁵¹ Gibson also found the same referral patterns induced by injection of hypertonic saline into the tibialis anterior muscle belly, proximal tendon-bone junction, and tendon. Several of the subjects also noted referral into the toes as well.⁵²

3.2. Symptoms

Patients with TrPs in the tibialis anterior muscle primarily report pain on the anteromedial aspect of the ankle and in the great toe. Other reports of symptoms may include the following: weakness of dorsiflexion that can present as falling or tripping due to insufficient toe clearance during gait, as well as general weakness of the ankle. Painful motion of the ankle may bother the patient in the absence of any evidence of joint injury.³⁹ Loss of function is especially evident when TrPs in the long extensor muscles of the toes contribute to additional dorsiflexion weakness.

Usually, patients with tibialis anterior TrPs do not report nocturnal pain, and a plantar flexed position of the ankle throughout the night does not bother this muscle unless its TrPs are sufficiently active to cause some degree of constant referred pain. Tibialis anterior myofascial pain syndrome occasionally presents alone as a single-muscle syndrome, but more commonly occurs in association with TrPs in other leg muscles.

3.3. Patient Examination

After a thorough subjective examination, the clinician should make a detailed drawing representing the pain pattern that the patient has described. This depiction will assist in planning the physical examination and can be useful in monitoring the progression of the patient as symptoms improve or change. The type, quality, and location of the pain should be carefully assessed, and the utilization of standardized outcome tools is imperative when examining patients with lower extremity dysfunctions.

Observation of static and dynamic posture is essential due to the role of the tibialis anterior muscle in postural stability. Functional testing such as double- and single-leg squat will allow a quick assessment of hip and knee control, as well as a quick assessment of dorsiflexion range of motion. Functional dorsiflexion is best tested by asking the subject to walk on the heels.¹ Timed single-leg stance with eyes open and closed will give a quantitative measure of balance and will allow the clinician to observe foot and ankle strategies related to balance and control.

Examination of the talocrural joint is necessary to identify a tight Achilles tendon or muscle length deficits in the gastrocnemius/soleus muscle complex, reduced accessory motion, or excessive pronation evident at the subtalar joint. These impairments can be significant contributing factors in tibialis anterior muscle overload during weight-bearing

activities.⁵³ A thorough gait analysis will assist in identifying compensatory patterns if the tibialis anterior muscle is weak or painful including the following: waddling gait (demonstrated by a lean to the contralateral side and “hiking” the hip), swing-out gait (in which the dysfunctional leg is circumducted laterally), or high-stepping, steppage gait (with excessive flexion at the hip and knee) to clear the toes in the swing phase.⁵⁴

Trigger points in this muscle cause some degree of inhibition weakness. This weakness is easily masked by compensatory contraction of the long extensor muscles of the toes or the fibularis tertius muscle. To test the tibialis anterior muscle for strength, the seated patient first inverts and then dorsiflexes the foot against resistance without extension of the great toe.⁵⁵ The clinician should observe the patient for foot slap and/or foot drop during ambulation. Foot slap occurs when the forefoot slaps to the floor immediately following heel strike. Foot drop is a failure to dorsiflex the foot sufficiently to provide adequate clearance between the toes and the floor, particularly during late swing.

Active or latent TrPs in the tibialis anterior muscle restrict the stretch range of motion into plantar flexion and eversion because of pain and muscle tightness. Deep palpation over the ankle and great toe may provoke pain in a patient with TrPs of the tibialis anterior muscle secondary to its pain referral pattern.³⁹

3.4. Trigger Point Examination

For examination of the tibialis anterior muscle, the patient may be positioned in long sitting or preferably supine (Figure 63-4). A pillow or bolster may be placed under the patient's knees to ensure relaxation. The most common TrP region is located at the sharp edge of the tibia at the junction of the proximal and middle third of the leg, approximately;⁴⁴ however, the entire muscle should always be thoroughly examined. Cross-fiber flat palpation reveals taut bands and TrP spot tenderness in the muscle mass lateral to the tibia (Figure 63-4). The taut bands in this muscle are parallel to the tibia. Digital pressure applied to a TrP will usually evoke or intensify the pain referred to the anterior ankle³⁹ and dorsum of the foot.

Figure 63-4. Cross-fiber flat palpation of TrPs in the left tibialis anterior muscle.

A recent study examined three ankle muscles, one of which was the tibialis anterior muscle, and found fair to moderate reliability for the presence or absence of TrPs (agreement 70%-85% and kappa 0.25-0.48), the presence of referred pain (agreement 63%-78% and kappa 0.26-0.51), and the palpation of a nodule in a taut band in the tibialis anterior muscle (agreement 65%-90% and kappa 0.25-0.43). The identification of a local twitch response and a jump sign by manual palpation was unreliable in this muscle.⁴⁰

4. DIFFERENTIAL DIAGNOSIS

4.1. Activation and Perpetuation of Trigger Points

A posture or activity that activates a TrP, if not corrected, can also perpetuate it. In any part of the tibialis anterior muscle, TrPs may be activated by unaccustomed eccentric loading, eccentric exercise in an unconditioned muscle, or maximal or submaximal concentric loading.⁵⁶ Trigger points may also be activated or aggravated when the muscle is placed in a shortened and/or lengthened position for an extended period of time.

Trigger points of the tibialis anterior muscle are likely to be activated by similar mechanisms as those that could result in other significant ankle injuries. Any force that could cause an ankle sprain or fracture or exertional overload sufficient to induce anterior compartment syndrome could also result in TrPs of the tibialis anterior muscle.

The TrPs of the tibialis anterior muscle are often the result of serious gross trauma but can also occur from overuse (repetitive, micromechanical trauma) injuries. Walking or running downhill can increase eccentric load placed on the anterior compartment muscles and activate tibialis anterior TrPs. Additionally, wearing shoes with an elevated heel, such as cowboy boots or high heels, will further increase the demand of the ankle dorsiflexor

muscles. Untrained persons ambulating on rough terrain, hard surfaces, or unusually soft surfaces (such as sand) for extended distances may also be predisposed to developing myofascial dysfunctions of the lower extremity.

Maximum angular velocity of the ankle joint during kicking in amateur soccer players is as high as 1720° per second in men and 1520° per second in women.⁵⁷ Activation of the tibialis anterior muscle is greater during the side-foot kick compared with the instep kick.³⁴ These forceful contractions can contribute to the development of TrPs and associated pain in the tibialis anterior muscle. This situation is commonly seen in athletes who are unaccustomed to the task or who quickly increase their training load, such as in the transition from offseason to preseason.

Catching the toe on an obstruction during the early-swing phase (tripping or stumbling during the contraction phase of the tibialis anterior muscle) can cause eccentric contraction overload that activates or perpetuates TrPs in this muscle. Athletes participating on artificial turf versus grass are more likely to experience this event, and it may occur simultaneously with a turf toe injury.⁵⁸ The overload is aggravated by a proportional increase in the reflex response to sudden stretch, a response that ranges from 0% to 40% of maximum voluntary contraction.⁵⁹

4.2. Associated Trigger Points

Associated TrPs can develop in the referred pain areas caused by TrPs.⁶⁰ Therefore, musculature in the referred pain areas for each muscle should also be considered. The fibularis longus and tibialis anterior muscles often become involved together; they operate as a pair of well-matched antagonists for achieving stabilization and balance of the foot. The extensor hallucis longus and, to a lesser degree, extensor digitorum longus muscles may also develop TrPs as agonists to the tibialis anterior muscle. Tibialis posterior TrPs are not usually identified as related to TrPs in the tibialis anterior muscle. The muscles of the functional unit of the tibialis anterior muscle should be examined for the presence of TrPs as these associated TrPs can perpetuate TrPs in the tibialis anterior muscle.

4.3. Associated Pathology

Lumbar radicular pain or radiculopathy from the L5 nerve root often results in the formation of TrPs in those muscles innervated by the same nerve root. Often, patients with L5 radicular pain will report having lateral thigh, lateral calf, and great toe pain, with or without paresthesias on the dorsal ankle and foot, and with radiculopathy weakness in ankle dorsiflexion.⁶¹ The presence of the tendon reflex of the tibialis anterior muscle reduces the likelihood of an L5 radicular compression as a contributing cause of the patient's pain. This reflex⁶² was absent bilaterally in 11%, and missing on only one side an additional 6%, of 70 healthy subjects. A hand-held reflex hammer elicited the reflex response and surface electrodes recorded it electromyographically. However, the reflex was absent on the affected side in 72% of 18 patients with L5 nerve root compression. Patients presenting with leg paresthesias, sensory changes, reports of weakness, or signs of central

nervous system disorders (excessive muscle tone or clonus) should receive a thorough neurologic examination including assessment of sensation, reflexes, muscle power, motor control, and movement coordination. If a potential serious medical condition is suspected, the patient should be referred to an appropriate medical practitioner.⁶³

The sciatic nerve divides into the common fibular and tibial nerves proximal to the popliteal fossa. The posterior divisions of the ventral rami ultimately form the common fibular nerve. The common fibular nerve then travels across the lateral head of the gastrocnemius muscle and courses laterally and just distal to the head of the fibula where the nerve becomes subcutaneous. It continues between the fibularis longus muscle and the fibula. At this point, it divides into two main branches, deep and superficial fibular nerves.^{7, 64}

The deep fibular nerve innervates the anterior muscles of the leg by traveling deep to the fibularis longus muscle and passing into the anterior compartment by piercing the interosseous membrane between the tibia and the fibula. In the foot, the nerve remains in close proximity to the interosseous membrane with the anterior tibial artery. Finally, it terminates in a cutaneous branch that innervates the web space between the first and second toes.^{1, 7}

The common fibular nerve is susceptible to injury because it has a superficial location near the fibula. Compromise has been reported due to numerous traumatic and insidious causes. Traumatic causes occur in association with musculoskeletal injury or with isolated nerve traction, compression, or laceration. Examples of traumatic injury to the common fibular nerve include proximal fibular fracture,⁶⁵ tibial plateau fracture,⁶⁶ traumatic knee dislocation,⁶⁷ ligamentous knee injury,⁶⁸ ligamentous or bony injury of the ankle,⁶⁵ improper casting after ankle injury,⁶⁹ or laceration.^{70, 71} Other less common causes include osteoarthritis,⁷² tumors,⁷¹ and iatrogenic injury experienced during orthopedic surgery.⁶⁹

Exertional compartment syndromes of the leg are a common form of overuse injury. Compartment syndromes are characterized by increased pressure within a muscular compartment sufficient to compromise the circulation of the muscles within it. The increased pressure obstructs venous outflow, which causes further swelling and more pressure. If prolonged, the resultant ischemia can lead to necrosis of the muscles and nerves within the compartment. When following a traumatic injury, it is most important that this condition be recognized immediately and managed properly to avoid possibly catastrophic consequences. Anterior compartment syndromes are recognized more commonly, followed by lateral, deep posterior and superficial posterior compartment syndromes.^{73, 74} Diffuse tightness and tenderness over the entire muscle belly of tibialis anterior muscle suggests an anterior compartment syndrome. The patients with this condition exhibit pain, paresthesias, and tenderness both in the ischemic muscles and in the region supplied by the deep fibular nerve. The muscles are sensitive to passive stretch and active contraction of the muscles increases symptoms.

Chronic exertional compartment syndrome is caused by abnormally high intramuscular pressure during exercise or sports participation such as running and weight lifting.⁷⁵

Among athletes and military service members, symptoms may develop over a period of time.^{73,74} Tight, shortened calf muscles overload weakened anterior compartment muscles and predispose athletes to developing an anterior compartment syndrome.⁷⁶ In non-traumatic acute cases, a brief period of rest and cryotherapy to reduce pain, swelling, and metabolic demand can be tried with close monitoring before further measures are considered. One case series investigated the effect of massage, exercise, and avoidance of exacerbating activities over 5 weeks and concluded that it was effective in reducing symptoms upon reinitiation of activities.⁷⁷ Diebal published a case series of 10 patients who underwent 6 weeks of therapy with a focus on changing subjects' running technique to promote a forefoot running pattern, decreased stride length, and increased cadence. This intervention led to reduced postrunning leg intracompartmental pressures and significantly reduced pain and disability for up to 1 year after intervention.⁷⁸

Shin splints is a common injury in runners and military personnel. This condition is the result of mechanical inflammation induced by repetitive stress of the broad proximal portion of any of the musculotendinous units originating from the lower part of the tibia during weight bearing.⁷⁹ Shin splints can be anterolateral or posteromedial. Anterolateral shin splints result from microtrauma and acute myositis of the tibialis anterior, extensor hallucis longus, and extensor digitorum longus muscles. Trigger points can develop in these muscles and exacerbate the patient's symptoms. Pain and tenderness will be present over the muscles of the anterior compartment. Commonly, muscle imbalance between weak dorsiflexor muscle groups and tight gastrocnemius-soleus muscles is noted.⁵³ The soleus muscle and excessive foot pronation have been reported as likely contributors to posteromedial shin splints, also known as medial tibial stress syndrome.^{80–82} Reinking et al⁸¹ found female gender, increased weight, greater navicular drop, previous running injury, and greater hip external rotation with the hip in flexion as risk factors in the development of medial tibial stress syndrome.⁸¹

Subcutaneous herniation of the tibialis anterior muscle through its investing fascia may be painful during standing and walking, or it may be of cosmetic concern.⁸³ Magnetic resonance imaging, unlike computed tomography, unequivocally identifies the extent of fascial splitting and the size of muscle herniation because it distinguishes more clearly between these two soft-tissue structures.^{84,85} The herniation will be pronounced with dorsiflexion of the foot, and if palpable and reducible, the outlined fascial defect may be appreciated.⁸⁶

5. CORRECTIVE ACTIONS

Pulling the foot up and maintaining that position for an extensive period of time, as when driving a car with a steeply angled pedal, can cause sustained shortening of the tibialis anterior muscle, which will, in turn, activate and perpetuate TrPs in it. The use of a cruise control provides an opportunity for the driver to change foot position and obtain periodic relief from immobility. When a person is seated for a prolonged period of time, the ankle pump exercise usually provides welcome relief as it stretches the tibialis anterior muscle as

well as the soleus muscle.

In general, the leg muscles feel better if the ankle is maintained in a neutral position throughout the night; therefore, adjusting a patient's sleeping posture may be necessary. This position is facilitated by having the bed sheets at the foot of the bed untucked to reduce external weight pulling the ankle into excessive plantar flexion. When side-lying, placing a pillow between the legs and knees will position the foot and ankle into a more restful position.

A major source of overload of the tibialis anterior muscle can be the result of increased tension or shortening of the calf musculature. An essential first step in the treatment of the tibialis anterior muscle is to reduce gastrocnemius-soleus (calf musculature) tightness and inactivate any responsible TrPs. When stretching the gastrocnemius/soleus muscle complex ("heel cord" or Achilles tendon), care should be taken to ensure that the subtalar joint (rear foot) is maintained in a neutral position and is not tilted in or out. Using the forefoot as a lever for stretching will result in additional dorsiflexion of the transverse tarsal joint, which may add further tendency toward pronation of the foot (flattening of the arch). To control this flattening of the foot, the patient should place a small towel under the medial aspect (inside border) of the bare foot during the standing stretch (see Figure 65-8). If the anterior compartment muscles are weak, a strengthening program consisting of both eccentric and concentric exercises for the tibialis anterior and other dorsiflexor muscles of the foot may be necessary to restore muscular balance at the ankle.⁵³

Walking on flat surfaces is preferred instead of uneven ground such as bricks, cracked pavement, grass, or sand. In addition, a surface that is level from side to side and not tilted laterally, as is the edge of a crowned road or a slanted beach, is optimal.

Self-pressure release for TrPs in the tibialis anterior muscle can be performed in long sitting by placing the heel of the unaffected side on a tender spot in the affected tibialis anterior muscle (Figure 63-5A), manually with the thumbs (Figure 63-5B), or with a TrP release tool (Figure 63-5C). Finding the sensitive spot with the opposite heel, thumbs, or a tool, light pressure (no more than 4/10 pain) should be applied and held for 15 to 30 seconds or until the pain reduces. This release can be repeated five times per session, several times per day.

Figure 63-5. Trigger point self-pressure release of the tibialis anterior muscle. A, Using the heel of the opposite leg. B, Using the thumb. C, TrP self-release tool (roller).

The patient can perform self-stretch of the tibialis anterior muscle by crossing the involved foot over the other thigh and using a hand to passively plantar flex and pronate (abduct and evert) the foot in a down and back motion (Figure 63-6A). Additional stretching of the extensor digitorum longus and extensor hallucis longus muscles (dorsiflexor muscles) can be accomplished in the same position by simply sliding the hand distally and pulling the toes into plantar flexion. The patient may hold the stretch for up to 30 seconds and repeat four times. This stretch of the tibialis anterior muscle can be performed several times daily. An alternate stretch can be performed with the patient sitting forward on a chair with the foot of the leg stretched back under the chair and placing the foot in plantar flexion and eversion with the top of the toes on the ground (Figure 63-6B). Adding a gentle calf muscle contraction to enhance plantar flexion during the stretch phase (reciprocal inhibition) can also be helpful.

Figure 63-6. Self-stretch of the tibialis anterior muscle. A, Overpressure pulling the foot back and down toward the floor. B, Top of the toes on the floor positioning the foot with more pressure on the great toe side. A stretch should be felt on the shin.

Fibularis Longus, Brevis, and Tertius Muscles

“Weak Ankle Muscles”

Wesley J. Wedewer

1. INTRODUCTION

Note: Following revised anatomic terminology published in 1998, the peroneal muscles are now known as the fibularis muscles, to prevent confusion of these muscles with those regions with similar names. “Perone” is another term for fibular and, thus, the revised terminology for these muscles, and related nerve and its branches, is based on language describing the location. Although both fibular and peroneal are considered acceptable terms, “fibular” and its related terminology is preferred and therefore will be used throughout this text.^{1, 2}

The fibularis longus and brevis muscles, along with the superficial fibular nerve, occupy the lateral compartment of the leg. The fibular muscles are important in foot and ankle function and are commonly seen in clinical practice to have trigger points (TrPs). They mainly control motion during gait and aid in proprioception of the foot and ankle. The collective group is responsible for ankle eversion; the fibularis longus and brevis muscles contribute to plantar flexion, whereas the fibularis tertius muscle assists in dorsiflexion. Trigger points in the fibularis muscles produce pain over the lateral malleolus of the ankle, above, behind, and below it. Pain can also extend a short distance along the lateral aspect of the heel and foot. On occasion, pain may cover the lateral aspect of the middle third of the leg. Trigger points in these muscles may be activated or perpetuated by excessive or vigorous running, walking, and jumping. Trigger points in these muscles are very common following an inversion ankle sprain or fibular fracture. Differential diagnosis should include fibular nerve entrapment, lumbar radicular pain or radiculopathy, compartment syndromes, ankle sprain, rupture of fibularis longus or brevis tendons, and an abnormal foot structure. Corrective actions include correcting or supporting abnormal foot posture and mechanics, modification of sitting and sleeping posture, self-pressure release techniques, self-stretch exercises, activity modification, and implementing lower extremity proprioceptive and motor control exercise programs.

2. ANATOMIC CONSIDERATIONS

The fibularis longus and fibularis brevis muscles, along with the superficial fibular nerve, occupy the lateral compartment of the leg (Figure 64-1). They evert the foot and plantar flex the ankle. The fibularis tertius muscle lies in the anterior compartment with the tibialis anterior muscle and the deep fibular nerve. It also everts the foot but additionally produces dorsiflexion of the ankle.³ The cross-section of the middle third of the leg, see Figure 63-2 in the previous chapter, shows the compartmental relationships.

A

Figure 64-1. Anatomical relations and attachments of the right fibularis muscles. A, Lateral view. B, Plantar view of the right foot. The bones to which the fibularis longus muscle attaches are darkened.

Anatomists report many variations of the fibular muscle group. The fibularis tertius muscle was absent in 5.0% to 8.2% of specimens.^{4,5} A bifid fibularis brevis muscle was reported as the cause of symptoms that required surgical correction.⁶ A commonly noted but rare (2%)⁴ muscle, the fibularis digiti minimi muscle, arises from the distal quarter of the fibula and attaches to the extensor aponeurosis of the fifth toe.^{7,8} Also, a fibularis quartus muscle was identified using magnetic resonance imaging in 7.6% to 10%^{9,10} of subjects. Incidence rates of the fibularis quartus muscle on cadaver specimens varied from 13% to 23%.¹⁰ It attaches proximally onto the back of the fibula between the fibularis brevis and flexor hallucis longus muscles, and distally to either the calcaneus or the cuboid.

Fibularis Longus

The fibularis longus muscle is located at the upper part of the outside leg and is the longer and more superficial of the fibularis muscles (Figure 64-1A). Proximally, it originates from the head and proximal two-thirds of the lateral surface of the fibula, the deep surface of the deep fascia, the anterior and posterior intermuscular septa, and occasionally by a few fibers from the lateral condyle of the tibia. Distally, it becomes tendinous in the middle third of the leg. The long tendon curves behind the lateral malleolus and passes in a groove it shares with the tendon of the fibularis brevis muscle. The groove is converted into a canal by the superior fibular retinaculum, so that the tendon of the fibularis longus muscle and that of the fibularis brevis muscle, which lies in front of the fibularis longus tendon, are contained in a common synovial sheath. If the fibular retinaculum is ruptured by injury and fails to heal, the tendons can dislocate from the groove. On the lateral side of the calcaneus, these tendons occupy separate osseoaponeurotic canals. The tendon of the fibularis longus muscle again curves sharply and runs in a groove on the anteroinferior aspect of the cuboid bone. It then crosses the sole of the foot obliquely and inserts by two slips, one to the lateral side of the base of the 1st metatarsal and one to the lateral aspect of the medial cuneiform (Figure 64-1B); occasionally, a third slip is attached to the base of the 2nd metatarsal. The long tendon of the fibularis longus muscle attaches opposite to the tendon of the tibialis anterior muscle on the medial aspect of the base of the 1st metatarsal bone.^{3,11,12} Tendinous slips from the fibularis longus muscle may extend to the base of the 3rd, 4th, or 5th metatarsals or to the adductor hallucis muscle.³

The tendon changes direction below the lateral malleolus and on the cuboid bone. At both sites, it is thickened, and at the second site, a sesamoid fibrocartilage is present.³ Some sesamoids ossify, whereas others remain fibrous or cartilaginous. When this fibrocartilage ossifies, it becomes the os peroneum. The os peroneum has an irregular shape and is visible in approximately 20%^{13,14} of foot radiographs in mature individuals. In a cadaver study, 30% of tendons displayed an os peroneum both radiographically and histologically. The

results of the study also suggested that the presence of os peroneum does not appear to be associated with increased endochondral ossification or degenerative joint disease. The bone formation may be associated with biomechanical functions within the foot.¹⁵ The origin of the os peroneum has given rise to much controversy. Its presence may stem from a response to the intense mechanical stresses involved at the angulated part of the fibularis longus tendon, and it may assist the tendon to glide without getting caught or impinged.^{16,17} Phylogenetically, it may be in the process of disappearing from the human race due to loss of its functional importance for hallux opposability.¹⁴

Fibularis Brevis

The fibularis brevis muscle is shorter and smaller than the fibularis longus muscle and lies deep to it. The belly of fibularis brevis muscle extends distally beyond that of the fibularis longus muscle (Figures 64-1A and 64-2). Proximally, fibularis brevis muscle originates from the distal two-thirds of the lateral surface of the fibula, anterior to the fibularis longus muscle, and adjacent to the intermuscular septa (Figure 64-2). The tendon of this muscle travels with that of the fibularis longus muscle within a common synovial sheath as it curves behind the lateral malleolus under the superior fibular retinaculum (Figures 64-1 and 64-2). Farther distally, these tendons have separate synovial sheaths. The fibularis brevis tendon then runs forward on the lateral side of the calcaneus above the tendon of the fibularis longus muscle and inserts distally to the tuberosity on the dorsolateral aspect of the base of the 5th metatarsal (Figure 64-1A). Fusion of the fibularis longus and brevis muscles has been reported, but is rare.³

Figure 64-2. Attachments of the deeper fibularis muscles (light red), right side, lateral view. The more superficial fibularis longus muscle (dark red) is cut and reflected. The fibularis tertius muscle is partly covered by the fibularis brevis muscle. The bones to which the fibularis brevis and tertius muscles attach are darkened.

Fibularis Tertius

The fibularis tertius muscle (Figure 64-2) differs anatomically and functionally from the other two fibularis muscles. This muscle is absent in hominoid apes and is hypothesized to have emerged as a recent addition of the human foot with the acquisition of the bipedal gait to support the relatively weak human mid-foot and make the bipedal gait more effective and efficient.^{18,19} Although the fibularis tertius muscle is located just lateral and

runs parallel in close proximity to the extensor digitorum longus muscle, it is usually anatomically distinct from the extensor digitorum longus muscle.⁴ Some describe the fibularis tertius muscle to be part of the extensor digitorum longus muscle and might label it as its “fifth tendon.”³ A recent meta-analysis including 3628 legs demonstrated that the fibularis tertius muscle is highly prevalent in humans (93.2%). It originates on the distal half of the fibula (70.2%), distal third of the fibula (13%), or from the extensor digitorum longus muscle itself (15.8%).¹⁸ Additionally, it attaches to the adjoining anterior surface of the interosseous membrane and the anterior intermuscular septum.³ The two lateral fibularis muscles attach to the other side of this septum. The fibularis tertius muscle is usually as large as, or larger than, the extensor digitorum longus muscle. Distally, the fibularis tertius tendon inserts broadly on the tubercle along the mediodorsal surface of the base of the 5th metatarsal, unlike the extensor digitorum longus tendon, which attaches to the lateral four proximal phalanges.^{3,4} Insertional points in addition to the 5th metatarsal have been observed on the fascia covering the 4th interosseous space (16.7%) and the base of the 4th metatarsal (11.9%).^{18,20} These tendinous projections spiral and tighten during passive inversion of the foot or straighten and relax during passive eversion.⁴

2.1. Innervation and Vascularization

Branches of the superficial fibular nerve supply the fibularis longus and fibularis brevis muscles. This nerve contains fibers from the L4, L5, and S1 spinal nerves. The deep fibular nerve supplies the fibularis tertius muscle in the anterior compartment with fibers from only the L5 and S1 spinal nerves. Branches of the anterior tibial artery primarily provide vascularization to the three fibularis muscles.³

Fibularis Longus and Fibularis Brevis

Branches of the superficial fibular nerve supply the fibularis longus and fibularis brevis muscles as well as the skin of the leg. The segmental innervation comes from the L5, S1,^{3,12} and sometimes from the S2 spinal nerves.¹² The superficial fibular nerve begins at the bifurcation of the common fibular nerve. It passes anteroinferiorly between the fibularis longus, fibularis brevis, and extensor digitorum longus muscles, and pierces the deep fascia in the distal third of the leg. Cutaneous branches supply the distal third of the anterior leg and skin of the dorsum of all toes except that of the fifth toe, supplied by the sural nerve, and the adjoining sides of the great and second toes, supplied by the deep fibular nerve.³

The vascularization of the fibularis longus and brevis muscles is derived from superior and inferior branches of the anterior tibial artery. There is also a lesser, variable contribution from the fibular artery in the distal part of the leg. Distally, the tendons are supplied by the fibular perforating, anterior lateral malleolar, lateral calcaneal, lateral tarsal, arcuate, lateral plantar, and medial plantar arteries.³

Fibularis Tertius

The deep fibular nerve supplies the fibularis tertius muscle in the anterior compartment with fibers from the L5 and S1 spinal nerves.³ The deep fibular nerve innervates the anterior muscles of the leg by traveling deep to the fibularis longus muscle. In the foot, the nerve remains in close proximity to the interosseous membrane with the anterior tibial artery. Finally, it terminates in a cutaneous branch, which innervates the web space between the first and second toes.^{3, 21}

The vascularization of the fibularis tertius muscle is derived from anteriorly and laterally placed branches of the anterior tibial artery, supplemented distally from the perforating branch of the fibular artery. The tendon is supplied at the ankle and in the foot by the anterior lateral malleolar artery and malleolar network, and by lateral tarsal, metatarsal, plantar, and digital arteries. In the foot, it receives an additional supply from the termination of the arcuate artery and the 4th dorsal metatarsal artery.³

2.2. Function

The fibularis longus, brevis, and tertius muscles function as dynamic stabilizers of the ankle and are important in proprioception, independent of the status of the lateral ankle ligaments. Poor fibularis muscle function can give patients a sense of instability, even in a mechanically stable ankle.²² The fibularis muscles all act to evert the nonweight-bearing foot. A major difference in these muscles is that the fibularis tertius muscle dorsiflexes the foot because its tendon crosses in front of the ankle joint, whereas the fibularis longus and fibularis brevis muscles plantar flex the foot because their tendons pass behind the ankle joint.³

The fibularis muscles, like most other lower extremity muscles, frequently function to control movement rather than to produce it. This function is particularly evident for the fibularis longus and brevis muscles when the foot is fixed in the stance phase during jogging, standing, and walking. At this time, these muscles often function through eccentric contractions. In contrast, the fibularis tertius muscle is thought to work primarily during the swing phase in conjunction with extensor digitorum longus and tibialis anterior muscles to clear the foot.²³

Fibularis Longus and Fibularis Brevis

The primary function of the fibularis longus and fibularis brevis muscles is not to elevate the lateral margin of the foot as commonly thought. Instead, they appear to act during weight-bearing activities and sports to depress or fix the medial margin of the foot to the contact surface in order to resist inadvertent or excessive inversion of the foot, which is the most vulnerable position of the ankle.^{12, 24} Because they attach to opposite sides of the 1st metatarsal, the tibialis anterior and fibularis longus muscles form an effective sling for control of inversion and eversion of the foot.¹¹ The protective mechanisms, in an event of excessive ankle inversion, involve fibularis longus and fibularis brevis muscle contractions guided by central reflexes and mediated by spinal and cortical centers.^{25, 26}

In the nonweight-bearing position, the fibularis longus and fibularis brevis muscles cause the foot to abduct (toe out) and to evert (elevate its lateral side); together, these two movements act at the subtalar and transverse tarsal joints to produce pronation.³ Basmajian and Deluca²⁷ established that during level walking, the fibularis longus muscle helps stabilize the leg and foot in mid-stance. The fibularis longus and the tibialis posterior muscles, working in concert, control the shift from inversion during early stance to a neutral position at mid-stance. The fibularis brevis muscle acts synchronously with the fibularis longus muscle during ordinary walking. Throughout most of the stance phase, the fibularis longus muscle is generally more active in individuals with hypermobile feet (“flatfooted”) than in individuals with more typical foot flexibility.

The control of mediolateral balance of the foot was studied during walking in 11 normal adults.²⁸ When the force plate measured a large lateral component of ground reaction force, electromyographic (EMG) activity of the fibularis longus muscle was marked during the mid-stance phase of gait, whereas the amount of pronation (eversion and abduction) of the foot was small. The researchers suggest that the fibularis longus muscle was active during the mid-stance phase to prevent medial inclination of the leg of the fixed foot, moreover to stabilize the head of the 1st metatarsal because this muscle inserts on the 1st metatarsal. Matsusaka concluded that the fibularis muscles (as well as the tibialis posterior and flexor digitorum longus muscles) contribute to the control of mediolateral balance during ambulation.²⁸

Tropp and Odenrick²⁹ studied postural control in single-leg stance using surface EMG and force plate recordings of 30 physically active men. They found that the ankle played a central role in minor corrections of postural balance. Fibularis longus muscle EMG activity and the location of the center of pressure on the force plate correlated closely with ankle position. When the body experienced major disequilibrium, however, subjects made corrections at the hip. The subject’s internal strategy of maintaining balance changed from an inverted pendulum model (at the ankle) to a multisegmental chain model when adjustments at the ankle were no longer able to maintain adequate postural control.

Landry and colleagues³⁰ compared healthy subjects’ postural sway and muscle activity in an unstable shoe with standing barefoot and in a traditional shoe with stability and support features. Standing in an unstable shoe increased postural sway and EMG activity of the fibularis longus, flexor digitorum longus, and anterior compartment muscles in comparison with standing barefoot or wearing stability controlled shoes. Interestingly, no differences were noted in activity of the soleus muscle. Postural sway while standing in the unstable shoe also reduced over a 6-week period.

Patients with ankle instability, when tested by standing on one foot following an ankle inversion injury, showed no significant inversion or eversion weakness compared with the unaffected ankle.³¹ The problem was apparently one of impaired muscle control and balance rather than one of muscle weakness. In a more recent study, subjects with chronic ankle instability demonstrated significantly slower reaction time for ankle eversion on the affected side than the control group, because of slower onset of muscle activity to

movement (motor time) for the fibularis longus muscle.³²

Konradsen and colleagues²⁶ investigated the role of a muscular defense in the stabilization and protection of the ankle joint against sudden forced inversion. Ten volunteers with mechanically stable ankles were tested in different standing and walking situations. Standing on a custom platform with a secret trap door under the examined foot, the trap door was able to tilt 30°, in approximately 80 msec, in the frontal plane and provide a sudden ankle inversion perturbation to the subject. EMG activity of the fibularis longus and brevis muscles were detected, prior to the quadriceps and hamstring muscles, at approximately 54 msec from the start of ankle inversion. The time for the neuromuscular system to perceive the sudden inversion and generate a protective goniometric subtalar eversion muscular response was after 176 msec. The fibularis muscles' reflex alone during standing or walking does not appear to be fast enough to protect the ankle from injury in the case of sudden inversion (less than 100 msec).^{26,33} The potential for ligamentous injury to the ankle is high whenever the rate and magnitude of ankle loading exceeds the response time for the neuromuscular system.³⁴

Fibularis Tertius

The function and significance of the fibularis tertius muscle is not well studied, and there is limited data to suggest the importance of this phylogenetically young structure. There is consensus that it dorsiflexes the foot and assists in eversion at the ankle.^{3,8,35,36} Duchenne observed that when there is absent or weak development of the fibularis tertius muscle, the extensor digitorum longus muscle substitutes for the fibularis tertius muscle in dorsiflexion, abduction, and eversion.³⁶ Some authors theorize that the fibularis tertius muscle may also play a special proprioceptive role in sensing sudden inversion and then contracting reflexively to protect the anterior talofibular ligament, the most commonly sprained ligament of the body.¹² In contrast, Witvrouw et al³⁷ performed a prospective study on 100 students and concluded that congenital absence of the fibularis tertius muscle does not increase risk for an ankle ligament injury.

Krammer and associates⁴ concluded that the fibularis tertius muscle evolves in bipedal posture for the purpose of shifting the line of body weight toward the medial margin of the foot. This shift from lateral to medial develops in infant standing balance and with the onset of walking, and it occurs in each walking cycle of an adult human.

Conversely, Jungers et al²³ used EMG to test the fibularis tertius muscle, among other muscles, for recruitment and function in human bipedal walking and running and compared it with the data of three species of nonhuman primates typically lacking fibularis tertius muscles. In humans, both walking and running elicited highly predictable recruitment of the fibularis longus and fibularis brevis muscles only during stance phase, peaking just after mid-stance. The recruitment of the fibularis tertius muscle occurred predominantly during the swing phase. It functions in concert with tibialis anterior and extensor digitorum longus muscles, likely assisting to dorsiflex the foot at the ankle, so that the toes clear the ground in anticipation of the next stance phase. In doing so, the inverting

effect of the tibialis anterior muscle is balanced by the everting component of the fibularis tertius muscle and the sole of the foot is leveled prior to initial contact. In nonhuman primates lacking a fibularis tertius muscle, the fibularis longus or brevis muscle is active during the swing phase. Although these muscles are evertors of the foot, they are also plantar flexors. A more economical way to counter the inverting effect of the tibialis anterior muscle is to recruit a dorsiflexor/evertor, which may explain the evolution of the fibularis tertius muscle in humans as an adaptation to insure functional efficiency.

2.3. Functional Unit

The functional unit to which a muscle belongs includes the muscles that reinforce and counter its actions as well as the joints that the muscle crosses. The interdependence of these structures is functionally reflected in the organization and neural connections of the sensory motor cortex. The functional unit is emphasized because the presence of a TrP in one muscle of the unit increases the likelihood that the other muscles of the unit will also develop TrPs. When inactivating TrPs in a muscle, one must be concerned about TrPs that may develop in muscles that are functionally interdependent. Boxes 64-1 and 64-2 grossly represent the functional unit of the fibularis longus and brevis muscles, and the fibularis tertius muscle, respectively.³⁸

Box 64-1 Functional unit of the fibularis longus and brevis muscles

3. CLINICAL PRESENTATION

3.1. Referred Pain Pattern

The fibularis muscles can exhibit TrPs in any part of the muscle. Fibularis longus and fibularis brevis TrPs project pain and tenderness primarily to the region over the lateral malleolus of the ankle, above, behind, and below it; they also extend a short distance along the lateral aspect of the foot (Figure 64-3A).³⁹⁻⁴¹ A pain pattern of fibularis longus TrPs may cover the lateral aspect of the middle third of the leg as well.^{39,40}

Figure 64-3. Pain patterns (dark red) referred from TrP locations in the fibularis muscles. The essential patterns of referred pain and tenderness are solid red, and the red stippling shows the less common extension of pain. These TrPs all refer pain distally. A, Composite pain pattern for the fibularis longus and fibularis brevis muscles (medium red). The stippled pattern proximally applies only to the fibularis longus TrP. B, Pain pattern of the fibularis tertius muscle (light red).

Jacobsen⁴² reported a pain pattern referred from fibularis longus and fibularis brevis TrPs as going around the back of the lateral malleolus. Bates and Grunwaldt⁴³ reported that, in children, the referred pain pattern of the fibularis longus muscle also concentrates behind the lateral malleolus but tends to extend up to the side of the leg rather than along the side of the foot. Good⁴⁴ attributed the symptoms in 15 of 100 patients with painful feet to myalgic spots in the fibularis brevis muscle. Kellgren⁴⁵ reported that the injection of 6% hypertonic saline solution into the fibularis longus muscle evoked pain referred to the lateral ankle.

Fibularis tertius TrPs refer pain and tenderness along the anterolateral aspect of the ankle and project downward behind the lateral malleolus to the lateral aspect of the heel (Figure 64-3B). A less commonly referred pain pattern runs distally over the dorsum of the foot.

3.2. Symptoms

Weakness of any of the three fibularis muscles can contribute to a patient report of “weak ankles.” Patients with fibularis TrPs report pain and tenderness behind the ankle and over the lateral malleolus, especially after an inversion sprain of the ankle. These patients often report spraining their ankles frequently. Ankle instability limits performance during higher-level activities in sports such as basketball, soccer, gymnastics,⁴⁶ or hockey.

Patients with fibularis TrPs, in addition to inverting and spraining their ankles potentially because of inadequate fibularis muscle support, are also prone to ankle fractures. Treatment of the fracture by a cast on the ankle, which immobilizes the fibularis muscles, may aggravate and perpetuate fibularis TrPs that cause ankle pain. In this situation, the fracture can be healing, or fully healed, and not be the cause of the patient’s reported and continuous ankle pain.

3.3. Patient Examination

After a thorough subjective examination, the clinician should make a detailed drawing representing the pain pattern described by the patient. This depiction will assist in planning the physical examination and can be useful in monitoring the progression of the patient as symptoms improve or change. The type, quality, and location of the pain should be carefully assessed, and the utilization of standardized outcome tools is imperative when examining patients with lower extremity dysfunctions.

Observation of static and dynamic posture is essential, given the role of the fibularis

muscles in postural stability. Functional testing such as double- and single-leg squat will allow a quick assessment of hip and knee control, as well as a quick assessment of talocrural, subtalar, and mid-foot range of motion. Timed single-leg stance with eyes open and closed will give a quantitative measure of balance and will allow the clinician to observe foot and ankle strategies related to balance and control.

The clinician should observe the patient's gait pattern from behind to note excessive pronation of the foot or other related deviations. A mediolaterally rocking foot with associated fibularis longus TrPs can produce a sense of ankle weakness severe enough to convince some patients to use an assistive device or ambulate with an antalgic gait where stride length of the uninvolved leg is notably decreased due to perceived instability of the stance leg. Patients with latent TrPs in the fibularis longus muscle are asymptomatic with regard to pain but, for years, these latent TrPs may cause characteristic calluses and inhibition weakness of the ankles.⁴⁷

For proper assessment and examination of the fibularis muscles, the clinician should assess bilateral ankle and foot posture, range of motion, and accessory motion of the talocrural, subtalar, transverse tarsal, talon naviculocuneiform, and cuboid-fifth metatarsal joints. Examination may identify underlying dysfunction contributing to joint hypermobility and/or hypomobility and can lead to a mechanically or functionally unstable ankle. The clinician should also examine the patient's shoes for proper fit and for abnormal wearing patterns.

To examine for fibularis longus and fibularis brevis muscle weakness, the patient lies on the side not being tested. The clinician stabilizes the uppermost leg and places the foot in plantar flexion and eversion; with the toes relaxed, the patient then holds the foot in that position against resistance supplied by the clinician, who presses against the lateral border of the foot in the direction of inversion and dorsiflexion.^{48,49} While applying resistance, the tendons are visualized at the lateral ankle and in the foot. The calf muscles and long flexors of the toes can also produce powerful plantar flexion, but the fibularis longus and brevis muscles are the chief force for eversion of the foot in plantar flexion. The fibularis tertius and extensor digitorum longus muscles also produce eversion, but they dorsiflex, rather than plantar flex the foot. Patients with fibularis longus and fibularis brevis TrPs have difficulty holding the foot in eversion and plantar flexion against resistance when compared with the uninvolved side. Baker⁴⁶ describes a ratchety resistance to movement as "breakaway" weakness. The more active the TrPs, the more marked is this weakness.

Active fibularis longus and fibularis brevis TrPs cause pain on eversion effort with the foot already everted, and they also painfully restrict passive inversion range of motion. Fibularis tertius TrPs cause pain on active dorsiflexion in the dorsiflexed (shortened) position and limit passive plantar flexion.

3.4. Trigger Point Examination

Fibularis Longus

For examination of the fibularis muscles for TrPs, the patient lies side-lying or supine with the foot free to move (Figure 64-4). Although the most common TrP location in the fibularis longus muscle is about 2 to 4 cm (approximately an inch or slightly more) distal to the head of the fibula over the shaft of the fibula, the entire muscle should be examined for TrPs (Figure 64-4A). Taut bands are clearly delineated by cross-fiber flat palpation against the underlying bone. The common fibular nerve crosses diagonally over the neck of the fibula just below the fibular head and has a cordlike consistency. The nerve is distinguished from a taut band by its proximal position and a course running across the muscle rather than running the length of the muscle nearly parallel to the shaft of the fibula.⁵⁰ Excessive pressure on the nerve may cause painful tingling sensations (dysesthesias) over the lateral side of the leg and the foot.

Figure 64-4. Cross-fiber flat palpation of A, Fibularis longus muscle. B, Fibularis brevis muscle. C, Fibularis tertius muscle.

Fibularis Brevis

For clinical examination of fibularis brevis TrPs, the patient is side-lying or supine so that the muscle is relaxed. Trigger points in the fibularis brevis muscle can be found on either side of, and deep to, the fibularis longus tendon near the junction of the middle and lower third of the leg (Figure 64-4B). These TrPs also are palpable against the shaft of the fibula utilizing a cross-fiber flat palpation. Pressure on TrPs in either of these muscles characteristically elicits referred pain in, behind, and distal to the lateral malleolus, and this

area also exhibits referred tenderness.

Fibularis Tertius

Trigger points in the fibularis tertius muscle (Figure 64-4C) are identified using cross-fiber flat palpation slightly distal and anterior to the fibularis brevis muscle and proximal and anterior to the lateral malleolus. The tendon of this muscle stands out and is readily palpable in the anterolateral aspect of the ankle and foot (lateral to the extensor digitorum longus tendons) when the patient attempts to evert the foot by lifting the 5th metatarsal up and out (dorsiflexion with eversion). Taut bands in this muscle are often difficult to delineate by palpation, but pressure on the sensitive TrP usually refers pain to the anterolateral ankle and sometimes to the lateral side of the heel and dorsum of the foot (Figure 64-3B).

4. DIFFERENTIAL DIAGNOSIS

4.1. Activation and Perpetuation of Trigger Points

A posture or activity that activates a TrP, if not corrected, can perpetuate it. In any part of the fibularis muscles, TrPs may be activated by unaccustomed eccentric loading, eccentric exercise in an unconditioned muscle, or maximal or submaximal concentric loading.⁵¹ Trigger points may also be activated or aggravated when the muscle is placed in a shortened or lengthened position for an extended period of time. For instance, a fall with twisting and inversion of the ankle can activate TrPs by overloading the fibularis longus and fibularis brevis muscles. Weakness or inhibition induced by prolonged immobilization, as by an ankle cast, predisposes these muscles to developing TrPs.

Sleeping with the foot strongly plantar flexed places the fibularis longus and fibularis brevis muscles in the shortened position for prolonged periods. This common position aggravates fibularis TrPs.

A tight elastic top of a long sock can constrict circulation in the fibularis longus, extensor digitorum longus, and gastrocnemius muscles by direct compression, like a tourniquet, and thus perpetuate their TrPs. An indented red line or marking around the leg indicates a high probability of this constriction. The soleus muscle usually is too deep to be affected.

Wearing high heels perpetuates fibularis TrPs by shifting the body weight forward onto the ball of the foot during standing, which reduces the base of support, thus increasing the length of the lever arm against which the muscles must operate. The resultant functional instability overloads the fibularis longus and fibularis brevis muscles. A shoe with a spike heel of any height provides an unstable base of support that can overload the fibularis muscles.

Clinically, individuals with flat feet and unsupported arches are likely to have spot tenderness and taut bands in the fibularis longus and fibularis brevis muscles,⁵² as these muscles are more active during the stance phase of gait.^{23, 27}

4.2. Associated Trigger Points

Associated TrPs can develop in the referred pain areas of other TrPs.⁵³ Therefore, muscles in the referred pain areas for each muscle should also be considered for examination. The fibularis longus muscle is almost always involved when either of the other two fibularis muscles has TrPs. Not surprisingly, the muscle that most commonly develops TrPs associated with TrP-weakened fibularis muscles is their prime agonist for eversion, the extensor digitorum longus muscle. The fact that the extensor digitorum longus muscle also serves as a prime antagonist to the fibularis longus muscle can account for the likelihood of both muscles developing TrPs. Fibularis longus TrPs are also likely to occur in association with tibialis posterior TrPs as these two muscles are specific antagonists in regard to inversion-eversion, but they are synergistic in regard to plantar flexion and to stabilizing the weight-bearing foot.

Although the fibularis longus and fibularis brevis muscles are weak assistants to the prime plantar flexors, TrPs in the powerful gastrocnemius and soleus muscles are not likely to induce associated TrPs in the fibularis muscles. The function of the triceps surae muscle is also not likely to be compromised because of TrPs in the fibularis muscles.

Gluteus minimus TrPs refer pain to the lateral aspect of the leg and can induce associated TrPs in the fibularis muscles. The extensor digitorum longus and fibularis tertius muscles work closely together as synergists and TrPs in one can induce associated TrPs in the other. Five extensor muscles of the leg project referred pain in patterns that might be confused with those of the fibularis muscles: the tibialis anterior muscle, the long and short extensor muscles of the hallux, and the long and short extensor muscles of the lesser toes. However, TrPs in these other muscles do not refer pain behind the lateral malleolus, to the heel, or to the lateral side of the leg.

The lateral heel pain referred from fibularis tertius TrPs contrasts from the soleus muscle referral pain pattern, as it does not include the entire Achilles tendon or the plantar surface of the heel. Because of the local tenderness associated with the pain referred to the ankle by TrPs in the fibularis muscles, these myofascial pain symptoms are easily mistaken for arthritis of the ankle joint.⁵⁴

4.3. Associated Pathology

Trigger points in the fibularis muscles are associated with, and can mimic, many different conditions; therefore, a thorough medical screening and examination with possible referral to another healthcare practitioner may be necessary. Fibular nerve entrapment,² lumbar radiculopathy,⁵⁵ Morton foot structure,^{56,57} acute or chronic exertional compartment syndrome,⁵⁸ ankle sprains or fractures,⁵⁹ and rupture of fibularis longus or brevis muscles^{22,60} can all be associated with TrPs in the fibularis muscles.

Fibular neuropathy is the most frequent mononeuropathy encountered in the lower extremity and the third most common focal neuropathy encountered overall, after median and ulnar neuropathies.^{2,61,62} In children, the common fibular nerve was the most often

injured (59%), as opposed to the deep (12%), superficial (5%), or a nonlocalizable level of injury (24%). These findings are similar to those of adults.⁶³ Entrapment of the common fibular nerve, the superficial fibular nerve, or the deep fibular nerve can produce symptoms of pain and paresthesias in the anterolateral ankle and dorsum of the foot with concomitant weakness of the ankle,² which can be suggestive of fibularis myofascial pain syndromes.

Numbness and tingling caused by entrapment of the common fibular nerve appears on the lateral part of the posterior aspect of the proximal leg, distal third of the anterior surface of leg, and dorsum of the foot. The superficial branch supplies the anterolateral leg and dorsum of the foot, except for the triangular area of the first interdigital web space that is supplied by the deep fibular nerve (Figure 64-5B). The Achilles reflex will be preserved in the presence of nerve entrapment.^{3, 12}

The superficial fibular nerve emerges through the deep fascia in the lower third of the leg³ where it is vulnerable to acute or chronic trauma and subject to entrapment by the fascia. The pain and altered sensation without motor deficit in the distribution of this nerve appears confusingly like a combination of tibialis anterior and fibularis tertius muscle myofascial pain syndromes. This entrapment, however, is not dependent on TrPs in these muscles.

Taut bands caused by TrPs in the fibularis longus muscle increase the tension of the muscle and can cause entrapment of the common fibular nerve and/or the superficial and deep fibular⁴⁷ nerves, if the nerve branches far enough proximally (Figure 64-5A). The nerve compression may occur against the fibula, or it may result from compression of the nerve by muscle tension on the bands of fascia that surround the nerve.^{64, 65} The compression of motor fibers in the common fibular nerve or in the deep fibular nerve by taut bands in the fibularis longus muscle can cause significant foot drop.^{39, 40} Foot drop and changes in sensation caused by entrapment of the fibular nerve may result from residual fibularis TrPs that originated during an L4, L5 radiculopathy that was later resolved.

Figure 64-5. Entrapment of the common, deep, or superficial fibular nerve. A, By a tense fibularis longus muscle (dark red) that is reflected. Entrapment of the deep fibular nerve can be caused by a tense extensor digitorum longus muscle (medium red). Both the deep and superficial branches of the fibular nerve pass between the fibularis longus muscle and the underlying fibula where taut bands associated with TrPs in the fibularis longus muscle can compress the nerve and cause neurapraxia. B, Deep fibular nerve zone of entrapment numbness (Zs) on the dorsum of the first and second toes due to taut TrP bands in the fibularis longus muscle.

Reported causes of fibular nerve palsy in the leg include proximal fibular fracture,⁶⁶ tibial plateau fracture,⁶⁷ traumatic knee dislocation,⁶⁸ ligamentous knee injury,⁶⁹ ligament

or bony injury of the ankle,⁶⁶ improper casting after ankle injury⁷⁰ or laceration.^{71,72} Other less common causes include osteoarthritis,⁷³ tumors,⁷² and iatrogenic injury suffered during orthopedic surgery.⁷⁰

Two common tests were evaluated for their diagnostic accuracy of fibular nerve compression neuropathy. The scratch collapse test showed a sensitivity of 0.77 and a specificity of 0.99, whereas the Tinel sign showed 0.65 and 0.99, respectively. Both are sensitive and specific provocative tests that aid in the diagnosis of common fibular neuropathy.⁷⁴

Together, the symptoms of common fibular nerve entrapment and the referred pain of fibularis TrPs may suggest a radicular source of pain which, if present, can also activate fibularis TrPs in a segmental distribution. Therefore, patients with such symptoms may have a myofascial pain syndrome with or without neurologic symptoms and signs; or their symptoms may be due to a combination of radicular pain, fibular nerve entrapment, and referred myofascial pain.

The Morton foot structure (relatively short first and long second metatarsal) with a mediolaterally rocking foot may perpetuate TrPs primarily in the fibularis longus^{39,40,47} and also fibularis brevis muscles but rarely in the fibularis tertius muscle. Individuals may have an equally marked Morton foot structure bilaterally but have pain only on one side, usually the side of a shorter lower extremity. Similarly, bunions may appear the same on both feet but may be painful on only one foot. Even with the same foot structure bilaterally, pain may be present in one foot if there is a leg length discrepancy that results in unequal force distribution.

The Morton foot structure must be distinguished from Morton neuroma (Morton metatarsalgia). The latter is generally thought to result from interdigital nerve entrapment in the region of the transverse metatarsal ligament.⁷⁵ The Morton foot structure is a variation in skeletal structure⁵⁷ that is usually not painful but can cause problems for muscles and other structures. Indeed, abnormal pressures caused by the structure could be a factor in development of the neuroma. The foot squeeze test and web space tenderness between the 2nd and 3rd metatarsals are sensitive tests that can be performed easily in the clinic to identify a potential interdigital neuroma.⁵⁶

Acute or chronic exertional lateral compartment syndrome with pain along the lateral side of the leg that is aggravated by activity can be suggestive of fibularis longus and fibularis brevis TrP pain, but the tenderness and tension of the musculature in the compartment syndrome is diffuse, not localized, as in the myofascial syndromes. Immediate referral to a physician is warranted when acute compartment syndrome is suspected after major trauma and/or a fracture. The subject may present with one or all of the five Ps: pain, pallor, paresthesias, paralysis, and pulselessness. Time is of the essence in referral to a specialist, as an emergency fasciotomy may be indicated, with tissue necrosis occurring after only 4 to 6 hours of ischemia.⁷⁶

Chronic exertional or exercise induced compartment syndrome is likely to develop in runners, military personnel, or endurance athletes.^{58,77} It occurs with repetitive activity and

microtrauma, which increases intramuscular pressure causing transient ischemia. Unlike acute compartment syndrome, tissue necrosis does not occur because symptoms typically resolve when the aggravating activity is stopped and the patient rests.⁵⁹ Conservative treatment addressing biomechanical issues, soft tissue restriction, and activity modification with proper progression of load and exercise can manage this condition in some athletes.⁷⁸ Diebal⁷⁹ published a case series of 10 patients who underwent 6 weeks of therapy with a focus on changing subjects running technique to promote a forefoot running pattern, decreased stride length, and increased cadence. This intervention led to reduced post-running leg intracompartmental pressures, and significantly reduced pain and disability for up to 1 year following intervention.⁷⁹ When conservative treatment fails, an open fasciotomy is successful in approximately two-thirds of the athletic population.⁵⁸

The trauma that causes a lateral ankle sprain can also readily activate fibularis TrPs that refer pain and tenderness to the ankle. Examination of the fibularis muscles for TrPs reveals this source of the symptoms; however, other causes of the pain should be ruled out. Usually, injury to the lateral ligaments of the ankle results from an inversion-plantar flexion sprain. The first structures to tear are the anterior lateral joint capsule and the anterior talofibular ligament.⁸⁰ The immediate region of the torn ligament is tender and swollen. Tenderness referred from TrPs usually includes a larger area without such marked swelling.

Patients sustaining a plantar flexion and inversion ankle sprain, or who have an unstable foot, are at risk for a subluxation or misalignment of the cuboid in an inferomedial direction. This condition can potentially irritate the surrounding joint capsule, ligaments, and the fibularis longus tendon. The fibularis longus muscle's strength and function depends on proper position and stability of the cuboid.⁵⁹ Jennings and Davies⁸¹ found 7 of 104 (6.7%) patients with lateral ankle sprains had subluxed cuboids. In ballet dancers, 17% of foot injuries involve the cuboid.⁸² One or two treatment sessions of manual (cuboid squeeze) or manipulative (cuboid whip) therapy prove to be extremely effective in treating this poorly recognized condition.^{81, 82} The fibularis longus muscle should be examined for TrPs and, if present, they should be released prior to treating the cuboid dysfunction.

An acute fibularis tendon dislocation or tearing occurs when the ankle sustains a sudden forced dorsiflexion accompanied by a concomitant reflexive contraction of the fibularis muscles. Fibularis brevis longitudinal tendon tears are more frequent than fibularis longus tendon tears and are present in up to 30% of patients undergoing surgery for ankle instability.^{22, 83} Squires et al²² identified six findings that are key to diagnosis of tendon tears: swelling posterolaterally along the course of the tendons, pain on palpation along the course of the tendon, pain exacerbated by compression of the superior fibular retinaculum as the patient actively everts the ankle, crepitation or squeaking of the tendons, pain with extreme active dorsiflexion, difficulty maintaining stability on single-stance heel rise, and retro malleolar pain with anterior drawer testing. Conservative treatment consists of anti-inflammatory medication, lateral heel wedge, bracing, and physical therapy. Treatment of an established tear has a high failure rate and often requires operative management.

Fibularis tendon subluxation can also be the result of ankle sprains, contributing to

prolonged pain and dysfunction. The integrity of the fibularis retinaculum can be tested with the patient in prone with the knee bent to 90° (Figure 64-6). While stabilizing the leg, the foot is placed in dorsiflexion with eversion while palpating gently over the lateral malleolus and heel. The patient then moves through plantar flexion and dorsiflexion of the ankle while maintaining eversion. The clinician will see and/or feel for sliding of the fibularis tendon over the lateral malleolus. Surgical repair is often required if the fibularis retinaculum is disrupted.⁸⁴

Figure 64-6. Test for subluxation of the fibularis tendons. The patient's foot is placed in dorsiflexion with eversion. The clinician maintains eversion while the patient performs plantar flexion and dorsiflexion. The clinician palpates the tendons to monitor if the tendons sublux over the lateral malleolus.

The os peroneum is a sesamoid bone of the fibularis longus tendon that develops in about 10% of individuals. When it has suffered trauma and becomes painful, it can be treated successfully either surgically⁶⁰ or conservatively.⁸⁵ The os peroneum may fracture and rupture the fibularis longus tendon⁶⁰ when the individual tries to prevent a fall⁸⁶ or imposes sudden inversion stress on the ankle, often with an audible snap.⁸⁵

5. CORRECTIVE ACTIONS

Adjusting posture can decrease prolonged shortening of these muscles especially if the individual's feet do not rest firmly on the floor when seated. For correction of under thigh compression caused by too high of a chair seat, possible solutions include a footstool to raise the feet, shortening of the chair legs, or tilting the seat pan downward at the front of the seat.

In general, the leg muscles feel better if the ankle is maintained in a neutral position throughout the night; therefore, adjusting the patient's sleeping posture may be necessary. This position is facilitated by having the bed sheets at the foot of the bed untucked as this will reduce external stresses of the ankle into excessive plantar flexion (see Figure 65-6). When side-lying, placing a pillow between the legs and knee will place the foot and ankle into a more restful position. Patients with irritable TrPs should avoid lying on the affected side as the pressure from the bed may perpetuate TrP activity.

Shoes that provide good arch and foot support, such as some sneakers, jogging shoes, and boots that are snug, effectively reduce strain on the fibularis muscles, thus making specific TrP therapy more effective. High heels, and especially stiletto heels, should be avoided. For exercise such as walking, the individual is encouraged to walk on flat surfaces instead of uneven ground such as uneven bricks, cracks, grass, or sand. In addition, a surface that is level from side to side and not tilted laterally, as is the edge of a crowned road or a slanted beach, is optimal. The patient with TrPs and weakness of the fibularis longus and fibularis brevis muscles should avoid walking on a slanted sidewalk or running on a laterally slanted track, which contributes to overload of those muscles.

Self-pressure release for TrPs in the fibularis muscles can be performed in long sitting, or while seated in a chair (Figure 64-7A, B, and C). Pressure can be provided manually with the thumbs (Figure 64-7A and B), with a TrP release tool, or with a lacrosse or tennis ball (Figure 64-7C). Finding the sensitive spot with the thumbs or a tool, light pressure (no more than 4/10 pain) should be applied and held for 15 to 30 seconds until pain reduces. This technique may be repeated five times per session, several times per day (Figure 64-7A, B, and C).

Figure 64-7. Trigger point self-pressure release. A and B, Manual release using thumbs. C, Using a lacrosse ball.

Gentle passive self-stretch of the fibularis longus and fibularis brevis muscles can be performed in the sitting position. The patient grasps the forefoot and gently pulls the foot up and toward the nose until a stretch is felt on the outside of the leg (inversion, adduction, and dorsiflexion) (Figure 64-8). Postisometric relaxation can facilitate a painless stretch. For this technique, the patient uses one hand to stabilize the leg just above the ankle and the other hand to resist an active effort to evert and plantar flex the foot gently while slowly taking in a deep breath. Then, while exhaling slowly and fully relaxing the leg and foot, the patient takes up any slack that develops by maintaining a steady pull up toward the nose (inversion and dorsiflexion). After a pause, this cycle should be repeated until no further gain in the range of inversion and dorsiflexion occurs.

Figure 64-8. Self-stretch of the fibularis longus and fibularis brevis muscles. The arrow identifies the direction of pull: inversion first with plantar flexion, then dorsiflexion of the fully inverted foot. This stretch can be effectively combined with postisometric relaxation.

For patients able to handle the additional complexity, voluntarily trying to invert and dorsiflex the foot while using the hand to assist moving it in the same direction may increase further gains. This contraction activates the tibialis anterior and posterior muscles, and the antagonists of the fibularis longus and fibularis brevis muscles, reciprocally inhibiting them and thereby increasing their relaxation and tolerance to stretch.

It is important to avoid stretching to their full range of motion those muscles that cross hypermobile joints, especially after an acute lateral ankle sprain or fracture. Care should be taken to avoid stretching into inversion for the first several weeks after injury, as this could

cause pain, apprehension, and further injury.

Gastrocnemius Muscle

“Calf Cramp Muscle”

Kathleen Geist, Jennifer L. Freeman, and Jeffrey Gervais Ebert

1. INTRODUCTION

The gastrocnemius muscle is a bipennate muscle located in the posterior compartment of the leg that, along with the soleus and plantaris muscles, comprises the muscle group known as the triceps surae muscles. The primary function of the gastrocnemius muscle is plantar flexion of the ankle and flexion of the knee joint at the end range. The gastrocnemius muscle creates quick dynamic force activity such as jumping and running with a high percentage of type 2 fast twitch muscle fibers. Trigger points (TrPs) are commonly identified in the mid-portion of the medial or lateral muscle belly. Trigger points in the gastrocnemius muscle can refer pain proximally to the posterior aspect of the knee joint or distally into the foot. Active TrPs identified in the medial head of the gastrocnemius muscle commonly refer pain into the medial longitudinal aspect of the foot. Symptoms may be exacerbated by walking, especially uphill, and can cause nocturnal calf cramps. Nocturnal calf cramps are described as a painful stimulus from a sudden, involuntary contraction of the gastrocnemius muscle that can disrupt the quality and duration of sleep. Symptoms of TrPs in the gastrocnemius muscle include posterior knee or calf pain and range-of-motion restrictions in the knee and ankle during a single-leg squat. Differential diagnosis should include assessment of ligamentous injury of the knee, muscle strain of the hamstring and popliteus, common fibularis nerve injury, meniscal or bone injury, Baker or ganglion cysts, neurovascular injury, or an S1 radiculopathy from the lumbar spine. Additionally, TrPs in the gastrocnemius muscle can also be present in individuals with Achilles tendinopathy. Corrective actions include postural education, especially sleeping and sitting positions, activity and footwear modifications, TrP self-pressure release, and self-stretching techniques.

2. ANATOMIC CONSIDERATIONS

The gastrocnemius muscle comprises a medial and lateral head and is the most superficial muscle in the posterior compartment of the leg. The medial head originates from the popliteal surface of the femur, posterior to the medial supracondylar line, and the posterior aspect of the adductor tubercle of the femur.¹⁻³ The lateral head originates from the posterolateral aspect of the lateral femoral condyle and the inferior aspect of the supracondylar line (Figure 65-1).^{2,3} Several cadaveric and human studies have reported differences in the structural characteristics between the medial and the lateral heads of the gastrocnemius muscle.^{4,5} For instance, the muscle belly of the medial head has a unipennate structure and is larger than that of the lateral head, which has a bipennate structure.⁶ The medial and the lateral heads of the gastrocnemius muscle cross the tibiofemoral joint, and fibers from the posterior aspect of the knee capsule blend into both heads along with a contribution of the popliteal ligament blending into the lateral head of the gastrocnemius muscle.⁷ The medial and the lateral heads of the gastrocnemius muscle descend inferiorly, with the medial head muscle fibers extending below the lateral head muscle fibers, and both muscle bellies stay separate until they blend into a broad aponeurosis that, in turn, blends with the soleus muscle to form the calcaneal (Achilles) tendon and cross the talocrural and subtalar joints.^{2,3,8} The Achilles tendon inserts into the calcaneal tuberosity on the posterior surface of the calcaneus.² The insertion of each muscle of the triceps surae into the Achilles tendon is not uniform as the largest component comes from the subtendon of the lateral gastrocnemius muscle (44.4%), followed by the soleus muscle (27.9%), and the medial gastrocnemius muscle (27.7%).⁹

Figure 65-1. Attachments of the right gastrocnemius muscle (red) seen from the rear. The distal (deep) aponeurosis of the gastrocnemius muscle merges with the superficial soleus aponeurosis to form the Achilles tendon.

2.1. Innervation and Vascularization

The gastrocnemius muscle is innervated by the tibial nerve from the S1 and S2 nerve roots of the lumbosacral plexus. The tibial nerve branches off the sciatic nerve in the posterior aspect of the thigh and descends through the popliteal fossa into the posterior compartment of the leg. The tibial nerve innervates the superficial and deep muscles of the posterior aspect of the leg. The tibial nerve continues distally through the posterior compartment of the leg and courses between the flexor digitorum and flexor hallucis longus tendons

posterior to the medial malleolus of the tibia.³ The sural nerve is a cutaneous nerve, consisting of branches from the tibial and common fibular nerve, that courses lateral to the Achilles tendon in the posterior-lateral compartment of the leg.¹ The sural nerve crosses the Achilles tendon approximately 3.5 cm distal to the myotendinous junction and approximately 11 cm proximal to the calcaneal tuberosity.¹ Anatomic variations in the formation and course of the sural nerve are quite common in the general population.¹⁰

The arterial supply to the medial and the lateral heads of the gastrocnemius muscle course distally into the muscle bellies following the nerve supply. The medial and the lateral heads of the muscle are supplied by individual sural arteries that branch from the proximal popliteal artery. The sural arteries usually enter the medial and lateral heads of the gastrocnemius muscle at the level of the tibiofemoral joint line. Additionally, the medial sural artery has several perforators into the medial gastrocnemius muscle that run to the subfascial plexus through the deep fascia and nourish the perforator-based flaps.¹¹ The sural artery supplying the medial head of the gastrocnemius muscle enters proximal to the tibiofibular joint line compared with the sural artery supplying the lateral head of the gastrocnemius muscle, which usually enters the muscle distal to the tibiofibular joint line. Arterial supply to the proximal and distal portion of the Achilles tendon is provided by the recurring branch of the posterior tibial artery, with the mid-section of the tendon receiving blood supply from the fibular artery. However, the vascular supply to the calcaneal tendon is relatively poor, and most of the blood supply is allocated to the paratenon. The posterior tibial and fibular veins course proximally adjacent to the posterior tibial and fibular artery, respectively.³

2.2. Function

The primary functions of the gastrocnemius muscle are ankle plantar flexion and supination of the subtalar joint as well as flexion or extension of the knee joint, depending if the lower extremity is in a weight-bearing position or not, respectively.¹²

The gastrocnemius muscle crosses the knee joint and, collectively with the rectus femoris and hamstring muscles, make up approximately 98% of the total cross-sectional area of the musculature surrounding the knee.¹³ When the lower extremity is in a nonweight-bearing position, the gastrocnemius muscle can function as a knee flexor along with the hamstring muscles. In a weight-bearing position, when the knee is in full extension, the gastrocnemius muscle provides an increased amount of torque into knee flexion.¹⁴ It prevents hyperextension of the knee and excessive strain on the posterior capsule due to the anatomic connections between the capsule and the medial and the lateral heads of the muscle. As the knee joint moves into flexion, the gastrocnemius muscle is unable to generate a sufficient amount of torque into flexion.¹⁴ The rectus femoris and gastrocnemius muscles work synergistically as dynamic stabilizers of the knee in weight-bearing positions.¹⁵

The gastrocnemius muscle is active during the stance and pre-swing phase of gait. Most authors agree that a role of the gastrocnemius muscle is providing vertical support of the

lower extremity during the stance phase of gait; however, there is current debate as to the propulsive role of the gastrocnemius muscle during the mid-stance phase of gait. Toward the end of the loading response during the gait cycle, the gastrocnemius muscle provides stability and support of the knee joint to prevent excessive hyperextension.¹⁶ The gastrocnemius and soleus muscles are also considered to be strong supinators of the subtalar and talocalcaneonavicular joint during ambulation.

Research suggests that the gastrocnemius muscle serves as an antagonist to prevent excessive strain on the anterior cruciate ligament (ACL) and may be important to consider during the rehabilitation process. Oeffinger et al¹⁷ demonstrated that a latency in the gastrocnemius muscle demonstrated a significant amount of angular displacement of the tibia during sudden perturbations in patients with ACL repair. Fleming et al¹⁶ studied the amount of translatory strain on the anteromedial bundle of the ACL through the individual electrical stimulation of the gastrocnemius, quadriceps, and hamstrings muscles and measured the strain rates based upon a paired combination of the muscles. The results demonstrated that when the knee joint was positioned in 15° and 30°, the simultaneous stimulation of the gastrocnemius and hamstrings muscles resulted in a reduction in strain on the ACL compared with gastrocnemius muscle stimulation alone.¹⁶

2.3. Functional Unit

The functional unit to which a muscle belongs includes the muscles that reinforce and counter its actions as well as the joints that the muscle crosses. The interdependence of these structures functionally is reflected in the organization and neural connections of the sensory motor cortex. The functional unit is emphasized because the presence of a TrP in one muscle of the unit increases the likelihood that the other muscles of the unit will also develop TrPs. When inactivating TrPs in a muscle, one must be concerned about TrPs that may develop in muscles that are functionally interdependent. Box 65-1 grossly represents the functional unit of the gastrocnemius muscle.¹⁸

Box 65-1 Functional unit of the gastrocnemius muscle		
Action	Synergists	Antagonists
Plantar flexion	Soleus Plantaris Fibularis longus Fibularis brevis Flexor digitorum longus Tibialis posterior	Extensor hallucis longus Extensor digitorum longus Tibialis anterior Fibularis tertius
Knee flexion	Hamstrings Popliteus Plantaris	Rectus femoris Vastus medialis Vastus lateralis

	Gracilis Sartorius	Vastus intermedius
--	-----------------------	--------------------

3. CLINICAL PRESENTATION

3.1. Referred Pain Pattern

An individual with TrPs in the gastrocnemius muscle may present with posterior knee, calf, or plantar heel pain (Figure 65-2).¹⁹ Trigger points in the lateral head of the gastrocnemius muscle may refer pain to the posterior and lateral aspect of the calf. Trigger points in the medial head of the gastrocnemius muscle can refer pain into the posteromedial aspect of the leg and the medial longitudinal arch of the foot or can cause painful muscle cramps in the posterior leg.¹⁸ Individuals with TrPs in the gastrocnemius muscle may report sharp pain along the plantar surface of the heel upon weight-bearing activities with the first few steps upon waking in the morning and heel pain with weight-bearing activity following a period of nonweight bearing such as prolonged sitting.²⁰ Activities such as walking on inclines or stair climbing may also be painful with TrPs in the gastrocnemius muscle.

Figure 65-2. Pain (dark red) referred from TrPs in the right gastrocnemius muscle (light red). The essential pain pattern is solid red. Red stippling indicates the extension of the essential pattern. Trigger point in the belly of the medial head, and to a lesser extent TrPs in the

belly of the lateral head, are likely to be present when the patient has painful nocturnal calf cramps.

3.2. Symptoms

Individuals with TrPs in the gastrocnemius muscle primarily report pain located in the medial longitudinal arch especially with walking and stair climbing. The patient may report pain in the back of the knee on effort, as when climbing up steep slopes, over rocks, or when walking along a slanted surface, such as a beach or the side of a domed street. Patients with gastrocnemius TrPs rarely report weakness or restricted range of motion even when dorsiflexion of the ankle is found to be limited upon testing. The individual may also report calf or plantar heel pain and nocturnal calf cramping.^{18,21} The presence of latent TrPs in the gastrocnemius muscle can give rise to painful, involuntary muscle cramps in the calf region. Muscle cramps can occur as part of a myopathic or pathoneurologic process but can also occur in healthy individuals during pregnancy, sport activities, and sleep.²²

Latent TrPs are more commonly found in the medial head of the gastrocnemius muscle and can cause nocturnal calf cramps, negatively impacting sleep quality. Several studies evaluated the effects of TrP injections in the gastrocnemius muscle and found that using a local anesthetic both reduced the intensity and the frequency of pain associated with nocturnal calf cramps and appears to lessen the severity of insomnia during the night.^{22,23} The pathophysiologic effects of latent TrPs causing nocturnal calf cramps are not clearly understood; however, several theories, including spontaneous discharges or abnormal excitability from motor nerves and overexcitability of the motor unit in the presence of spinal disinhibition, have been suggested.²² In a study conducted by Ge et al²¹ glutamate injection into a latent TrP in the gastrocnemius muscle reproduced the onset of muscle cramps in the calf. The authors suggest that there may be an association between excitation of the afferent muscle fibers and a subsequent increase in nociceptive sensitivity that elicits muscle cramping.²¹ The authors propose that there may be a relationship between the presence of TrPs and the development of muscle cramps.

3.3. Patient Examination

After a thorough subjective examination, the clinician should make a detailed drawing representing the pain pattern described by the patient. This depiction will assist in planning the physical examination and can be useful in monitoring the progression of the patient as symptoms improve or change. The type, quality, and location of the pain should be carefully assessed, and the utilization of standardized outcome tools is imperative when examining patients with lower extremity dysfunctions.

Observation of static and dynamic posture is essential due to the role of the gastrocnemius muscles in postural stability. During an observation of static standing posture, the patient may be unable to fully extend the involved extremity when keeping the heel on the floor.¹⁸ Functional testing such as double- and single-leg squat will allow a quick assessment of hip and knee control, as well as a quick assessment of talocrural,

subtalar, and mid-foot range of motion. Timed single-leg stance with eyes open and closed will give a quantitative measure of balance and will afford the clinician to observe foot and ankle strategies related to balance and control.

Restricted active or passive range of motion in ankle dorsiflexion may be identified during the clinical examination.^{24,25} A reduction in the amount of passive ankle dorsiflexion when the knee is extended, and an increase with the knee flexed, suggests that the motion restriction is related to tightness of the gastrocnemius muscle rather than a joint or capsular restriction of the talocrural joint.¹⁵ The clinician should maintain the rearfoot in a varus position to accurately measure the amount of dorsiflexion at the talocrural joint. Passive dorsiflexion of the talocrural joint with the rearfoot in valgus allows excessive motion to occur at the mid-foot and subtalar joint.²⁶ Patients with TrPs in the gastrocnemius muscle may display alterations in their gait, exhibiting a flat-footed or a stiff-legged gait pattern.

Examination of the extensibility of the gastrocnemius muscle is performed with the individual in a supine or prone nonweight-bearing position (Figure 65-3). A lack of dorsiflexion of the talocrural joint by $>10^\circ$ is known as a talipes equinus.²⁷ A common cause of restricted ankle dorsiflexion is adaptive shortening of the triceps surae muscles. Restricted passive ankle dorsiflexion with the knee extended and an increase in passive ankle dorsiflexion with the knee flexed is known as the Silfverskiöld sign²⁶ (Figure 65-3A and B). To date, the psychometric properties of the Silfverskiöld sign are not known. A reduction in the amount of passive ankle dorsiflexion when the knee is extended and an increase with the knee flexed suggest that the motion restriction is related to tightness of the gastrocnemius muscle rather than a joint or capsular restriction of the talocrural joint.¹⁴ To test for the presence of talipes equinus, a 2 kg force should be placed under the forefoot while providing a passive dorsiflexion force to minimize a false-positive test.²⁶

Figure 65-3. Muscle length testing. A, Gastrocnemius muscle. B, Soleus muscle. Note the change in dorsiflexion with the knee flexed.

Passive accessory motion of the talocrural joint, as well as the distal and proximal tibiofibular joints, should be examined. Passive accessory motion of the tibiofemoral joint should be examined when the patient reports posterior knee pain and loss of knee extension range of motion that may be associated with gastrocnemius TrPs.

The results on the effects of the gastrocnemius muscle stretching on ankle dorsiflexion range of motion remain equivocal. A systematic review by Young et al²⁸ evaluated the efficacy of the gastrocnemius muscle stretching alone compared with a multimodal approach. A meta-analysis of 8 studies showed that passive gastrocnemius muscle stretching had a significant effect on an increase in ankle dorsiflexion, whereas 12 other studies demonstrated no significant effect of the gastrocnemius muscle stretching on ankle dorsiflexion compared with a control group.²⁸ The results of a 3-week gastrocnemius stretching program were shown to be effective in increasing passive ankle dorsiflexion range of motion; however, the increases in range of motion did not translate to an increase in time-to-heel off during gait.²⁹ Edama et al⁶ investigated on cadavers the best position for stretching the medial gastrocnemius muscle and reported that knee extension, with dorsiflexion and inversion of the ankle, induced the greatest tension in the medial head. However, none of these studies investigated the presence of TrPs in the gastrocnemius muscle prior to the stretching program, which could account for the equivocal findings.

There is moderate to strong evidence that supports the utilization of manual TrP release to relieve muscle pain associated with active and latent TrPs.³⁰ A study by Grieve et al²⁵ assessed the effect of manual TrP release of latent TrPs and passive stretching of the triceps surae muscles in healthy, recreational runners. Following combined treatment of manual TrP release and passive stretching of the triceps surae muscles, the runners demonstrated an improvement in the extensibility of both the soleus and gastrocnemius muscles. Based on a paired *t*-test, the participants showed a statistically significant increase in muscle extensibility of the soleus and gastrocnemius muscles.²⁵

A multimodal approach that includes TrP release techniques and stretching for the triceps surae muscle is an effective treatment for the management of plantar heel and foot pain. Grieve et al²⁴ reported on the effects of a multimodal treatment approach for participants with calf pain. All participants received an initial evaluation for an assessment of the independent variables including pain scale, pain pressure threshold (PPT), functional status on the lower extremity functional scale (LEFS), and ankle dorsiflexion range of motion. Ten participants received TrP release to the tricep surae muscles, instructed in a self-pressure TrP release technique, and a home-stretching program. Nine of the participants demonstrated an increase in ankle dorsiflexion range of motion and an increase in the individual LEFS scores.²⁴ Ordine et al²⁰ found that manual TrP release directed over TrPs identified in either muscle bellies of the gastrocnemius muscle, in addition to a self-stretching exercise for the triceps surae muscles and plantar fascia, resulted in a significant decrease in pain and a significant improvement in the Short-Form (SF)-36 Questionnaire and the PPT over the gastrocnemius and soleus muscles.²⁰

3.4. Trigger Point Examination

A suspicion of the presence of the TrP is usually made based on a combination of subjective and objective physical examination findings.¹⁸ A cross-fiber flat or pincer palpation is effective in identifying TrPs within the medial or lateral heads of the gastrocnemius muscle.

A cross-fiber flat palpation approach is selected when the subcutaneous soft tissue of the posterior calf is tight and nonmobile. For those patients who have pliable and mobile subcutaneous soft tissue of the calf, a cross-fiber pincer palpation may be used. Manual palpation of the gastrocnemius muscle can be performed with the patient prone, side-lying, or hook-lying (Figures 65-4 and 65-5). When examining the gastrocnemius muscle in side-lying, the patient should lie on the side with the involved extremity to be treated uppermost. When examining the patient in a prone position, a pillow should be placed under the patient's feet to maintain knee flexion of approximately 20° and to allow some slack in the gastrocnemius muscle.¹⁸

Figure 65-4. Palpation of the gastrocnemius muscle's lateral head. Cross-fiber pincer palpation. A, Side-lying. B, Prone. C, Hook-lying. D, Cross-fiber flat palpation proximal portion.

Figure 65-5. Palpation of the gastrocnemius muscle's medial head. Cross-fiber pincer palpation. A, Prone. B, Hook-lying. Cross-fiber flat palpation. C, Mid-muscle belly. D, Proximal portion.

Cross-fiber pincer palpation to identify TrPs in the lateral head of the gastrocnemius muscle can be performed in side-lying (Figure 65-4A), prone (Figure 65-4B), or hook-lying (Figure 65-4C). Cross-fiber flat palpation is utilized to identify TrPs in the proximal portion of the lateral head or the entire muscle belly if the tissue on the posterior calf is immobile or too taut.

Cross-fiber pincer palpation of the medial head of the gastrocnemius muscle is performed in the prone or side-lying position (Figure 65-5A and B). Cross-fiber flat palpation is utilized to identify TrPs in the proximal portion of the medial head or the entire muscle belly if the tissue on the posterior calf is immobile or too taut.

4. DIFFERENTIAL DIAGNOSIS

4.1. Activation and Perpetuation of Trigger Points

A posture or activity that activates a TrP, if not corrected, can also perpetuate it. In any part of the gastrocnemius muscle, TrPs may be activated by unaccustomed eccentric loading, eccentric exercise in an unconditioned muscle, or maximal or submaximal concentric loading.³¹ Trigger points may also be activated or aggravated when the muscle is placed in a shortened and/or lengthened position for an extended period of time.

Trigger points can develop in the gastrocnemius muscle from mechanical overload or

activity that involves forceful plantar flexion of the ankle when the knee is in a flexed position. Activity that involves cycling, walking, running on inclined surfaces, or climbing steep terrain can promote the development of TrPs within the gastrocnemius muscle that produces posterior knee pain. Other causes of muscle overload include swimming with the toes pointed in a flutter kick, wearing high heeled shoes, or sitting with prolonged pressure on the back of the thigh or calf. Sleeping supine with the feet held in plantar flexion by tucked in blankets may also perpetuate TrPs.

Immobilization of the lower extremity after an injury, such as a fracture, can facilitate the development of TrPs in the gastrocnemius muscle from the resultant trauma. During the immobilization period, the gastrocnemius muscle can become atrophied and deconditioned and once weight bearing is initiated, the individual may report a painful and stiff calf muscle.

Perpetuation of TrPs in the gastrocnemius muscle can occur from sustained external compression of the leg that creates a localized ischemic event. External compression of the gastrocnemius muscle that may contribute to the perpetuation of TrPs can occur from tight socks or elastic bands around the leg, from sustained compression of a chair seat or from maintaining knee flexion and ankle plantar-flexion during prolonged sitting tasks.¹⁸

4.2. Associated Trigger Points

Associated TrPs can develop in the referred pain areas caused by primary TrPs.³² Therefore, musculature in the referred pain areas for each muscle should also be considered. Associated TrPs develop in response to muscular compensation patterns or from referred phenomena when a muscle is within a referred pain pattern from a proximal or adjacent to the gastrocnemius muscle. For example, a TrP in the gluteus medius or gluteus minimus muscles can refer pain into the proximal region of the calf, and an associated TrP can develop in the gastrocnemius muscle.¹⁸

Patients who develop active TrPs in the gastrocnemius muscle can develop associated TrPs in the hamstring, popliteus, soleus, flexor hallucis longus, and flexor digitorum longus muscles on the ipsilateral lower extremity. Once the active TrPs in the gastrocnemius muscle are treated, the patient's report of pain may change to a more distal pain distribution due to the referred pain pattern of the long toe flexors or soleus muscles.¹⁸

4.3. Associated Pathology

An individual with primary reports of calf pain should be evaluated for the presence of a lumbar radicular pain or radiculopathy. Radiculopathy refers to a disorder of a spinal nerve root and is associated with leg or back pain and a neurologic impairment such as hypoesthesia, weakness, or paresthesia in the lower extremity.³³ A neurologic examination should be performed in the lower extremities to assess for the presence of dermatomal, myotomal, or reflex changes. This examination should also assess for the presence of a nerve root irritation or compression of the L5 nerve root that can give rise to pain along the lateral aspect of the leg with weakness of the ankle plantar flexors or a diminished or absent

Achilles reflex. Lumbar radiculopathy associated with an S1 nerve root can result in pain along the lateral border of the foot, weakness of the ankle plantar flexors, and a diminished or absent Achilles reflex.³⁴

Radicular pain originating from a spinal nerve root can cause sharp, shooting pain distal to the knee. The examination cannot always deduce the level of spinal involvement based on the pattern of sensory deficits or pain. There is little evidence to support that radicular pain follows a specific dermatomal pattern that corresponds to the level of the involved spinal nerve root. In a study of 169 patients with lumbar radiculopathy, 64.1% of those patients experienced radicular pain in a nondermatomal pattern.³⁵ Objective findings from the clinical exam including a positive crossed straight leg raise (SLR) (sensitivity 0.29, specificity 0.88) and absent reflexes (sensitivity 0.14, specificity 0.93, +LR 2.21, -LR 0.78) assist in ruling in a nerve root syndrome, whereas the absence of symptoms with a SLR (sensitivity 0.91, specificity 0.26) can be used to rule out a diagnosis of radiculopathy.^{36,37}

Pain in the posterior aspect of the calf can include injuries from repeated overload, mechanical stress, or trauma. Achilles tendinopathy is one of the most common overuse injuries of the foot and ankle, particularly among recreational and competitive athletes.³⁸⁻⁴² The etiology of Achilles tendinopathy is multifactorial and includes intrinsic and extrinsic factors leading to a failed healing response and degenerative changes.⁴³ Depending on the type and level of activity, this condition affects as many as 9% to 40% of athletes,^{44,45} especially runners.⁴⁵⁻⁴⁷ Although athletes tend to be at greatest risk of developing this condition, it can affect relatively sedentary individuals as well.^{48,49} Achilles tendinopathy can generally be classified into two categories: insertional tendinopathy and noninsertional, or mid-portion, tendinopathy. Noninsertional tendinopathy is the most commonly occurring classification.⁴⁴ Achilles tendinopathy is typically a noninflammatory condition and instead involves degenerative changes within the substance of the tendon, especially in chronic presentations that make up the majority of cases.⁵⁰⁻⁵³ The incidence of Achilles tendinopathy tends to increase with age,^{54,55} with an average age range of 30 to 50 years of age.^{42,56,57} This condition appears to affect men more than women.^{40,57,58}

Several risk factors for Achilles tendinopathy have been documented. These risk factors include limited ankle dorsiflexion range of motion,⁵⁹ excessive pronation,^{40,60} reduced ankle plantar flexion strength,^{60,61} abnormal subtalar range of motion,^{40,59} obesity,⁴⁸ diabetes,⁴⁸ training errors,³⁹ and medication usage—specifically, the antibiotic fluoroquinolone.^{62,63}

Patients with chronic Achilles tendinopathy will most commonly report increased pain with activity⁶⁴ and ankle stiffness after periods of prolonged inactivity⁶⁵ that diminishes with continued activity.⁶⁶ In mild to moderate cases, patients may experience pain only at the end of their recreational activity⁶⁵ and, as the condition becomes more severe, they may experience pain throughout the activity and may need to discontinue the activity completely.⁶⁶ Typical findings utilized in the diagnosis of Achilles tendinopathy include local tenderness with palpation of the mid-portion of the tendon (approximately 2-6 cm proximal to its insertion) with noninsertional tendinopathy⁶⁷ and at the bone-tendon

junction with insertional tendinopathy⁶⁰; a positive arc sign⁶⁷; reduced ankle plantar flexion strength^{68,69}; and a positive Royal London Hospital Test.⁶⁷ Reiman et al⁷⁰ found that the presence of morning stiffness and local pain with palpation for crepitus showed high sensitivity and specificity for clinical diagnosis of Achilles tendinopathy.

In cases in which a diagnosis of Achilles tendinopathy is uncertain following the history and physical examination, magnetic resonance imaging (MRI) and/or diagnostic ultrasound can be utilized to rule in or rule out the condition more definitively^{64,71,72} if needed to change the clinical plan of care.

An acute onset of pain and swelling in the posterior aspect of the leg can be caused by localized inflammation in tendons or an acute tear of the muscle or tendon. Ruptures of the medial head of the gastrocnemius muscle, known as “tennis leg,” can occur with eccentric lengthening of the gastrocnemius muscle as the foot moves into dorsiflexion and the knee moves into extension following a serve in tennis.¹⁸ In fact, strain in the medial gastrocnemius muscle represents the most common injury of the posterior compartment of the lower extremity. Two-thirds of calf injuries occur at the junction of the fascia between the medial head of the gastrocnemius and the soleus muscles.⁷³

Muscles overlying the posterior compartment of the knee that are commonly subject to injury include the hamstring and popliteus muscles. The hamstring muscles can be injured during sprinting activity and may cause posterolateral knee pain with tenderness to palpation inferior to the joint. Resisted testing of the hamstring muscles with the knee flexed and the tibia rotated internally or externally can assist in the diagnosis of injury to the semimembranosus, semitendinosus, and biceps femoris muscles, respectively.¹⁴ Clinical findings of a tear within a muscle include the presence of swelling, tenderness, or a palpable defect within the muscle belly. A rupture of the popliteus muscle can occur with ligamentous injury to the posterior cruciate ligament. An acute tear of the plantaris tendon can often occur in association with a tear of the gastrocnemius muscle. A rapid diagnosis of an acute musculotendinous lesion can be identified by the utilization of musculoskeletal ultrasound from the localization of hypoechoic changes (<2 cm) for a partial tear or the presence of a hypoechoic hematoma formation in the presence of a full tear.⁷⁴ Days following the injury, a hematoma can form around the area of injury. Acute traumatic injuries associated with swelling or hematoma formation should also be screened for associated nerve injury to the common fibular nerve.⁷⁵

Additional causes of pain in the posterior aspect of the calf include Baker cysts, tumors, infections, arterial insufficiency, or deep vein thrombosis. A Baker cyst forms in the popliteal region from herniation and leaking of synovial fluid from the posterior knee capsule as a result of internal derangement within the knee joint.⁷⁵ The presence of a Baker cyst can be identified through palpation of a painful or tender nodule between the semimembranosus and medial head of the gastrocnemius muscles. The use of MRI is the best imaging modality used to diagnose the presence of a Baker cyst because an MRI can identify the presence of an intra-articular derangement and adjacent relationship of the anatomic structures.⁷⁵

Complications from Baker cysts include infection, rupture with concomitant compression of surrounding anatomic structures, and hemorrhage.^{74,75} The presence of an infection should be suspected in the presence of a systemic illness, presence of a cyst with posterior knee pain, and swelling with local signs of warmth and erythema. A Baker cyst can cause deep venous thrombosis and ischemia. The associated symptoms from a ruptured cyst can mimic the clinical examination findings of thrombophlebitis. Diagnosis of vascular injuries associated with posterior knee pain can be established with MRI or computerized tomography angiography.⁷⁵

5. CORRECTIVE ACTIONS

An individual with TrPs in the gastrocnemius muscle should avoid postures or activities with sustained active or passive ankle plantar flexion. Positions that should be avoided include sitting in high chairs in which the feet are not completely supported on the floor and prolonged driving activity with the ankle held in sustained plantar flexion. Patients should adjust sitting surfaces to allow their feet and ankles to rest in a neutral ankle position, and cruise control use during prolonged driving activities can prevent the perpetuation of TrPs in the triceps surae muscles. Other helpful activity modifications may include walking on level surfaces instead of inclined surfaces, avoiding tight or elastic materials around the calf, avoiding prolonged ankle plantar flexion with swimming activities, and avoiding wearing shoes with a heel greater than 2 in. Electromyographic assessment of the gastrocnemius muscle in individuals wearing a small heel lift demonstrates reduced activity of the gastrocnemius muscle during walking activity.⁷⁶ Therefore, the use of a small heel lift may be beneficial for temporary off-loading of the gastrocnemius muscle after an acute injury or after surgical repair of the Achilles tendon.

Nocturnal (nighttime) calf cramps are often associated with TrPs in the gastrocnemius muscle. Warming the calf with an electric blanket or heating pad for a few minutes prior to bed can help reduce the irritability of TrPs, and maintaining the ankles in a neutral position while sleeping can help reduce nocturnal night cramps. To prevent the onset of nocturnal muscle cramps, one can alternate full active range of motion in ankle dorsiflexion and plantar flexion. Active range of motion while sitting helps minimize immobility and promotes blood flow to the lower extremities.¹⁸

In general, the leg muscles feel better if the ankle is maintained in a neutral position throughout the night; therefore, adjusting the patients' sleeping posture may be necessary. This position is facilitated by having the bed sheets at the foot of the bed untucked to reduce external force into excessive plantar flexion (Figure 65-6). Using a pillow between the legs and knees in side-lying to place the foot and ankle in a neutral position may also be beneficial. Patients with irritable TrPs should avoid lying on the affected side as the pressure from the bed may perpetuate TrP activity.

Figure 65-6. Sleeping posture with the foot of the affected side outside the covers to avoid the weight of the covers pulling the foot and ankle down and placing the muscle in a prolonged shortened position.

Gastrocnemius TrP self-pressure release can be performed in the seated and long sitting positions (Figure 65-7). Pressure may be applied manually with a pincer grasp (Figure 65-7A), with a TrP release tool or firm ball (Figure 65-7B), or with a TrP release roller tool (Figure 65-7C). Finding the sensitive spot with the hands or a tool, light pressure (no more than 4/10 pain) is applied and held for 15 to 30 seconds until pain reduces. This technique can be repeated up to five times, several times per day (Figure 65-7A, B, and C).

Figure 65-7. Trigger point self-pressure release. A, Manual release. B, Using a lacrosse ball. C, Using a TrP self-release roller.

Gastrocnemius muscle self-stretching can be performed in a sitting or standing position. Self-stretching of the gastrocnemius muscle in a sitting position requires the patient to maintain a long sitting position with the involved knee fully extended. A long strap is placed under the forefoot, while maintaining the knee in an extended position, and a prolonged passive stretch into dorsiflexion is applied at the foot and ankle (Figure 65-8A).

Self-stretching of the gastrocnemius muscle in standing is performed with the individual in a stride-stance facing a wall, with both feet placed in a neutral position and their hands on the wall at shoulder height or on a chair (Figure 65-8B). With the affected leg behind, the foot should be placed in slight supination using a small wedge along the entire inside edge of the foot (Figure 65-6B, small pic) to emphasize dorsiflexion through the rear foot and prevent excessive forces into dorsiflexion through the mid-foot.⁷⁷ The individual should lean the trunk forward while maintaining the heels on the floor and shifting weight toward the lead foot, maintaining the knee in a fully extended position. This stretch may be augmented by postisometric relaxation. At the first onset of a stretch in the calf, the ball of the foot is pushed into the floor with a slight contraction of the calf muscles, but the heel or foot remains on the floor. Holding the contraction for 6 to 10 seconds, a deep inhalation is performed. Then, during a slow exhale through the mouth, the calf muscle is allowed to relax and another slight lean forward can be performed until a stretch is felt once again in the calf. This procedure can be repeated three to five times and can be performed three times daily.

Figure 65-8. Self-stretch of the gastrocnemius muscle. A, Gentle stretch with a strap or sheet for irritable TrPs in the gastrocnemius muscle. B, Runners stretch. A flat towel is placed along the inside of the foot to prevent flattening of the arch while stretching.

Soleus and Plantaris Muscles

“Jogger’s Heel”

Kathleen Geist and Joseph M. Donnelly

1. INTRODUCTION

The soleus and plantaris muscles are located in the superficial posterior compartment of the leg along with the gastrocnemius muscle. The primary function of the soleus muscle is plantar flexion of the ankle joint, inversion of the subtalar joint, and postural control. It is also an essential component of the lower extremity musculovenous pump. The plantaris muscle is thought to have a primary proprioceptive role at the foot and ankle. Trigger points (TrPs) in the soleus and plantaris muscles can cause posterior knee, calf, Achilles tendon, and heel pain. In rare instances, a TrP in the soleus muscle refers pain proximally to the ipsilateral posterior superior iliac spine. Trigger points in the soleus muscle can restrict active and passive ankle dorsiflexion with the knee flexed. Symptoms associated with TrPs in the soleus muscle include pain over the posterior aspect of the lower leg, posterior and inferior aspect of the heel, and arch of the foot, which is exacerbated by walking on inclined surfaces, stair climbing, or running. Differential diagnosis of soleus TrPs should include screening for lumbar radicular pain or radiculopathy, referred pain from the sacroiliac joint, Achilles tendinopathy, exertional compartment syndrome, and Haglund syndrome. Corrective actions for soleus TrPs include postural education, self-stretching, and TrP self-pressure release.

2. ANATOMIC CONSIDERATIONS

Soleus

The soleus muscle is a bipennate muscle located in the superficial posterior compartment of the leg and makes up the triceps surae muscle group together with the gastrocnemius and plantaris muscles. The soleus muscle lies deep to the gastrocnemius muscle in the posterior compartment of the leg (Figure 66-1).^{1,2} The proximal attachment of the soleus muscle originates from the soleal line and middle third of the posterior aspect of the tibia, the

proximal fourth of the posterior surface of the fibula, and the posterior aspect of the fibular head. A fibrous band forms between the proximal medial and lateral origin of the soleus muscle in which the popliteal artery, popliteal vein, and tibial nerve pass distally into the leg (Figures 66-2 and 66-3).³ The soleus muscle fibers attach to the underside of the aponeurosis that also provides an attachment for the gastrocnemius muscle. This aponeurosis forms the Achilles tendon and inserts into the posterior aspect of the calcaneus.^{1,4}

Figure 66-1. The proximal aspect of the soleus muscle arises from the head of the fibula,

proximal 1/3 and mid-shaft of the posterior tibia and soleal line and inserts into the posterior aspect of the calcaneus. The plantaris muscle takes origin from the lateral supracondylar line of the femur and inserts on the posterior aspect of the calcaneus.

Figure 66-2. Superficial view of the soleus canal with the major portion of the right soleus muscle (dark red) cut and removed. This shows the relations of the soleus tendinous arch and the muscle to the posterior tibial artery (bright red), posterior tibial veins (black cross hatching), tibial nerve (white), and neighboring muscles (light red). The fibrous band that extends upward from the medial side of the arch that forms the soleus canal is drawn from a photograph of an anatomic specimen in which the band was unusually well developed.

Figure 66-3. The soleus muscle (dark red) has been reflected upward showing the distal opening of the soleus canal and its relation to the tibial nerve (white), to the posterior tibial artery (bright red), to the posterior tibial veins (black cross hatching), and to the adjacent musculature (light red). This is an artist's reconstruction of what the canal would look like if it were possible to reflect the muscle without cutting its proximal attachments to the tibia and fibula. The gastrocnemius muscle is cut and reflected.

Morphologic three-dimensional studies demonstrate the separation of the soleus muscle into marginal, anterior, and posterior divisions based on fiber direction and location of the aponeurosis attachment. The anterior aspect of the soleus muscle gives rise from medial and lateral proximal aponeuroses that blend to form the anterior epimysium. A central tendon

emerges from the anterior aponeurosis of the soleus muscle and extends distally to blend into the anterior and central aspect of the Achilles tendon.² The distal attachment of the soleus muscle is blended with the gastrocnemius muscle to form the calcaneal, or Achilles, tendon, which inserts on the posterior surface of the calcaneus.^{2, 4} The fibers of the Achilles tendon twist approximately 90° before insertion. The tendinous fibers from the soleus muscle attach to the medial one-third of the calcaneus (Figure 66-4), and the fibers from the gastrocnemius muscle attach to the lateral two-thirds.⁵ In fact, the soleus muscle represents only 28% of the insertion of the triceps surae into the Achilles tendon.⁶

Figure 66-4. Attachment of the soleus portion of the right Achilles tendon to the os calcis, posterior view. Note the tendon's rotation of 90° and attachment to the medial one-third of the calcaneus. The gastrocnemius portion of the tendon (not shown) attaches to the lateral two-thirds of the os calcis. Reproduced with permission from Michael RH, Holder LE. The soleus syndrome. A cause of medial tibial stress (shin splints). *Am J Sports Med.* 1985;13:87-94.

The marginal soleus muscle is located at the periphery of the soleus muscle and has direct attachments to the anterior and posterior aponeuroses of the posterior leg. The direction of the fiber bundles of the marginal region of the soleus muscle facilitates a tightening of the anterior and posterior aponeuroses, improving the efficiency of muscle contraction.

The presence of an accessory soleus muscle is an atypical anatomic variant and is believed to occur from an early splitting of a soleus fascicle during embryologic development. An accessory soleus muscle is usually identified from incidental findings on magnetic resonance imaging (MRI) and can be an uncommon source of exertional compartment syndrome with concomitant tarsal tunnel syndrome. The anatomic variant is present in 0.7% to 5.6% of the general population.⁷ The origin of an accessory soleus muscle can arise posteriorly from the distal aspect of the tibia or from the ventral aspect of the soleus muscle. The distal attachments of an accessory soleus muscle can insert on the superior aspect of the calcaneus or on anteromedial aspect of the Achilles tendon.⁷ Others have reported that the accessory soleus muscle has three possible attachments: (1) a distal attachment to the medial aspect of the calcaneus by a separate tendon (26.1%), (2) a distal tendinous attachment to the calcaneal tendon (3.5%), and (3) a distal fleshy attachment to the medial surface of the calcaneus (4.3%).⁸

Plantaris

The plantaris muscle is located in the superficial posterior compartment of the leg and together with the gastrocnemius and soleus muscles are known as the tricep surae muscles. The plantaris muscle is considered to be an accessory to the lateral head of the gastrocnemius muscle. It is a small, thin muscle originating from the inferior aspect of the lateral supracondylar line of the femur and fibers of the oblique popliteal ligament that courses proximally in an inferior and medial direction in the popliteal fossa. The length of the plantaris muscle belly varies in size from 7 to 13 cm in length from the origin on the femur. The myotendinous junction of the plantaris muscle occurs in the proximal one-third of the leg at the level of the superior attachment of the soleus muscle on the tibia. The plantaris tendon travels along the medial aspect of the muscle belly and descends distally as the tendon courses between the soleus muscle and the medial head of the gastrocnemius muscle at the mid-portion of the leg. The tendon continues in an inferomedial direction along the medial aspect of the Achilles tendon and inserts on the calcaneal tuberosity^{3,9} (Figure 66-1).

A retrospective review was performed establishing the prevalence of an accessory plantaris muscle on routine MRI of 1000 individuals with acute or chronic knee pain.¹⁰ An accessory plantaris muscle was identified in 63 of the 1000 individuals, with the origin of 62 accessory plantaris muscles merging with the origin of the plantaris muscle and one accessory plantaris muscle merging with the lateral head of the gastrocnemius muscle and inserting distally to the insertion site of the vastus lateralis muscle. There was variability among the insertion sites of 43 individuals including the lateral patellar retinaculum and the iliotibial band.¹⁰

2.1. Innervation and Vascularization

The soleus and plantaris muscles are innervated by the tibial nerve from the L5, S1, and S2 nerve roots of the lumbosacral plexus. The soleus muscle receives most of its innervation from S1 and S2 and the plantaris muscle mostly from L5 and S1 nerve roots.³ The tibial nerve continues distally through the posterior compartment of the leg and courses between the flexor digitorum and flexor hallucis longus tendons posterior to the medial malleolus of the tibia at the tarsal tunnel.³

The popliteal artery descends inferiorly to the knee joint, giving rise to the posterior tibial artery that supplies the soleus, plantaris, and flexor digitorum muscles in the posterior compartment of the leg. As the posterior tibial artery courses distally, the fibular artery provides a muscular branch to the soleus, tibialis posterior, and flexor hallucis longus muscles.⁴

2.2. Function

Soleus

The soleus muscle has the largest cross-sectional area of any muscle in the leg and is comprised of primarily slow-twitch, type I muscle fibers that are responsible for postural control and activities that require slower speeds of motion such as walking.^{2,11} The predominance of type I muscle fibers in the soleus muscle suggests that the role of the soleus muscle is to provide tonic postural control of the limb in weight bearing and lower intensity muscle contractions in ankle plantar flexion.¹²

Because of the close proximity of the vascular structures to the soleus muscle, the gentle muscle contractions that occur in the soleus muscle with postural control suggest a secondary role with facilitation of venous blood return from the lower leg. The soleus muscle provides a major pumping action to return blood from the lower extremity to the heart. Venous sinuses in the soleus muscle are compressed by the muscle's strong contractions, so that its venous blood is forced upward toward the heart. This pumping action (the body's second heart) depends on competent valves in the popliteal veins. Valves in the veins to prevent reflux of the blood are most numerous in the veins of the lower extremities where the vessels must return blood against high hydrostatic pressure. The

popliteal vein usually contains four valves.³ Deeper veins that are subject to the pumping action of muscle contraction are more richly provided with valves.

Fiber orientation of the soleus muscle has distinct implications for the different biomechanical influences during movement. The fibers of the posterior aspect of the soleus muscle are of shorter length, have an oblique orientation, and serve to generate higher forces, creating a stabilizing effect at the leg. The fibers of the anterior aspect of the soleus muscle are longer on the lateral aspect and shorter on the medial aspect. The longer muscle fibers along the lateral aspect of the anterior surface are thought to contribute to generating ankle plantar flexion forces, and the shorter fibers of the medial aspect of the soleus muscle contribute to stabilization of the leg.¹³

The anterior and posterior fibers of the soleus muscle may contribute to variation in function by providing ankle plantar flexion and stabilization of the leg in weight-bearing positions. Some authors suggest that the variation of fiber sizes within the medial and lateral aspect of the soleus muscle may provide functional differences during activity.¹³ The muscles in the posterior aspect of the leg must have sufficient flexibility to allow for 10° to 15° of ankle dorsiflexion while providing eccentric control of the leg over the foot and stabilization of the knee joint during the early-stance phase of gait. During the late-stance and push-off phase of gait, the soleus and plantaris muscles contract concentrically to assist in forward propulsion of the lower extremity.

Studies suggest that age-related changes affect the muscular efficiency in the older adult and result in a reduction of plantar flexion torque at the ankle during the push-off phase of gait.^{14,15} The gastrocnemius and soleus muscles can have complimentary biomechanical influences at the ankle through shared tendon fascicles that blend into the Achilles tendon. In a younger adult, sonography studies indicate an independent gliding of the tendon fascicles within the superficial and deep portions of the Achilles tendon to allow for force production transfer to the ankle joint from the action of the gastrocnemius muscle and stabilization from the soleus muscle. In older adults, there is a 41% reduction in the amount of interfascicle gliding within the Achilles tendon, resulting in a reduction of plantar flexion torque at the ankle during gait, in turn, resulting in less peak ankle power during the push-off phase of gait.^{14,15}

Plantaris

The anatomic location and cross-sectional size of the plantaris muscle suggests that it may be a very weak flexor of the knee with minimal biomechanical influence at the foot and ankle.¹¹ Although the plantaris muscle is not a significant contributor to knee flexion or ankle plantar flexion, it is considered to have a large contribution to proprioception at the foot and ankle due to the higher proportion of high-density muscle spindles within the musculotendinous unit.⁹

2.3. Functional Unit

The functional unit to which a muscle belongs includes the muscles that reinforce and

counter its actions as well as the joints that the muscle crosses. The interdependence of these structures is functionally reflected in the organization and neural connections of the sensory motor cortex. The functional unit is emphasized because the presence of a TrP in one muscle of the unit increases the likelihood that the other muscles of the unit will also develop TrPs. When inactivating TrPs in a muscle, one must be concerned about TrPs that may develop in muscles that are functionally interdependent. Box 66-1 grossly represents the functional unit of the soleus and plantaris muscles.¹⁶

Box 66-1 Functional unit of the soleus and plantaris muscles

Action	Synergists	Antagonists
Plantar flexion	Gastrocnemius Flexor hallucis longus Flexor digitorum longus Tibialis posterior Fibularis longus Fibularis brevis	Tibialis anterior Extensor digitorum longus Extensor hallucis longus Fibularis tertius

3. CLINICAL PRESENTATION

3.1. Referred Pain Pattern

Soleus

An individual presenting with TrPs in the soleus muscle may report pain in the posterior aspect of the calf, plantar heel, and the ipsilateral sacroiliac joint (Figure 66-5A). Trigger points in the soleus muscle can be developed in any portion of the muscle; however, it has been clinically observed that there are three common areas. The most common area for the development of TrPs is distal within the muscle belly, medial to the Achilles tendon, with referred pain along the Achilles tendon and into the posterior and inferior aspects of the calcaneus. This clinical pattern may be related to the fact that this area of the soleus muscle receives the highest stress from the Achilles tendon. A second common location for TrP development is approximately 1 to 2 in inferior to the proximal attachment of the soleus muscle to the tibia and fibula. The common referred pain pattern is along the midline of the posterior aspect of the calf, inferior to the popliteal crease, and superior to the Achilles tendon. The least common area for TrP development is along the distal aspect of the soleus muscle lateral to the Achilles tendon. The referred pain pattern for a TrP in this area can be located on the ipsilateral sacroiliac joint (Figure 66-5A).

Figure 66-5. Referred pain patterns of the soleus muscle. A, More common pain referral symptoms. B, Exceptional pain pattern.

An exceptional pain pattern referred to the jaw from the TrP in the soleus muscle has been observed twice (Figure 66-5B). In one patient, this TrP referred pain to the ipsilateral face deep in the jaw and temporomandibular joint with malocclusion (“Now my teeth don’t meet,” she said) whenever the ankle on that side was actively or passively dorsiflexed, but with no pain that is usually characteristic of the soleus muscle. The jaw pain and spasm were eliminated immediately by injecting the soleus TrPs. Occasionally, such totally unexpected patterns of pain referred from TrPs may be noted with other muscles, which emphasizes the importance of obtaining a detailed and comprehensive pain history.¹⁷

Plantaris

Referred pain from TrPs in the plantaris muscle refers to the midline of the posterior aspect of the knee and proximal leg (Figure 66-6).

Figure 66-6. Referred pain pattern of the plantaris muscle.

3.2. Symptoms

An individual with TrPs in the soleus muscle will report pain along the Achilles tendon, both medially and laterally, extending down to the heel and to the plantar aspect of the heel. Additionally, TrPs located in the soleus muscle can reproduce an isolated sharp pain into the plantar aspect of the heel. The patient may report unbearable pain in the plantar aspect of the heel upon the first step in the morning or after prolonged periods of rest. These symptoms are compatible with a clinical diagnosis of plantar heel pain or plantar fasciitis. Heel pain is one of the most common reports of pain in recreational runners. These athletes may present with a previous diagnosis of heel spurs or plantar fasciitis when

the issue is actually arising from TrPs in the soleus muscle. A Delphi study reported that most physical therapists considered the soleus as a relevant muscle for the management of plantar heel pain.¹⁸ Renan-Ordine et al¹⁹ found that multimodal treatment intervention including TrP release, neuromuscular soft-tissue release, and stretching to the gastrocnemius and soleus muscles was effective for reducing pain and improving physical function in individuals with plantar heel pain. Nevertheless, no epidemiologic study has investigated the prevalence of soleus muscle TrPs in this population. The patient may also report nocturnal heel pain; however, reports of nocturnal calf cramping are more related to gastrocnemius TrPs.

Trigger points in the soleus muscle may also contribute to reports of pain and discomfort in the ipsilateral sacroiliac joint. The presence of TrPs within the soleus muscle can reproduce a “pulling” or aching sensation in the posterior aspect of the leg, especially with resisted ankle plantar flexion or with passive dorsiflexion range of motion with the knee flexed. Patients may also experience hypersensitivity to manual palpation or mechanical hyperalgesia.²⁰ In fact, pain referral from soleus TrPs is felt deep within the posterior part of the leg, which could help differentiate between more superficial symptoms induced by gastrocnemius TrPs.

Soleus TrPs often restrict ankle dorsiflexion; therefore, the patient may report difficulty with performing a squat because of the limitation in ankle dorsiflexion with the knee flexed. Individuals with soleus TrPs are prone to develop low back pain because the restriction of ankle dorsiflexion leads them to lean over and lift improperly or inefficiently. If soleus TrPs are highly irritable, the patient may also report increased difficulty with walking uphill or on an incline or with ascending and descending stairs. Different studies have demonstrated significant improvements in ankle dorsiflexion range of motion following one manual TrP release^{21,22} or multimodal treatment intervention including TrP release and stretching of gastrocnemius and soleus muscles in individuals with triceps surae dysfunction.²³ A case report has described the benefit of dry needling to the triceps surae muscles in a ballet dancer with chief reports of right posterior knee pain with jumping, pivoting, walking, and running activities. Following two sessions of dry needling of TrPs to the triceps surae muscles, the dancer was able to return to full dance activity without pain or activity limitations.²⁰ The randomized clinical trial conducted by Cotchett et al¹⁸ found that TrP dry needling of several muscles, including the soleus, was effective for the management of plantar heel pain; although its clinical significance was small. Finally, the application of extracorporeal shock wave therapy over TrPs in the soleus muscle has also been effective for patients with plantar heel pain.²⁴

Soleus TrPs located in the proximal portion of the muscle are more likely to interfere with the soleus musculovenous pump, causing symptoms of calf and foot pain together with edema of the foot and ankle.

3.3. Patient Examination

After a thorough subjective examination, the clinician should make a detailed drawing

representing the pain pattern that the patient has described. This depiction will assist in planning the physical examination and can be useful in monitoring the progression of the patient as symptoms improve or change. The type, quality, and location of the pain should be carefully assessed, and the utilization of standardized outcome tools is imperative when examining patients with lower extremity dysfunctions.

Individuals who report posterior leg and heel pain should be examined for radicular symptoms or radiculopathy from the lumbosacral spine and referred pain from proximal joints and muscles of the posterior aspect of the sacroiliac joint, hip, and thigh.²⁰

Observation of static and dynamic posture is essential because of the role of the soleus and plantaris muscles in postural stability and gait. During an observation of static standing posture, the patient may be unable to fully extend the involved extremity when keeping the heel on the floor or a genu recurvatum may be observed.¹⁶ Functional testing such as double- and single-leg squat will allow a quick assessment of hip and knee control, as well as a quick assessment of talocrural, subtalar, and midfoot range of motion along with soleus muscle extensibility. Timed single-leg stance with eyes open and closed will give a quantitative measure of balance and will allow the clinician to observe foot and ankle strategies related to balance and control.

Individuals with TrPs in the soleus muscle with concomitant muscle length deficits are unable to keep the heels in contact with the ground during the eccentric phase of a bilateral or single-leg squat. They may also experience posterior calf pain, demonstrate a weight shift to the uninvolved side to unload the involved extremity, and avoid ankle plantar flexion with the concentric phase of a double-leg squatting task.²⁰

Trigger points in the soleus muscle can cause a limitation of ankle dorsiflexion resulting in a postural alteration in standing, thus creating genu recurvatum at the knee joint. A limitation in soleus muscle extensibility limits the forward progression of the tibia over the foot during the stance phase of gait with a resultant early heel rise during the late-stance and push-off phases of gait.¹¹ Ankle dorsiflexion of 10° is required for tibial advancement over the foot during walking and 15° to 20° with running tasks.²⁵ The presence of TrPs in the soleus muscle can limit passive ankle dorsiflexion during gait, causing changes in the biomechanics of the knee, ankle, and subtalar joints that can predispose an individual to injury.²⁶ An analysis of kinetic and kinematic data of an individual with chronic myofascial dysfunction demonstrated increased knee flexion and an increase in the vertical ground reaction force during the early-and late-stance phases of gait.²⁷

To differentiate gastrocnemius muscle from soleus muscle length restrictions, the clinician passively dorsiflexes the talocrural joint first with the knee straight and then flexed to 90°. If range of motion in dorsiflexion increases with the knee flexed to 90°, more than likely there is a length deficit in the gastrocnemius muscle. Further, structural differentiation of the foot and ankle can direct the practitioner to evaluate if a restriction in ankle dorsiflexion is attributable either to limited extensibility of the soleus muscle or joint hypomobility of the talocrural joint. With the patient in the prone position with the knee flexed to 90°, the clinician passively dorsiflexes the ankle, and if the clinician feels a muscular end feel and the patient reports a feeling of stretch over the posterior aspect of the

lower leg, a soleus muscle length deficit is implicated. However, if a capsular end feel is experienced by the clinician and the patient reports a feeling of tightness over the anterior joint line of the talocrural joint, the talocrural joint is implicated (Figure 66-7).

Figure 66-7. Muscle length testing. A, Gastrocnemius muscle. B, Soleus muscle. Note the change in dorsiflexion with the knee flexed.

Soleus muscle weakness is tested by having the patient stand on the ball of one foot with the knee flexed to 10° to 15° with adequate stabilization. During this test, a strong tendency for the foot to invert indicates substitution by the tibialis posterior muscle and/or the long flexor muscles of the toes, whereas a strong tendency for it to evert indicates substitution by the fibularis longus and brevis muscles. These substitutions suggest soleus muscle weakness. Also, with normal triceps surae strength, the subject should be able to jump at least 10 times on the ball of the foot without heel contact on the floor.²⁸

In addition to talocrural joint testing, passive accessory motion of the distal and proximal tibiofibular joints should be examined, especially when the patient reports posterior knee pain and loss of knee extension range of motion that may be associated with soleus and/or plantaris TrPs.

Neurodynamic assessment should also be conducted to rule in or out symptoms caused by nervous tissue in the tibial, fibular, or sural nerves, which can give rise to symptoms in the posterior leg, ankle, and foot.

3.4. Trigger Point Examination

Trigger points in the soleus muscle contribute to limitations in joint range of motion, postural changes, alterations in muscular activation, and modifications in functional movement patterns.²⁰ Studies assessing the prevalence of TrPs have demonstrated a greater occurrence of latent TrPs within the soleus muscle.²⁶ Two hundred and twenty research participants were evaluated for the presence of latent TrPs. The results indicated that 33% of healthy, asymptomatic individuals had latent TrPs in one or both of the triceps surae muscles, with the identification of latent TrPs in the left soleus muscle more common than in the right.²⁶ The most common diagnostic criteria for the identification of latent TrPs in the soleus muscle were the presence of a taut band and a localized, tender spot upon

palpation. Similarly, Zuñil-Escobar et al²⁹ also reported that 30% of an asymptomatic sample of 206 individuals exhibited latent TrPs in the soleus muscle. This study also reported an average number of 7.5 latent TrPs in the lower extremity musculature in asymptomatic people.

Soleus

The soleus muscle can be palpated with an individual in a prone, side-lying or hook-lying position. In prone, the knee joint is flexed to 10° to 15° by placing a pillow under the ankle to ease muscular tension from the gastrocnemius (Figure 66-8). In side-lying, the knees are held in flexion to place the gastrocnemius muscle on slack. The soleus muscle can be palpated inferior to the medial and lateral heads of the gastrocnemius muscle and lateral to the Achilles tendon when an individual actively plantar-flexes the ankle joint.³⁰ Cross-fiber flat palpation is used to identify TrPs within the soleus muscle in the prone and side-lying positions (Figure 66-8A and B). A cross-fiber pincer palpation can also be used to identify TrPs in the soleus muscle in side-lying with the affected leg up or in hook-lying position (Figure 66-8C and D).

Figure 66-8. Palpation for TrPs in the soleus muscle. A, Prone cross-fiber flat palpation. B, Side-lying cross-fiber flat palpation. C, Side-lying cross-fiber pincer palpation. D, Hook-lying cross-fiber pincer palpation.

Plantaris

The plantaris muscle can be palpated in the popliteal fossa with an individual in the prone position with the knee flexed to 90°. Palpation of the proximal aspect of the plantaris muscle can be performed medial and superior to the lateral head of the gastrocnemius muscle (Figure 66-9). With the patient in prone and the knee passively flexed to 90°, the clinician asks the patient to perform a gentle contraction into knee flexion and ankle plantar flexion while maintaining palpation of the proximal insertion of the plantaris muscle with the cranial hand⁹ (Figure 66-9).

Figure 66-9. Cross-fiber flat palpation for TrPs in the plantaris muscle.

4. DIFFERENTIAL DIAGNOSIS

4.1. Activation and Perpetuation of Trigger Points

A posture or activity that activates a TrP, if not corrected, can also perpetuate it. In any part of the soleus and plantaris muscles, TrPs may be activated by unaccustomed eccentric loading, eccentric exercise in an unconditioned muscle, or maximal or submaximal concentric loading.³¹ Trigger points may also be activated or aggravated when the muscle is placed in a shortened and/or lengthened position for an extended period of time.

The mechanical stresses that activate TrPs in the soleus muscle include overuse caused by the foot slipping at toe-off and overloading the muscle, especially during forceful quick lengthening contractions. Additional stresses include direct trauma to the muscle, development of associated TrPs in the muscle, and chilling of the muscle. When a leg length discrepancy is present, soleus TrPs are more likely to be activated and perpetuated in the shorter limb, toward which the body weight is shifted.

Individuals wearing shoes with smooth leather soles while walking on a hard, slippery surface, such as wet pavement, waxed tile, or marble floor, usually experience slipping of

the forefoot on push-off. This slippage imposes an overload on the soleus muscles if the person proceeds at more than a slow pace.

A common report by joggers is heel pain, which is often pain referral from soleus TrPs. These TrPs are more likely to be activated when the jogger lands on the forefoot with the soleus muscle shortened, which induces a vigorous eccentric contraction. Active and athletic individuals are susceptible to overuse injuries and muscle strains leading to injury and associated myofascial pain.^{20,32} Soleus TrPs can occur with overtraining, muscular fatigue with activity, and overload from eccentric muscle contractions. Often, runners are predisposed to soleus TrPs from repetitive ankle dorsiflexion associated with long-distance running or running uphill. A common history involves a gradual onset of calf pain 24 hours following a long run that interferes with the individual's ability to walk or run normally.³² The soleus muscle is also vulnerable to overload when an individual is skiing or ice skating without adequate ankle support.

Prolonged unaccustomed activity, such as playing tennis or hiking up a long steep hill, can overload the soleus muscle sufficiently to induce TrPs. The soleus muscle and other muscles that cross the ankle region can be overloaded when an individual walks along the beach or on other laterally slanted surfaces. Muscles on either side may become overloaded, depending on how these muscles are used to compensate for the slant. In most cases, the soleus muscle on the downward side must work harder. This situation is worsened if the downward side is also the side of an uncorrected leg length discrepancy.

A somewhat similar overload occurs when an individual wears inflexible shoes with rigid soles that allow only ankle and no toe movement. The stiff sole greatly increases the lever arm against which the soleus muscle must work. Shoes must be examined specifically for flexibility of the sole.

The soleus muscles are obviously placed in a shortened position when one wears high heels. No treatment for soleus TrPs is likely to provide lasting relief as long as the individual continues to wear high heels regularly. The same effect as wearing a high heel can be produced unilaterally when a thick heel lift is placed inside the heel of one shoe to correct a leg length discrepancy.

Sustained plantar flexion while sitting in a chair that is too high for the heels to rest flat on the floor can be problematic for the soleus muscle. Prolonged soleus muscle shortening also results if the ankles are allowed to remain immobilized in a strongly plantar flexed position during nighttime sleep. These positions can activate latent soleus TrPs.

Compromise of circulation by compression of the calf can perpetuate soleus TrPs. Resting the weight of the calf on the high edge of an ottoman, or on the footrest of some dental chairs, directly compresses the soleus muscle, causing local ischemia, which aggravates TrPs. Sitting on a chair seat that is too high for the feet to reach the floor fully usually causes a degree of under thigh compression of the neurovascular trunk, especially if the seat is pitched backward (lower behind than in front), and blood flow to the soleus muscle can be compromised. Also, tight elastic at the top of a sock below the knee can act like a tourniquet, limiting blood flow in the calf muscles. Arcangeli et al³³ found that the occurrence of myalgic spots (TrPs) and the severity of limb ischemia were often parallel in

patients with peripheral vascular disease.

Plantaris muscle injuries are associated with ballistic jumping tasks involving forceful muscle contractions with ankle plantar flexion with the knee extended.³²

4.2. Associated Trigger Points

Associated TrPs can develop in the referred pain areas caused by TrPs.³⁴ Therefore, musculature in the referred pain areas for each muscle should also be considered. Associated TrPs are most likely to occur in the gastrocnemius and posterior tibial muscles and, not infrequently, in the long flexors of the toes, all of which are synergists of the soleus muscle. When there is extensive involvement of these plantar flexor muscles, their antagonists (the tibialis anterior, extensor digitorum longus, fibularis tertius, and extensor hallucis longus muscles) may also become activated. The ankle should be checked for restriction of plantar flexion, and these anterior leg muscles should be examined for TrPs.

When the patient with soleus TrPs also reports symptoms of knee pain, the clinician should examine for TrPs in the ipsilateral quadriceps femoris muscle group. Impairment of soleus muscle function places increased demands on the quadriceps femoris muscle group.

As patients with soleus TrPs cannot squat comfortably, they often lean over to pick up an object from the floor. This motion is likely to overload back and hamstring muscles and activate a new group of TrPs.

Trigger points in the gluteus medius and minimus, vastus lateralis, semitendinosus, semimembranosus, tibialis posterior, gastrocnemius, and flexor digitorum longus muscles can refer pain to the posterior aspect of the leg and/or heel that could cause the activation of associated TrPs in the soleus or plantaris muscles.

4.3. Associated Pathology

Differential diagnosis of etiologies of posterior lower leg pain include lumbar radicular pain or radiculopathy, involvement of musculotendinous and neurovascular structures, chronic exertional compartment syndrome, and referred pain from TrPs in adjacent muscles. Information obtained during the history and physical examination can guide the clinician as to the underlying mechanism of injury involving insidious onset, acute injury, or overuse.³²

Imaging studies of individuals with calf injuries suggest that 55% to 68% of injuries involve the soleus muscle, whereas injury to the plantaris muscle accounts for only 1.4% of muscle injury. Milder injuries associated with muscle strains include tenderness to palpation and pain with resisted muscle testing. Soleus muscle injuries can be tender to deep palpation distal to the medial and lateral heads of the gastrocnemius muscle. More severe injuries may also demonstrate bruising/ecchymosis or a visible defect within the muscle or tendon.³² In the presence of a complete muscle rupture, significant calf swelling can occur requiring careful screening for the development of acute compartment syndrome or the formation of a deep venous thrombosis.^{9,32}

Individuals with soleus TrPs may report symptoms similar to a clinical diagnosis of

plantar heel pain or plantar fasciitis with the onset of heel pain that is worse with the first step in the morning and with prolonged weight-bearing activity.

A patient who reports hearing an audible “pop” with onset of sharp calf pain during sport play or other intense physical activity may have an isolated tear in the triceps surae musculature muscle, known as “tennis leg.” Historically, a diagnosis of tennis leg denoted a tear in the plantaris muscle. Although the plantaris muscle can be involved with tennis leg,⁹ these injuries usually occur at the junction of the fascia between the medial head of the gastrocnemius and the soleus muscles.^{35,36} Imaging studies of individuals with a clinical diagnosis of tennis leg identified a rupture of the medial head of the gastrocnemius muscle in 66.7%, an isolated rupture of the plantaris muscle in 1.4%, and partial rupture of the soleus muscle in 0.7% of participants.⁹

Some cases of Achilles tendinitis, or peritendinitis, may result from shortening of the soleus and gastrocnemius muscles caused by TrPs that place increased tension on the Achilles tendon. Patients with tendinitis are likely to report diffuse pain in or about the Achilles tendon that is aggravated by activity and lasts for only a short period of time. If untreated, this pathology can result in Achilles tendinopathy, which is a failed healing response to injury.³⁷ Overuse is often considered to precipitate Achilles tendinopathy; however, it can also occur in inactive individuals. Clinical examination should rule out Achilles tendon rupture by utilizing the squeeze test. In the absence of tendon rupture, tendon loading activities such as hopping or repetitive loading should be utilized to provoke symptoms. Reiman et al³⁸ found that the presence of morning stiffness and local pain with palpation for crepitus showed high sensitivity and specificity for a clinical diagnosis of Achilles tendinopathy. If a clinical diagnosis is not clear, ultrasonography or MRI may be utilized to reveal the Achilles tendon pathology.³⁹ However, imaging should not be utilized solely for the diagnosis of Achilles tendinopathy and variation in symptoms in response to loading, stiffness, and morning symptoms should also be considered.⁴⁰ There is also an association between the duration of rearfoot eversion and Achilles tendinopathy confirming that abnormal pronation may lead to Achilles tendinopathy or medial tibial stress syndrome.⁴¹

Luck et al⁴² found a high association between the presence of an accessory soleus muscle and Achilles tendinopathy. An accessory soleus muscle is an uncommon variant, but when present, it is commonly associated with Achilles tendinopathy. It often presents as a painful mass at the posteromedial ankle and is associated with exercise-induced pain.^{43,44}

If pain and tenderness are referred to the tendon by active soleus TrPs, they can be distinguished from the symptoms of tendinopathy through treatment of the soleus TrPs. Inactivation of the soleus TrPs relieves the pain and tenderness immediately if these symptoms are referred and not due to tendinopathy.

Haglund syndrome is associated with posterior heel pain with or without a visible and palpable haglund deformity, or “pump bump.”⁴⁵ In this syndrome, there is a thickening of the soft tissues at the insertion of the Achilles tendon. It is seen in those who wear stiff shoes with a shallow heel while engaging in strenuous activity. Haglund syndrome is

characterized by a radiographically prominent calcaneal enlargement at the insertion of the Achilles tendon, retrocalcaneal bursitis, thickening of the Achilles tendon, and a convexity of the superficial soft tissues at the level of the Achilles tendon insertion. The degree of enlargement is measurable by radiography.⁴⁵

Singh et al⁴⁶ investigated the progression of isolated calf deep vein thrombosis in 156 patients and 180 limbs. There were no gender differences identified, and 15% had bilateral deep vein thrombosis with the soleal vein most commonly involved, followed by the fibular, posterior tibial, and gastrocnemius veins. Propagation to a proximal vein was found in 11 patients, and pulmonary embolism was found in 9 patients within the 1 to 3-month follow-up period. The investigators concluded that isolated calf deep vein thrombosis can be safely observed without anticoagulation therapy. However, if patients have comorbidities such as immobilization or status-postorthopedic surgery, anticoagulation therapy is recommended until they are fully ambulating and the follow-up duplex scan is negative.⁴⁶ Other investigators found that exercises intended to strengthen the muscular component of the musculovenous pump (posterior calf muscles) and correction of the step cycle during gait lead to clinical improvements in the course of varicose vein disease.⁴⁷ This finding supports the essential function of the triceps surae muscles as a musculovenous pump to improve limb circulation, and this function is dependent on talocrural joint accessory mobility and adequate extensibility of the gastrocnemius and soleus muscles.

Exertional compartment syndromes of the leg are a common form of overuse injury. Compartment syndromes are characterized by increased pressure within a muscular compartment sufficient to compromise the circulation of the muscles within it. The increased pressure obstructs venous flow, which causes further swelling and more pressure. If prolonged, the resultant ischemia can lead to necrosis of the muscles and nerves within the compartment. Following a traumatic injury, it is vital that this condition be recognized immediately and managed properly to avoid possibly catastrophic consequences. Anterior compartment syndromes are most common, followed by lateral, deep posterior, and finally superficial posterior compartment syndromes.^{48, 49}

Deep posterior chronic exertional compartment syndrome (dp-CECS) of the leg is usually gradually induced by exercise in young endurance athletes. It produces a sense of tightness, dull aching and cramping, and diminished sensibility of the involved muscles. As the condition intensifies, pain persists for longer periods following exercise. Posterior compartment syndromes are commonly bilateral, usually fail to respond to conservative therapy, are often relieved by prolonged periods of rest, and often require fasciotomy.⁵⁰ On examination, dp-CECS demonstrates tenderness deep in the calf in the muscle tissue itself. The diagnosis of dp-CECS is confirmed by finding elevated intracompartmental pressure within the deep posterior compartment. However, diagnostic techniques and surgical interventions are highly subjective and lack standardization.⁵⁰

The precise etiology of the posterior compartment syndromes has not yet been established. An initiating trauma or hypertrophy of the muscle has been postulated. The role of TrPs as part of this process is unknown, but there is a strong possibility that, in muscles prone to developing a compartment syndrome, TrPs may make a significant

contribution. Chapter 63 (Section 4.3) contains additional information on chronic exertional compartment syndrome.

5. CORRECTIVE ACTIONS

Individuals with TrPs in the soleus muscle may benefit from adopting sitting or standing postures that place the ankle in a small degree of plantar flexion. While sitting, an individual can sit with his or her knees in 50° or 60° of knee flexion allowing the foot to contact the floor for lower extremity support, while providing ankle plantar flexion to place more slack on the soleus muscle. A common perpetuating cause of TrPs in the soleus muscle is an improperly designed or improperly used leg rest that causes calf compression. People who sit in reclining chairs with built-in leg rests that concentrate weight on a portion of the calf may require additional pillows or may need to restrict elevation of the leg rest. If an ottoman is used for leg support, it should be designed and arranged, so that part of the weight is carried by the heels and not by the bulk of the calf muscle. In standing postures, individuals can place a wedge under the shoe insert to provide ankle plantar flexion and take tension off the Achilles tendon, or they can wear a running shoe with a higher inclination under the posterior aspect of the shoe.

In general, the leg muscles feel better if the ankle is maintained in a neutral position throughout the night; therefore, adjusting the patient's sleeping posture may be necessary. This position is facilitated by having the bed sheets at the foot of the bed untucked to reduce external force into excessive plantar flexion (see Figure 66-6). Using a pillow between the legs and knees in side-lying to place the foot and ankle in a neutral position may also be beneficial. Patients with irritable TrPs should avoid lying on the affected side because the pressure from the bed may perpetuate TrP activity.

Other activities that should be modified include walking on level surfaces instead of inclined surfaces, avoiding tight or elastic materials around the calf, avoiding prolonged or excessive ankle plantar flexion (toes pointed) with swimming activities, and avoiding wearing shoes with a heel greater than 2 in. During walking, the patient may be encouraged to facilitate an early heel off to prevent excessive stretching of the soleus muscle during late-stance phase of gait. Soleus muscle overload can be avoided by limiting walking in soft sand, unless the calf muscles are conditioned for it, and by not walking long distances on a sidewalk or beach slanted to one side.

Patients with soleus TrPs often experience pain when walking upstairs facing forward as usual. This problem may be corrected by approaching the stairway with the body erect and angled 45°, placing the entire foot flat on the step above without markedly pulling the toes and foot up toward the ceiling. This technique avoids painful strain and stretch of the soleus muscle by minimizing ankle plantar flexion and dorsiflexion. Keeping the body erect minimizes strain on the back muscles and gives the strong quadriceps femoris muscle a larger share of the load. This angling technique works equally well on a ladder. It can also be used when ascending a steep slope by turning the body and feet to one side and climbing sideways or by following a zigzag course up the hill. When driving on a long trip, one

should make frequent stops to walk around for a few minutes to restore circulation; cruise control also provides an opportunity to change positions.

Soleus TrP self-pressure release can be performed in the supine and seated positions (Figure 66-10A and B). Pressure can be provided by placing the affected soleus muscle on top of the opposite knee (Figure 66-10A). Moving the leg down over the knee along the back of the calf starting at the back of the ankle and moving slowly toward the knee, the patient stops and holds light pressure over the area of discomfort (no more than 4/10 pain) for 15 to 30 seconds. This can be repeated five times. Trigger point self-pressure release can also be performed with a manual technique (Figure 66-10B). Finding the most tender spot, light pressure (no more than 4/10 pain) is applied with a pincer grasp (Figure 66-10B), with a TrP release tool or ball (see Figure 65-7B), or with a TrP release roller tool (see Figure 65-7C). Pressure is held for 15 to 30 seconds or until pain reduces, and this technique can be repeated five times, several times per day (Figure 66-10A and B).

Figure 66-10. Trigger point self-pressure release. A, The patient uses the knee of the opposite side to apply pressure on the TrPs. B, Manual release with pincer grasp.

Soleus muscle self-stretching can be performed in a sitting or standing position. Self-stretching of the soleus muscle in a sitting position requires the patient to maintain a long sitting position with the involved knee flexed to 70°. A long strap is placed under the forefoot, while maintaining the knee in a flexed position to place the gastrocnemius muscle on slack, and a prolonged passive stretch is applied to the foot and ankle into dorsiflexion (Figure 66-11A). Self-stretching of the soleus muscle in standing is performed with the individual in a stride stance facing a wall, with both feet placed in a neutral position and the hands on the wall at shoulder height or on a chair (Figure 66-11B). With the affected

leg behind, the foot should be placed in slight supination using a small wedge along the entire inside edge of the foot (Figure 68-6B, small pic) to emphasize dorsiflexion through the hindfoot and prevent excessive forces into dorsiflexion through the midfoot.⁵¹ While maintaining the knee in a slightly flexed position and the heel on the floor, the individual leans forward until he or she feels a stretch in the lower aspect of the calf region. This stretch may be augmented by postisometric relaxation. At the first onset of a stretch in the calf, the ball of the foot is pushed into the floor with a slight contraction of the calf muscles, but the heel or foot remains on the floor. Holding the contraction for 6 to 10 seconds, a deep inhalation is performed. Then, during a slow exhale through the mouth, the calf muscle is allowed to relax, and another slight lean forward can be performed until a stretch is felt once again in the calf. This procedure can be repeated three to five times and can be performed three times daily. Although there is debate regarding the value of static stretching alone on pain and range of motion in the long term for individuals with plantar fasciitis, a majority of the literature supports the inclusion of stretching as part of a multimodal treatment plan.^{19, 52}

Tibialis Posterior Muscle

“Runner’s Nemesis”

Orlando Mayoral del Moral, Isabel Salvat, and Joseph M. Donnelly

1. INTRODUCTION

The tibialis posterior muscle is a deep bipennate muscle with a proximal attachment consisting of three tapered portions: two medial portions from the interosseous membrane and tibia, and one lateral portion from the fibula and the intermuscular septa. Distally, it inserts into the navicular tuberosity, all of the tarsal bones except for the talus, and the 1st through 4th metatarsals. It is a strong invertor and an adductor of the foot, and it assists in ankle plantar flexion. In weight bearing, and especially during gait, the tibialis posterior muscle functions to distribute body weight among the heads of the metatarsals and prevent excessive pronation of the foot, thus contributing to ankle stability. Trigger points (TrPs) in the tibialis posterior muscle will produce pain over the Achilles tendon that can extend through the midcalf down to the heel and over the entire plantar surface of the foot. Activation and perpetuation of TrPs usually results from walking, running, or jogging, especially on uneven ground or on laterally slanted surfaces. Ill-fitting shoes or worn footwear that promote eversion and rocking of the foot, along with excessive pronation, can contribute to the activation and perpetuation of TrPs in the tibialis posterior muscle. Differential diagnosis should include tibialis posterior tendon dysfunction, medial tibial stress syndrome, and deep posterior chronic exertional compartment syndrome. Corrective actions include proper sitting and sleeping postures along with self-pressure release techniques. Early recognition and treatment of tibialis posterior TrPs or muscle/tendon dysfunction is critical to slow the progression to a tendon tear or rupture and prevent surgical intervention.

2. ANATOMIC CONSIDERATIONS

The tibialis posterior muscle is the deepest muscle in the posterior calf. It lies between the interosseous membrane anteriorly and the posterior tibial vessels and soleus muscle

posteriorly, in between the flexor hallucis longus and flexor digitorum longus muscles (Figure 67-1). Proximally, its attachment consists of three portions separated by an interval traversed by the anterior tibial vessels. The two medial portions attach to the interosseous membrane and to a lateral area of the posterior surface of the body of the tibia. The lateral portion attaches to the medial surface of the fibula, from the transverse intermuscular septum, and from the intermuscular septa of adjacent muscles.¹ The tibial attachment of the muscle commonly continues into the distal third of the leg as far as, or more distal than, the crossing of the tibialis posterior tendon with that of the flexor digitorum longus muscle. The attachment to the fibula usually includes an intramuscular septum, in which case the muscle is multipennate.² In the distal quarter of the leg, its tendon passes anterior to the tendon of the flexor digitorum longus muscle, behind the medial malleolus. To enter the foot, it passes deep to the flexor retinaculum and superficial to the deltoid ligament. In the foot, it divides into anterior, middle, and posterior components just proximal to the navicular bone. The anterior component is the most superficial and largest, and this component is a direct continuation of the main tendon that inserts into the navicular tuberosity and the medial cuneiform. The middle portion of the tendon extends to the second and third cuneiforms, the cuboid bone, and the bases of the 2nd, 3rd, and 4th metatarsals. The posterior component is recurrent, arises from the main tendon, proximal to the navicular bone, and inserts as a band into the anterior aspect of the sustentaculum tali of the calcaneus³ (Figure 67-2). Occasionally, a sesamoid bone occurs in the tendon of the tibialis posterior muscle on the plantar aspect of the navicular tuberosity.¹

Figure 67-2. Attachments of the right tibialis posterior muscle (red). The bones to which this muscle attaches are darkened.

The tibialis secundus muscle, an uncommon, anatomic variant muscle of small size, has been described as arising from the back of the tibia and inserting into the capsule of the

ankle joint.¹ An anomalous muscle has also been described as running close to the tibialis posterior muscle and presenting with compression neuropathy. It arises from the posterior compartment and inserts into the posteromedial portion of the calcaneus.⁴ Occasionally, the tibialis posterior muscle may have an anomalous insertion of its tendon to an enlarged navicular tuberosity.³

2.1. Innervation and Vascularization

The tibial nerve supplies the tibialis posterior muscle with contributions from L4 and L5.¹ The mean distance of the nerve entry point was located at a 75% of the distance from the lateral malleolus to the fibular head. The intramuscular branching demonstrates a minimum of one and a maximum of four intramuscular branches, located at 80% to 90% of the muscle length. The arborization patterns appear as these fine branches extended distally. The most distally located intramuscular nerve ending may be observed at around 30% to 40% of the muscle length.⁵

The tibial nerve, after emerging from the sciatic nerve, passes anterior to the arch of the soleus muscle to continue into the leg with the posterior tibial vessels. Its muscular branches supply all of the muscles in the posterior compartment of the leg. Proximally, the tibial nerve is located deep to the gastrocnemius and soleus muscles and then becomes overlapped by the flexor hallucis longus muscle. The tibial nerve demonstrates a wide range of variation in branching, but in all the cases, the tibialis posterior muscle was innervated by both proximal and distal branches that arise from the fibular side of the main nerve.⁶

Vascularization of the tibialis posterior muscle is provided by the posterior tibial and fibular arteries. Distally, the tendon is supplied by arteries of the medial malleolar network and by the medial plantar artery.¹ The middle portion of the tibialis posterior tendon between the proximal musculotendinous junction and the distal tenoperiosteal junction is commonly referred to as the watershed zone, which is a zone of hypovascularity. This zone of the tendon is where tendinopathy is commonly observed.⁷

2.2. Function

The tibialis posterior muscle acts to invert and strongly adduct (supinate) the hindfoot and midfoot, and it assists in plantar flexion of the ankle.² It is a powerful muscle and is the principal invertor of the foot.¹ The tibialis posterior muscle, along with the flexor digitorum longus and flexor hallucis muscles, is the primary supinators of the foot, with the tibialis posterior muscle producing the greatest force in supination in both the hindfoot and midfoot.⁸ The tibialis posterior muscle's moment arm is advantageous for ankle inversion, whereas the moment arm for the tibialis anterior muscle is small for inversion.⁹

Under bodyweight, the medial longitudinal arch of the foot tends to be lowered to the ground and the hindfoot pronated, which induces pronation of the subtalar joint and midfoot. In this regard, the tibialis posterior muscle has a better counteraction force in supination than any other muscle, and it has classically been considered the major dynamic

supporting structure maintaining the medial longitudinal arch during weight bearing.^{9,10} Based on electromyographic (EMG) activity, the tibialis posterior muscle does not contribute significantly to arch support under static load conditions.^{1,11,12} However, the changes in the foot that occur in the absence of the force exerted by the tibialis posterior muscle show that it is essential for maintenance of normal foot configuration and posture.¹³ Co-contractions of the tibialis posterior and the fibularis longus muscles may help support the medial arch to prevent hyperpronation of the foot, especially during fast walking and running.^{2,14} The tibialis posterior muscle also assists in distributing bodyweight on the heads of the metatarsals, helping shift weight toward the lateral side of the foot that has strong plantar ligaments that equip it to bear bodyweight.^{12,15}

Regarding the role of the tibialis posterior muscle in plantar flexion, the previous edition of this text² pointed out a controversy because some authors considered the tibialis posterior muscle as a major plantar flexor,^{16–18} whereas others did not.^{19,20} Perry et al²¹ investigated the role of the tibialis posterior muscle in plantar flexion utilizing EMG and reported that during plantar flexion, the force created by the tibialis posterior muscle was equal to the force created by the flexor digitorum longus and the fibularis brevis muscles; however, it was much less than the force created by the other plantar flexor muscles. They concluded that the relative plantar flexor force of the tibialis posterior muscle is 1.8% of the force that is exerted by the soleus muscle.²¹ Sutherland²² reported that the tibialis posterior muscle is potentially the third most powerful plantar flexor; however, it could exert only 6% of the moment of force contributed by the gastrocnemius and soleus muscles combined.

During gait, the function of the tibialis posterior muscle is to prevent excessive foot pronation during the contact phase and to supinate the hindfoot and midfoot to provide increased stiffness in the forefoot for the propulsion phase.^{23,24} The tibialis posterior muscle is the strongest supinator of the midfoot and hindfoot. It is active in the first 55% of the gait cycle. During the initial 35% of the gait cycle, it controls or decelerates pronation of the foot, followed by supination of the hindfoot and midfoot along with external rotation of the tibia, which is a necessary coupled motion from mid-stance to toe off to create a rigid lever that improves the efficiency of force transmission to the forefoot for propulsion.^{13,25,26}

In the gait cycle, the tibialis posterior muscle has biphasic activity and activates just prior to initial contact (as the first muscle to activate), peaks at initial contact, and peaks again during the propulsive phase^{21,24,27}; however, these results are inconsistent among subjects.²⁴ The tibialis posterior muscle restrains the pronation forces that occur during the limb-loading response and early-stance phase of gait. During mid-stance, it prevents excessive pronation and provides transverse plane balance and control. Sutherland²² concluded that the plantar flexors, including the tibialis posterior muscle, also decelerate the forward movement of the tibia over the fixed foot during stance, thus indirectly providing knee stabilization. This deceleration function is also supported by recent research.²⁷

Perry et al²⁸ compared the EMG activity of the tibialis posterior muscle during slow, free, and fast gait with the amount of activity generated by various degrees of voluntary effort graded according to muscle-testing criteria. Results showed that EMG activity increased directly as more muscular force was required during the different manual muscle test levels and with increased walking speeds. Investigators^{29,30} utilizing fine-wire EMG examined the effects of different gait speeds on the function of the tibialis posterior muscle. They found that this muscle had a significant increase in peak EMG amplitude at faster gait speeds when compared with normal and slower gait speeds. At faster gait speeds, the tibialis posterior muscle showed a significant delay in time to peak amplitude which occurred later in the gait cycle; however, it maintained its characteristic biphasic amplitude.^{29,30} At subject-preferred gait speeds, the tibialis posterior muscle was active just prior to initial contact and hit its first peak EMG activity at limb loading and again at mid-stance.³⁰

The tibialis posterior muscle demand and action increases at initial contact and mid-stance at increased gait speeds.^{29,30} During the entire stance phase, the tibialis posterior muscle tendon unit lengthens, whereas the muscle fascicle shortens and functions almost isometrically.³⁰

Akuzawa et al²⁷ investigated calf muscle activation during the stance phase of gait during barefoot walking, walking with footwear, and walking with an orthosis that supported the medial longitudinal arch, transverse arch, and lateral arch. Utilizing fine-wire EMG, they studied the tibialis posterior, peroneus longus, and flexor digitorum longus muscles during all three conditions at initial contact, mid-stance, and at propulsion phases of gait. The percent of maximum volitional isometric contraction (%MVIC) of the tibialis posterior muscle was significantly reduced in walking with an orthosis when compared with barefoot walking during the mid-stance and propulsion phase of gait. There was also a difference between %MVIC of the tibialis posterior muscle under all three conditions during the initial contact and mid-stance phase of gait. They concluded that an orthosis that supports all three arches of the foot may be beneficial to offload the tibialis posterior muscle for individuals with muscle and/or tendon dysfunction.²⁷

2.3. Functional Unit

The functional unit to which a muscle belongs includes the muscles that reinforce and counter its actions as well as the joints that the muscle crosses. The interdependence of these structures is functionally reflected in the organization and neural connections of the sensory motor cortex. The functional unit is emphasized because the presence of a TrP in one muscle of the unit increases the likelihood that the other muscles of the unit will also develop TrPs. When inactivating TrPs in a muscle, one must be concerned about TrPs that may develop in muscles that are functionally interdependent. Box 67-1 grossly represents the functional unit of the tibialis posterior muscle.³¹

Box 67-1 Functional unit of the tibialis posterior muscle

Action	Synergists	Antagonist
Plantar flexion of the foot	Gastrocnemius Soleus Fibularis longus and brevis Flexor digitorum longus Flexor hallucis longus	Extensor digitorum longus Extensor hallucis longus Fibularis tertius
Inversion of the foot	Tibialis anterior Flexor digitorum longus Flexor hallucis longus Extensor hallucis longus	Fibularis longus and brevis Fibularis tertius Extensor digitorum longus

The long toe flexors are also agonists for the weight-bearing function of assisting transverse plane balance.

3. CLINICAL PRESENTATION

3.1. Referred Pain Pattern

The tibialis posterior muscle can exhibit TrPs in any part of the muscle. The referred pain concentrates primarily over the Achilles tendon, proximal to the calcaneus, and can extend through the midcalf down to the heel and over the entire plantar surface of the foot and toes (Figure 67-3). Pain due to TrPs in the tibialis posterior muscle is not likely to present as a single-muscle syndrome.²

Figure 67-3. Composite pain pattern (bright red) referred from TrPs in the right tibialis posterior muscle (darker red). The essential pain pattern (solid dark red) denotes where pain is usually experienced when these TrPs are active. Red stippling indicates the occasional extension of the essential pain pattern.

3.2. Symptoms

An individual with TrPs in the tibialis posterior muscle is likely to report pain in the foot when running or walking. The pain may be felt quite severely in the plantar surface of the foot and Achilles tendon, and to a lesser degree in the midcalf and heel. The patient will report increasing difficulty with walking or running, especially on uneven surfaces, for example, on gravel or cobblestones that are sufficiently irregular as to require additional

stabilization of the foot.²

3.3. Patient Examination

After a thorough subjective examination, the clinician should make a detailed drawing representing the pain pattern that the patient has described. This depiction will assist in planning the physical examination and can be useful in monitoring the progression of the patient as symptoms improve or change. The type, quality, and location of the pain should be carefully assessed, and the utilization of standardized outcome tools is imperative when examining patients with lower extremity dysfunctions.

Observation of static and dynamic posture is essential because of the role of the tibialis posterior muscle in postural stability and gait. If the tibialis posterior TrPs are active or have been present for some time, the patient may walk with the foot partly everted and abducted, in a flatfooted gait. The patient should be observed walking barefoot to identify relevant gait deviations such as early excessive pronation, excessive pronation at mid-stance (pes planus), or late pronation during push-off. At heel off, the tibialis posterior muscle contracts to supinate the hindfoot and midfoot to create a rigid lever for propulsion. Tibialis posterior and/or flexor digitorum longus muscle weakness may be indicated if the calcaneus does not move into inversion at heel-off.

A collapse of the medial longitudinal arch or a midfoot posture with forefoot abduction is commonly observed with tibialis posterior muscle dysfunction. Observation of the ankle and foot from behind with a focus on the relationship of the hindfoot to forefoot may reveal a “too many toes” sign on one side that may be indicative of tibialis posterior muscle dysfunction. Static measures such as the navicular drop test³² and the windlass mechanism³³ should be assessed in standing as a predictor of dynamic function of the foot. Functional testing, such as double- and single-leg squat, will allow a quick assessment of hip and knee control, as well as a quick assessment of talocrural, subtalar, and midfoot range of motion. Timed single-leg stance with eyes open and closed gives a quantitative measure of balance and will afford the clinician to observe foot and ankle strategies related to balance and control.

The usual method of manually testing the tibialis posterior muscle for strength³⁴ is unsatisfactory to identify relatively slight weakness. Manual testing of this muscle poorly discriminates its function from force substituted by agonist muscles.^{28,35} Muscles with TrPs are likely to develop cramp-like pain when contracted in the shortened position. If the tibialis posterior muscle is involved and the patient tries to invert, adduct, and plantar-flex the foot fully, cramp-like pain is likely to occur deep in the calf, where the muscle is located. If manual muscle testing is used, the clinician should watch for substitution by the long flexor muscles of the toes which would be evident by the toes flexing during the test. The single-heel-rise test is the recommended test to assess function of the tibialis posterior muscle in a functional position.³⁵ The patient tries to perform the single-heel-rise test while standing on one foot in an attempt to achieve 8 to 10 repetitions.³⁶ Normally, the tibialis posterior muscle first inverts the foot and locks the calcaneus to provide a rigid structure

that permits transfer of weight to the forefoot. In the event of tibialis posterior muscle weakness or dysfunction, initial heel inversion is weak and the patient either raises the heel incompletely without locking the hindfoot or fails to rise onto the ball of the foot. Pain and tenderness may be experienced along the path of the tendon, mainly behind the medial malleolus and medial to its primary insertion on the navicular tuberosity. Unfortunately, patients do not usually present with this dysfunction as a chief report, but it is at this early stage that the condition should be fully correctable, often with conservative measures. Active TrPs in this muscle cause a perceptible degree of functional inhibition weakness.

To test this muscle for restricted range of motion, the patient may be supine or seated. The clinician first fully everts and abducts the foot and then attempts to place it into dorsiflexion. Tibialis posterior TrPs painfully restrict this movement. Restriction of this movement can also be caused by tightness of the flexor digitorum longus and flexor hallucis longus muscles. If, at the limit of the restricted range of motion, the clinician can extend all five toes without pain, the restriction is caused by the tibialis posterior muscle and not by either of the long toe flexors.

Passive physiologic and accessory motion should be tested in the talocrural, subtalar, midtarsal, and forefoot joints. It is also imperative to assess for great toe and first ray range of motion in dorsiflexion, as limitation in this motion may cause abnormal pronation of the foot during the propulsive phase of gait, placing an abnormal tensile load on the tibialis posterior muscle.

The clinician should identify abnormal foot structure by examining the patient's feet and shoes and analyzing the role of abnormal foot structure in observed and tested function. By the time patients with tibialis posterior TrPs are seen for their persistent foot pain, they usually have tried one or more corrective devices. One device frequently used is an insert that adds support to the foot but often ends short of the head of the 1st metatarsal. A total contact foot orthoses, extending past the metatarsal heads to maximize foot function, is preferred over this common, shorter orthosis. However, people with tibialis posterior TrPs frequently find that wearing a corrective orthotic device is painful because it presses on the region of tenderness referred from the TrPs to the sole of the foot. This referred tenderness disappears promptly with inactivation of the responsible TrPs in the tibialis posterior muscle.

3.4. Trigger Point Examination

The tibialis posterior muscle lies deep in the posterior leg and its TrPs are accessible to examination by palpation only indirectly through other muscles with the patient side-lying with the affected side down and the knee flexed to place the gastrocnemius muscle on slack (Figure 67-4). At most, one can determine only a direction of deep tenderness. Interpreting this tenderness that is caused by tibialis posterior TrPs depends on the preceding examination having established evidence of this muscle's involvement and on having reason to believe that the intervening muscles are free of TrPs. As shown in Figure 67-1, the tibialis posterior muscle is inaccessible to digital examination anteriorly because of the

intervening tibialis anterior muscle and interosseous membrane.

Figure 67-4. Cross-fiber flat palpation for TrPs in the tibialis posterior muscle. Arrow depicts the anteriorly directed force against the posterior surface of the tibia.

From behind, one can usually elicit tenderness of tibialis posterior TrPs and tenderness of that muscle's tibial attachment by pressing deeply between the posterior border of the tibia and the soleus muscle, which can be partially displaced posteriorly (Figure 67-4). The muscle should be examined for tenderness, as illustrated in Figure 67-4, proximal to the midleg by cross-fiber deep flat palpation. As one palpates from the location illustrated distally, the flexor digitorum longus muscle will also be encountered behind the tibia. Occasionally, on the lateral side, tenderness of the tibialis posterior muscle through the soleus and the flexor hallucis longus muscles can be elicited. Discerning which muscle may be involved is a very difficult task.

No neural or vascular entrapments by this muscle have been observed, nor are any expected, because it lies deep to the vessels and nerves. A monofilament or injection needle may be used to identify the tibialis posterior TrPs; however, one should proceed very cautiously because of the extensive neurovascular bundle that lies between the soleus and tibialis posterior muscles.

4. DIFFERENTIAL DIAGNOSIS

4.1. Activation and Perpetuation of Trigger Points

In any part of the tibialis posterior muscle, TrPs may be activated by unaccustomed eccentric loading, eccentric exercise in unconditioned tibialis posterior muscle, or maximal or submaximal concentric loading.³⁷ Trigger points may also be activated or aggravated when the muscle is placed in a shortened or lengthened position for an extended period of

time.

Mechanical stresses from running can cause the formation of TrPs in the tibialis posterior muscle, especially running on uneven or laterally slanted surfaces. Interestingly, tibialis posterior TrPs are not commonly observed in tennis players who characteristically train on smooth, level surfaces and wear shoes that provide ample foot support; however, footwear that is worn down and that encourages eversion and rocking of the foot contribute to TrPs in this muscle.

Although pronation in early stance is normal to accommodate the weight-bearing surface and for lower extremity shock absorption, excessive pronation can overload the tibialis posterior muscle and may contribute to the activation of, and certainly to the perpetuation of, TrPs in it. The foot may excessively pronate because of a hypomobile hindfoot, hypermobile midfoot, ankle equinus, loss of great toe dorsiflexion, muscular imbalance, or some other structural or functional cause.

4.2. Associated Trigger Points

Associated TrPs can develop in the referred pain areas caused by TrPs.³⁸ Therefore, musculature in the referred pain areas for each muscle should also be considered. The two long toe flexors that also invert and plantar-flex the foot, the flexor digitorum longus and flexor hallucis longus muscles, are commonly involved with the tibialis posterior muscle. The primary foot plantar flexors, the gastrocnemius and soleus muscles, are not prone to develop TrPs in association with the tibialis posterior muscle; however, it has been clinically observed.

Trigger points in the fibularis muscles, especially in patients with abnormal foot structure, are commonly associated with TrPs in the tibialis posterior muscle. The fibularis longus and fibularis brevis muscles are primary antagonists to the inversion action of the tibialis posterior muscle but are agonists to its roles in plantar flexion and stabilization of the foot.

Tibialis posterior TrPs could develop in response to TrPs in gluteus minimus, hamstrings, gastrocnemius, soleus, and flexor digitorum longus muscles. In addition, the plantar intrinsic foot muscles should also be considered for examination, because they are within the referred pain area of tibialis posterior TrPs. Imamura et al³⁹ studied the effects of treatment for myofascial pain components in individuals with plantar fasciitis with very good results.³⁹ In this study, 30% of the patients were found to have TrPs in the tibialis posterior muscle and were successfully treated. In a modified Delphi study attempting to elucidate the best dry needling protocol for the treatment of plantar heel pain (commonly diagnosed as plantar fasciitis), the tibialis posterior muscle was included as one of the muscles that should be assessed for the presence of TrPs as a possible source of the patient's pain and was included in the dry needling treatment.⁴⁰ A randomized controlled trial following the indications of the modified Delphi study described previously reported good results in the reduction of plantar heel pain.⁴¹

4.3. Associated Pathology

Serious dysfunction of the tibialis posterior muscle and/or tendon is not unusual and deserves careful consideration in the differential diagnosis of ankle and foot pain. Some common conditions include dysfunction of the tibialis posterior muscle-tendon complex, medial tibial stress syndrome (“shin splints”), and deep posterior chronic exertional compartment syndrome. Tibialis posterior TrPs are thought to be a contributing factor to these leg, ankle, and foot conditions, although there is no solid scientific evidence to support this notion.

Tibialis posterior tendon dysfunction is thought to be a progressive disorder and is believed to lead to altered foot biomechanics. Johnson and Strom developed a scheme in 1989 to explain the successive stages of tibialis posterior tendon dysfunction,³⁵ and this has since been modified by Bluman and Myerson to include a Stage IV.⁴² The first two stages are isolated to soft-tissue changes, and the third and fourth stages have associated arthritic changes⁴³: *Stage I: tendon length is normal* and inflamed with minimal pain and dysfunction; *Stage II: tendon elongated*, acquired pes planus but passively correctable, commonly unable to perform a heel raise; *Stage III: tendon elongated, hindfoot deformed and stiff* with lateral foot pain and marked eversion of the foot when bearing weight. Subtalar joint arthropathy and degeneration are noted; *Stage IV: end-stage disease* with a fixed valgus angulation of the talus, midfoot planus, and early degeneration of the ankle joint.^{42, 44} In Stage 1, the tibialis posterior muscle strength and function are mildly decreased. When the patient attempts to perform the single-heel-rise test, reduced endurance may be noted with an inability to perform multiple attempts.³⁶ Normally, the tibialis posterior muscle first everts and locks the calcaneus to provide a rigid structure that permits transfer of weight to the forefoot. In stage 1, initial calcaneal inversion is weak, and the patient either raises the heel incompletely without locking the hindfoot or fails to rise onto the ball of the foot. Pain and tenderness are found along the path of the tendon, chiefly just before it passes behind the medial malleolus and medial to its insertion on the navicular. Unfortunately, patients do not usually present with this dysfunction as a chief report, but it is at this early stage that the condition should be fully correctable, often with conservative measures. Radiographs are typically unremarkable and magnetic resonance imaging (MRI) revealing a tenosynovitis is the gold standard for diagnosis in this stage.⁴³

With progression to stage 2, pain increases in severity and distribution, and the patient has serious difficulty with walking. The single-heel-rise test is more abnormal, and the patient stands with the foot everted and abducted sufficiently to display “too many toes” when viewed from behind. This is a simple, reproducible, and recordable measure of foot posture. Routine radiographs from the anteroposterior view show the forefoot abducted in relation to the hindfoot, because the calcaneus and navicular are subluxed laterally off the head of the talus. In the lateral view, the talus is tipped forward in relation to the calcaneus. This stage has been subdivided into 2a, which identifies tendon changes with elongation, and 2b, in which the tendon has ruptured. This latter stage requires surgical repair of the tendon.⁴³

In stage 3, there is evidence of subtalar joint arthropathy and degeneration⁴³ along with associated damage to the static supporting structures of the foot that have resulted in fixed flatfoot and requires realignment of the foot structures and arthrodesis. An isolated subtalar arthrodesis suffices in most cases; however, a triple arthrodesis may be required.^{35, 43}

In stage 4, the rigid hindfoot and the valgus angulation of the talus usually require a tibiototalcalcaneal arthrodesis and deltoid ligament reconstruction.⁴⁴

Muscles with TrPs are under continuous increased tension because of taut bands; thus, TrPs in the tibialis posterior muscle is one condition that could possibly account for Johnson and Strom's stage 1 findings: a detectable muscle weakness under high-load conditions, and degenerative changes of the tendon exposed to abnormal sustained tension caused by muscle length deficits. Subsequent stages could follow failure to correct the condition in its initial stage.

A number of authors⁴⁵⁻⁵² and one comprehensive review⁵³ discuss rupture of the tibialis posterior tendon as a separate entity (stages 2 and 3 of Johnson and Strom). The patient presents with a report that may include the following: "My foot is becoming flat," "My shoe is running over," "I can't walk like I used to," or "I have trouble going up and down stairs." Frequently, the absence of the displaced tendon is noted on palpation when compared with the normal side. The discontinuity of the tendon has been imaged by ultrasound^{47, 54} and by MRI.^{47, 55} Duchenne noted that, in patients with tibialis posterior musculotendinous deficit, the foot turned outward when they were walking or standing.¹⁹ EMG data obtained by Ringleb et al⁵⁶ suggest that tibialis posterior tendon dysfunction is associated with compensatory activity in the fibularis, tibialis anterior, and gastrocnemius muscles. Weakness of the tibialis posterior muscle can lead to an excessively pronated foot, unlocking of the midtarsal joint that allows plantar subluxation of the hindfoot on the forefoot, and development of a severe pes planus deformity.⁵⁷ Tendon rupture or weakness of the tibialis posterior muscle caused by slippage of the tendon around the medial malleolus will quickly cause a flexible pes valgus deformity.⁵⁸ Loss of tibialis posterior muscle function may result in progressive and dramatic pes planus deformity with a marked abduction component. If uncorrected within months of loss, tendon transfer alone will no longer suffice and arthrodesis will be required.⁵⁹

Rupture of the tibialis posterior tendon due to rheumatoid arthritis can cause a sag in the medial longitudinal arch on weight bearing within 10 days. In one patient, examination 2.5 years after rupture revealed a collapsed, but mobile, longitudinal arch. Radiographs of the foot showed marked osteopenia, a calcaneal valgus angle, and an anterior and inferior displacement of the talar head.^{35, 47}

Medial tibial stress syndrome is defined as painful symptoms on the medial aspect of the tibia, often located at the middle or distal portion.⁶⁰ Onset usually occurs with running or impact loading of the lower extremity, and the resulting pain will typically limit running activity. Variation in nomenclature such as "shin splint syndrome" and "soleus enthesopathy" is evident in the historic and current literature, and it is likely that such has contributed to the current lack of understanding of the condition.⁶¹ Some authors

attributed it to the tibialis posterior muscle, but cadaveric studies of the myofascial anatomy are inconsistent as to which myofascial element is involved because there is large variation in the site of attachment of tibialis posterior, soleus, and flexor digitorum longus muscles.^{61, 62} However, posteromedial muscular tenderness is a consistent clinical feature of the syndrome. Whether this tenderness is a primary cause or an effect of the condition remains unclear.⁶¹

It is probable that a combination of structures is involved in medial tibial stress syndrome, and some authors have suggested grading systems based on this premise.⁶² Increased navicular drop (difference in height of the navicular tuberosity in the subtalar neutral stance position and the height of the navicular tuberosity in relaxed stance) is significantly associated with an increased risk of developing medial tibial stress syndrome in runners.

Exertional compartment syndromes of the leg are a common form of overuse injury. Compartment syndromes are characterized by increased pressure within a muscular compartment sufficient to compromise the circulation of the muscles within it. The increased pressure obstructs venous outflow that causes further swelling and more pressure. If prolonged, the resultant ischemia can lead to necrosis of the muscles and nerves within the compartment. When following a traumatic injury, it is vitally important that this condition be recognized immediately and managed properly to avoid possibly catastrophic consequences. Anterior compartment syndromes are most common, followed by lateral, deep posterior, and superficial posterior compartment syndromes.^{63, 64}

The superficial posterior compartment contains the soleus and gastrocnemius muscle bellies. The deep posterior compartment encloses the flexor digitorum longus, flexor hallucis longus, popliteus, and tibialis posterior muscle bellies.¹

Deep posterior chronic exertional compartment syndrome (dp-CECS) of the leg is usually gradually induced by exercise in young endurance athletes. It produces a sense of tightness, dull aching and cramping, and diminished sensibility of the involved muscles. As the condition intensifies, pain persists for longer periods following exercise. Posterior compartment syndromes are commonly bilateral, usually fail to respond to conservative therapy, are often relieved by prolonged periods of rest, and often require fasciotomy.⁶⁵ On examination, dp-CECS demonstrates tenderness deep in the calf in the muscle tissue itself. The diagnosis of dp-CECS is confirmed by finding elevated intracompartmental pressure within the deep posterior compartment. However, diagnostic techniques and surgical interventions are highly subjective and lack standardization.⁶⁵

The precise etiology of the posterior compartment syndromes has not yet been established. An initiating trauma or hypertrophy of the muscle has been postulated. The role of TrPs as part of this process is unknown, but there is a strong possibility that, in muscles prone to developing a compartment syndrome, TrPs may make a significant contribution. Chapter 63 contains additional information on chronic exertional compartment syndrome.

Surgical intervention to relieve symptoms identified as resulting from a chronic compartment syndrome is controversial. One group of surgeons reported an 88% success

rate on 26 legs of patients with compartment syndromes, performing the operation only after conservative measures failed but without measuring intramuscular pressures.⁶⁶ Other surgeons who performed a fasciotomy of the deep posterior compartment based on intramuscular pressure criteria did not achieve results that were as good as those obtained when treating the anterior compartment syndrome surgically.⁶⁷ In this series of eight patients, a deep posterior compartment syndrome was diagnosed if intramuscular pressure was more than 15 mm Hg at rest, if it increased during exercise, and if it demonstrated a delayed return to the pre-exercise level.⁶⁷ A more recent systematic review on the effectiveness of surgery for the deep posterior compartment syndrome of the leg reported a modest success rate (ranging from 30% to 65%) after fasciotomy and argued for an optimization of diagnostic criteria and a standardization of treatment modalities for the condition.⁶⁵ Another recent review showed a success rate of 61% of surgical treatment for deep posterior compartment syndrome.⁶⁴

5. CORRECTIVE ACTIONS

Individuals with TrPs in the tibialis posterior muscle may benefit from adopting sitting or standing postures that place the ankle in some degree of plantar flexion. While seated, an individual can sit with his or her knees in 50° or 60° of flexion, allowing the foot to contact the floor for lower extremity support, while providing ankle plantar flexion to place more slack on the tibialis posterior muscle. A common perpetuating cause of TrPs in the tibialis posterior muscle is an improperly designed or improperly used leg rest that causes calf compression. People who sit in reclining chairs with built-in leg rests that concentrate weight on a portion of the calf may require additional pillows or may need to restrict elevation of the leg rest.

A patient with tibialis posterior TrPs who walks or runs for exercise should do so on a flat surface and always wear shoes with adequate support. Excessive pronation due to a hypermobile midfoot should be corrected with a good medial longitudinal arch support. Initially, corrections made by the insert of the shoe may be uncomfortable due to referred tenderness from the TrPs, but with resolution of the tibialis posterior TrPs, this related tenderness of the sole of the foot disappears. Whether or not the individual walks, runs, or jogs, he or she should always wear well-fitted shoes with high-enough sides to enhance lateral stability of the foot. Proper footwear should be recommended by a clinician with knowledge of the structure and function of the foot and ankle and its relationship to the entire lower extremity, pelvis, and spine.

If the TrP activity responds poorly to treatment, running as a form of exercise could be replaced by swimming or cycling. High heels and stilettos must be avoided. High top shoes may be necessary if other measures do not suffice.

In general, the leg muscles feel better if the ankle is maintained in a neutral position throughout the night; therefore, adjusting the patients' sleeping posture may be necessary. This position is facilitated by having the bed sheets at the foot of the bed untucked to reduce external force into excessive plantar flexion (see Figure 66-6). Using a pillow

between the legs and knees in side-lying to place the foot and ankle in a neutral position may also be beneficial.

Tibialis posterior TrP self-pressure release can be performed in the seated position with the affected leg crossed over the opposite leg at the ankle (Figure 67-5). Manual TrP self-pressure release can be provided with the thumb on the undersurface of the tibia (Figure 67-5). Finding the most sensitive spot along the posterior surface of the tibia, often about a hand width below the knee, and gentle light pressure (no more than 4/10 pain) is applied manually with a thumb or fingers. A TrP release tool should be used with caution because of its proximity to the bone and neurovascular structures as well as the depth of the tibialis posterior muscle (Figure 67-5). If tingling or numbness is felt with self-pressure release of TrPs, the technique should be discontinued.

Figure 67-5. Self-pressure release of TrPs in the tibialis posterior muscle.

Self-stretch of the tibialis posterior muscle is typically not recommended because of the potential of tibialis posterior tendon dysfunction. Stretching the tibialis tendon may be more harmful than helpful due to the watershed (hypovascular) zone of the tendon between the medial malleolus and its insertion on the navicular bone in the midfoot. Consultation with a clinician who treats patients with lower extremity, ankle, and foot dysfunctions is highly recommended.

Long Toe Extensor Muscles

Extensor Digitorum Longus and Extensor Hallucis Longus: “Muscles of Classic Hammer Toes”

Carol A. Courtney and Dhinu J. Jayaseelan

1. INTRODUCTION

The extensor hallucis longus (EHL) and extensor digitorum longus (EDL) muscles are considered long toe extensor muscles. Together with the tibialis anterior muscle, they inhabit the anterior compartment of the leg. These muscles are primarily active during gait and functionally provide dynamic stability for balance. Dysfunction in these muscles, or other muscles involved in gait (such as the tibialis anterior or fibularis muscles), could contribute to the development of trigger points (TrPs). Trigger points in these muscles contribute to a patient report of “sore feet” focused on the dorsal aspect of the ankle and foot, anterior leg, and spreading to the related great and lesser toes. Activities such as walking, climbing, and running can activate TrPs in these muscles. Kicking a ball or stubbing a toe as in a “turf toe” injury may also overload the long toe extensor muscles. Differential diagnosis should include tibial stress fractures, compartment syndrome, lumbar spine radicular pain or radiculopathy, hammer toe, claw toe, or mallet toe deformity. Corrective actions include TrP self-pressure release, self-stretching of the long toe extensor muscles and the gastrocnemius/soleus muscle complex, and activity and shoe modification to reduce recurrent overload of these muscles.

2. ANATOMIC CONSIDERATIONS

The long toe extensor muscles, the EDL and EHL muscles, share their position at the anterior compartment of the leg with the tibialis anterior and fibularis tertius muscles. Given their origin proximal to the ankle, and insertion within the foot itself, the EDL and EHL muscles are considered extrinsic toe extensor muscles.¹

Extensor Digitorum Longus

The EDL muscle is a penniform muscle that originates proximally on the lateral surface of

the lateral condyle of the tibia, the proximal two-thirds to three-quarters of the medial surface of the fibula, deep surface of the deep fascia, and adjacent anterior surface of the interosseous membrane above the EHL muscle (Figure 68-1). The part of the muscle that originates from the tibial condyle and head of the fibula covers the deep fibular nerve as it courses around the neck of the fibula to reach the intermuscular septum. The deep fibular nerve and the anterior tibial vessels lie between the EDL and tibialis anterior muscles. At the ankle, the tendon passes deep to the superior and inferior extensor retinacula that prevent bowstringing of the tendon. Distally, the EDL tendon inserts into the extensor hood mechanism on the dorsum of the metatarsophalangeal joints and the proximal phalanges of the lateral four toes. A central slip inserts to the base of the middle phalanx, and two collateral slips insert to the base of the distal phalanx.¹ The EDL muscle has the second largest cross-sectional area of the anterior compartment muscles, second to the tibialis anterior muscle. The mean width of the EDL muscle is 12.4 mm in a cadaveric dissection of 68 feet.²

Figure 68-1. Attachments of the right long extensor muscles of the toes, anterolateral view. The extensor digitorum longus muscle is medium red, and the extensor hallucis longus

muscle is dark red. The superior extensor retinaculum is not pictured.

Extensor Hallucis Longus

The EHL muscle originates on the middle half of the medial surface of the fibula and the adjacent anterior surface of the interosseous membrane. It lies between the tibialis anterior and the EDL muscles and is also partially overlapped by these two muscles (Figure 68-1). The deep fibular nerve and anterior tibial vessels lie between the EHL and the tibialis anterior muscles. After coursing distally, beneath the extensor retinaculum at the anterior aspect of the talocrural joint, the EHL muscle inserts at the dorsal aspect of the base of the distal phalanx of the first toe.¹ In comparison with other muscles occupying the anterior compartment of the leg, the EHL muscle has the third largest cross-sectional area, behind the tibialis anterior and the EDL muscles, respectively. In the same cadaveric study by Solomon and colleagues, the mean width of the EHL muscle was 7.5 mm.²

Interestingly, cadaveric and operative studies have demonstrated different insertion patterns of the EHL muscle. One study performed found three different insertional patterns in 60 cadavers: 65% had a single tendinous insertion, 26.7% had two tendinous insertions, and 8.3% had three insertional tendon slips.³ However, when evaluating 60 cases presenting for correction of severe hallux valgus and interphalangeus, in 98.3% of cases (all but one), there was an accessory medial EHL tendon inserting at the dorsomedial aspect of the metatarsophalangeal joint capsule. The authors referred to this tendon as the extensor hallucis capsularis, which was consistent with previous research.⁴ In fact, a recent study has found that 26% of cadavers show an accessory tendon that inserts on the dorsomedial side of the 1st metatarsophalangeal joint capsule of the EHL muscle.⁵

Although the EDL and EHL muscles are distinctly different in their form and function, their anatomic relationship is strong. Solomon et al² reported that the space between the EDL and EHL muscles was, on average, 3.7 mm. In 14 cases, there was no space between the EDL and EHL muscles, and in 3 cases, these muscles overlapped up to 2 mm. Given their intimate anatomic relationship, it can be difficult for clinicians to examine or treat either in isolation. Consequently, clinicians, researchers, and educators are reminded to understand anatomic variations exist and to consider how these variations may affect typical motion.

2.1. Innervation and Vascularization

The lumbosacral plexus provides innervation to the long toe extensor muscles via the L4, L5, and S1 spinal nerve root levels. The common fibular nerve branches off the sciatic nerve laterally in the posterior aspect of the knee, wrapping anteriorly to lie just inferior and posterior to the fibular head. The common fibular nerve then divides into the superficial and deep fibular nerve. The deep fibular nerve goes on to provide motor supply to the EDL and EHL muscles and also provides cutaneous sensory input to the dorsal aspect of the space between the first and second toes. Although anatomic variations will occur, a recent

cadaveric study elucidated common nerve distribution patterns.⁶

For the EDL muscle, after entering the posterosuperior aspect of the muscle, two branching patterns were seen: (1) the deep fibular nerve branches into two components, supplying the anterosuperior and posteroinferior compartments, and then it further divides into 1 to 2 branches distally and (2) just before or after entering the EDL muscle, the deep fibular nerve separates into 2 to 3 branches and travels parallel to the tendon distally.⁶

For the EHL muscle, the deep fibular nerve enters the anterior surface nearly 5 cm inferior to the fibular head and divides into 1 to 3 more branches. In most cases, two nerve branches continue distally in parallel to supply the anterosuperior and posteroinferior compartments.⁶

Proximal vascular supply to the EDL and EHL muscles is provided by the anterior tibial artery, with perforating branches of the fibular artery. Distally, closer to the ankle, the anterior lateral and medial malleolar arteries supply the EDL and EHL muscles, respectively. Additional arterial branches are present to ensure adequate perfusion and oxygenation.

2.2. Function

Given their location on the leg, the EDL and EHL muscles are active during many functional activities. Proper coordination of the extrinsic and intrinsic foot and ankle muscles allows for functional gait and sport-based movement. In the presence of muscle performance or length impairments, movement abnormalities will be present. The tibialis anterior, EDL, and EHL muscles have primary weight-bearing functions. They maintain standing balance by controlling excessive posterior postural sway and assist in keeping the leg vertical over the fixed foot.⁷⁻¹⁰

Working as a unit, the long toe extensor muscles assist the tibialis anterior muscle in producing dorsiflexion at the talocrural joint. Adequate ankle dorsiflexion is integral to a functional gait cycle. Typical dorsiflexor muscle activity during gait is biphasic, with peak intensity noted during initial swing and loading response. The muscle activity starts in the preswing phase, as the foot prepares to clear the ground, and ends after the loading response. At initial contact, the pretibial muscles are active eccentrically to combat the rotational demand of the forefoot. Progressing into the loading response, the ankle dorsiflexors contract concentrically to facilitate anterior translation of the tibia.

During pre- and initial swing, the anterior compartment muscles are again active concentrically to clear the foot. During mid- and terminal swing, these muscles function isometrically to resist the downward force of gravity. These muscles are generally not active during mid- and terminal stance, as the heel rocker facilitates forward momentum, and the gastrocnemius muscle eccentrically controls anterior tibial translation.¹¹

Although the tibialis anterior, EDL, and EHL muscles work in coordination during ankle dorsiflexion, weakness of any or all of these muscles will lead to muscle and joint compensation. Unopposed tibialis anterior muscle activity during swing, for example, secondary to EDL muscle weakness or paralysis, would lead to excessive inversion and a

cavus appearing foot. Subsequently, without further compensation, this reaction would likely lead to excessive loading of the lateral border of the foot during initial contact and loading response and, subsequently, inadequate force absorption.¹¹

Although the function of the long toe extensor muscles is primarily described in the context of gait, clinicians should consider the role of the EDL and EHL muscles in sport and functional activities as well. For example, dynamic multiplanar activities such as soccer, football, or basketball all require rapid directional changes. Although the long toe extensor muscles function primarily to extend the toes and dorsiflex the ankle, they work in conjunction with other soft tissues around the foot. In activities requiring active eversion, the EDL muscle should be examined separately from the fibularis muscles, which perform the same action. The EHL muscle is also thought to help the foot adapt to the ground during walking.

Extensor Digitorum Longus

The EDL muscle has multiple actions. Proximally, it acts to dorsiflex the ankle, and because its tendon runs lateral to the axis of the subtalar joint, it everts the foot as well.¹¹ This eversion action is thought to balance the inversion pull of the tibialis anterior muscle. The EDL muscle also provides primary extension of the lateral four metatarsophalangeal joints and contributes to extension of those proximal and distal interphalangeal joints in conjunction with the foot intrinsic muscles.

Extensor Hallucis Longus

The EHL muscle assists the tibialis anterior and EDL muscles in ankle dorsiflexion. Although it has been reported that the EHL muscles assist with inversion,¹¹ the muscle crosses the subtalar joint close to its axis, making its role in moving the subtalar joint questionable.^{12,13} One study examining both cadavers and live subjects reported an ability of the EHL muscle to slightly supinate the foot. Electromyographic activity of the EHL muscle was noted during supination tasks, such as lifting the medial border of the foot when in weight bearing.¹¹ Additionally, the EHL muscle serves an important function in providing the only active extension to the great toe interphalangeal joint and the primary active extension force of the 1st metatarsophalangeal joint. This extension movement is crucial for the beginning of the swing phase of the gait cycle when action of the EHL muscle is required for great toe extension to clear the supporting surface.

2.3. Functional Unit

The functional unit to which a muscle belongs includes the muscles that reinforce and counter its actions as well as the joints that the muscle crosses. The interdependence of these structures is functionally reflected in the organization and neural connections of the sensory motor cortex. The functional unit is emphasized because the presence of a TrP in one muscle of the unit increases the likelihood that the other muscles of the unit will also

develop TrPs. When inactivating TrPs in a muscle, one must be concerned about TrPs that may develop in muscles that are functionally interdependent. Box 68-1 grossly represents the functional unit of the EDL and EHL muscles.¹⁴

Box 68-1 Functional unit of the EDL and EHL muscles

Action	Synergists	Antagonists
Dorsiflexion of the foot	Fibularis tertius Tibialis anterior	Gastrocnemius Soleus Fibularis longus and brevis Flexor digitorum longus Flexor hallucis longus Tibialis posterior
Inversion of the foot (EHL)	Tibialis posterior Tibialis anterior Flexor digitorum longus Flexor hallucis longus	Fibularis longus and brevis Fibularis tertius Extensor digitorum longus
Eversion of the Foot (EDL)	Fibularis longus and brevis Fibularis tertius	Tibialis posterior Tibialis anterior Flexor digitorum longus Flexor hallucis longus

3. CLINICAL PRESENTATION

3.1. Referred Pain Pattern

Extensor digitorum longus TrPs refer pain primarily over the dorsum of the foot and toes, nearly to the tips of the middle three toes (Figure 68-2A), as previously reported.¹⁵ Sometimes, the pain referred from EDL TrPs concentrates more strongly at the ankle than over the dorsum of the foot. The pain pattern may extend halfway up the leg from the ankle toward the muscle belly (Figure 68-2A). Jacobsen¹⁶ reported pain spreading to the anterolateral region of the ankle from TrPs in this muscle. Extensor hallucis longus TrPs refer pain primarily to the dorsum of the foot over the distal aspect of the 1st metatarsal and the base of the great toe. The pain may extend downward to the tip of the great toe and upward over the dorsum of the foot and leg, sometimes as far as the muscle belly (Figure 68-1B).

Figure 68-2. Pain patterns (bright red) referred from TrPs in the right long extensor muscles of the toes. The essential pain pattern (solid bright red) denotes the pain experienced by nearly everyone with TrPs. Red stippling indicates occasional spreading of the essential pattern. A, Extensor digitorum longus muscle (light red). B, Extensor hallucis longus muscle (dark red).

3.2. Symptoms

Patients with TrPs in the EDL or EHL muscles will typically report pain along the anterior aspect of the leg and dorsum of the foot with or without activity. In addition to pain, patients may report tenderness in the front of their leg, weakness, and possibly reduced function. Other symptoms may include the following: weakness of dorsiflexion when walking, falling, dragging of the foot that causes tripping, and general weakness of the ankle. Painful motion of the ankle may bother the patient in the absence of any evidence of joint injury. Loss of function is especially evident when TrPs in the tibialis anterior muscle contribute to additional dorsiflexion weakness.

Unlike in the tibialis anterior muscle, when there are TrPs in the EDL and/or EHL muscles, night cramps are common, especially when the muscles are fatigued or placed in a shortened position for an extended period of time.

3.3. Patient Examination

After a thorough subjective examination, the clinician should make a detailed drawing

representing the pain pattern that the patient has described. This depiction will assist in planning the physical examination and can be useful in monitoring the progression of the patient as symptoms improve or change. The type, quality, and location of the pain should be carefully assessed, and the utilization of standardized outcome tools is imperative when examining patients with lower extremity dysfunctions.

The objective examination should identify a symptom provoking functional movement such as ascending/descending stairs, walking, squatting, or climbing. Typically, the clinician will ascertain a functional movement that provokes symptoms. Finding this movement early can provide the clinician an important reassessment sign and provide an opportunity to differentiate the source of symptoms early in the examination.

Observation of static and dynamic posture is essential because of the role of the EDL and EHL muscles in postural stability. Functional testing such as double- and single-leg squat will allow a quick assessment of hip and knee control, as well as a quick assessment of talocrural, subtalar, and midfoot range of motion. Timed single-leg stance with eyes open and closed will give a quantitative measure of balance and will allow the clinician to observe foot and ankle strategies related to balance and control.

The position of the toes should be examined because these muscles often contribute to hammertoe and/or claw toe. If these abnormalities are noted, each toe should be examined to determine if the abnormality is flexible or rigid. The clinician should assess active range of motion with passive overpressure in all planes of motion. In addition, the assessment of physiologic and/or accessory joint movement of the ankle, hindfoot, midfoot, and forefoot is often valuable because TrPs and joint dysfunction are often found concurrently.

A thorough gait analysis will assist in identifying compensatory patterns if the EDL and/or EHL muscles are weak or painful. Common compensations include waddling gait (a lean to the contralateral side and “hiking” the hip), swing-out gait (in which the dysfunctional leg is circumducted laterally), or high-stepping/steppage gait (in which extra flexion is utilized at the hip and knee) to clear the toes in swing phase.¹⁷

The long toe extensor muscles receive their innervation via deep fibular nerve branches that contain fibers from the L4, L5, and S1 spinal nerves, though L5 is the primary contributor.¹⁸ Injury to these nerves may occur subtly, with only pain or sensory signs and symptoms. With progression or persistence of nerve injury, symptoms may include muscle weakness. Functionally, the patient may describe catching a toe or a subtle foot slap, indicating L5 myotomal weakness.¹⁹

3.4. Trigger Point Examination

For examination of the EDL and EHL muscles, the patient may be in long sitting or, preferably, supine (Figure 68-3). A pillow or bolster may be put under the patient’s knees to ensure relaxation. A cross-fiber flat palpation technique should be utilized to identify taut bands and TrPs in the EDL and EHL muscles. Focal bands of taut muscle tissue should be evaluated with firm pressure to determine if the patient’s familiar symptoms are reproduced, if there is referral of symptoms, or if symptoms are reduced. As it is common

for multiple TrPs to exist in the same muscle, palpatory examination should not terminate after finding a single TrP. However, as both EDL and EHL muscles are covered by the tibialis anterior muscle, direct palpation of these muscles is not possible. A recent study has reported that palpation of TrPs in the EDL muscle exhibits moderate to substantial reliability.²⁰

Figure 68-3. Cross-fiber flat palpation of long toe extensor muscles. A, Extensor digitorum longus muscle. B, Extensor hallucis longus muscle.

In a study of healthy subjects, Zuñil-Escobar et al²¹ found a prevalence of 24% and 22% of latent TrPs in the EDL muscle in people with and without dropped medial longitudinal arch of the foot, respectively. Another study found a prevalence of 57% latent TrPs in this muscle.²² The findings of a taut band and tender spot were the most prevalent diagnostic criteria in these studies, but the topic of referred pain was not clearly present.

4. DIFFERENTIAL DIAGNOSIS

4.1. Activation and Perpetuation of Trigger Points

A posture or activity that activates a TrP, if not corrected, can also perpetuate it. In any part of the tibialis anterior muscle, TrPs may be activated by unaccustomed eccentric loading, eccentric exercise in an unconditioned muscle, or maximal or submaximal concentric loading.²³ Trigger points may also be activated or aggravated when the muscle is placed in a shortened and/or lengthened position for an extended period of time.

Trigger points can develop and become active in individuals for a variety of reasons. Impairments in muscle performance (ie, weakness, impaired endurance) can contribute to overload of a muscle tissue during functional task performance, such as walking or running. Postural impairments could also contribute to hyperirritable bands within the muscle tissue, typically related to adaptive shortening. Overload of the EDL and EHL muscles can occur from stubbing the toes, kicking a ball, climbing long flights of stairs, or pedaling a bike.

4.2. Associated Trigger Points

Associated TrPs can develop in the referred pain areas caused by TrPs.²⁴ Therefore, muscles in the referred pain areas for each muscle should also be considered. When considering possible causes of anterior leg pain, clinicians should consider other tissues beyond the long toe extensor muscles. Given their intimate anatomic relationship and shared action of ankle dorsiflexion, it is common for the tibialis anterior muscle to develop active TrPs in association with EDL and EHL TrPs.

Trigger points in the fibularis longus, fibularis brevis, fibularis tertius, extensor digitorum brevis, and interossei muscles have similar pain patterns as those of EDL muscles and should be examined because they can be associated with EDL TrPs.

The tibialis anterior and extensor hallucis brevis muscles should also be examined for associated TrPs for the EHL muscle. All muscles in the functional unit should also be examined for associated TrPs.

4.3. Associated Pathology

A number of tissues could contribute to symptoms at the anterior aspect of the leg and dorsum of the foot. Tibial stress fracture is the most common stress fracture and is the result of excessive bone loading. Stress fractures account for 0.7% to 20% of all injuries sustained by athletes.²⁵ Pain onset from a tibial stress fracture is often gradual and may be characterized as sharp and localized. The patient may describe a recent increase in activity levels and experience more pain during weight-bearing activities than at rest. The location of tibia stress fracture symptoms is more often the anteromedial rather than anterolateral leg.

A vascular source of leg symptoms to consider is chronic exertional compartment syndrome. This condition is defined as an increased pressure in the fascial compartment during exercise which stimulates nociception in the muscular tissues and may compress neurovascular structures. Anterior compartment syndrome is the most common of the leg compartment syndromes, occurring in this area 45% of the time.²⁶ The clinical presentation includes recurrent, exercise-induced pain with a consistent onset described by the patient in terms of amount of time of exercise or distance. The pain of chronic exertional compartment syndrome is described as dull achy tightness that may progress to paresthesia. It is typically gradual in onset and resolves with cessation of activity.

Syndesmosis sprains in the leg often occur traumatically and yet may go undiagnosed.^{27,28} The patient may describe an injury during which the leg rotates on a planted foot.^{27,28} The pain is typically in the lower anterolateral aspect of the leg, but symptoms may extend proximally along the syndesmosis. When the injury is less severe, this condition is commonly misdiagnosed and functional limitations persist. History of trauma should provide a clue that the condition is articular rather than muscular.

The clinician must also consider neuropathic sources for anterolateral leg symptoms. The potential sources of unilateral neuropathic symptoms could be an L5 or S1 radicular pain or radiculopathy or an injury to the deep fibular nerve. The L5 and S1 nerve roots are the most commonly pathologic in lumbar radiculopathy.²⁹ Although burning and tingling

are often described with neuropathic pain, symptoms may be limited to lateral leg pain that may mimic a musculoskeletal origin of pain. Careful examination is critical to differentiate between peripheral nerve injury versus L5 nerve root.³⁰ The common fibular nerve is vulnerable to injury because of its superficial location near the proximal fibular head and between the tibialis anterior and EDL muscles.³¹

Hammer toe can manifest in different ways, including the classic hammer toe, claw toe, or mallet toe.³² In classic hammer toe (of the four lesser toes), the metatarsophalangeal (MP) joint is extended, the proximal interphalangeal (PIP) joint is flexed, and the distal interphalangeal (IP) joint is extended, producing a flat “hammer head” at the end. Hammer toe is often associated with ill-fitting footwear and less commonly associated with congenital or neuromuscular conditions.³³ The prevalence of hammer toe is more common in women and older adults. The dorsal aspect of the PIP joint is subject to excessive pressure against the toe box, resulting in pain in this region, as well as the distal plantar aspect of the toe. This abnormality is of great concern in patients with diabetic neuropathy because it increases the risk of ulcer development along the dorsal aspect of the PIP joint and the plantar surface of the toe.³³

In claw toes, the MP joints are markedly extended and the proximal and distal IP joints are fixed in flexion, producing a claw curvature. Dynamic claw toes can be passively corrected with overpressure of the MP and IP joints. Dynamic claw toe is typically observed during gait, and this abnormality may be self-correcting during static standing.³⁴ True claw toe deformity is often associated with cavus foot deformity and neuromuscular conditions. Claw toe deformity tends to create a more severe functional disability than the hammer toe.^{32, 34}

In the mallet toe, only the distal PIP joint is flexed, but a medial and/or lateral deviation of the distal phalanx may also be present. Mallet toe is the least common of the lesser toe deformities and accounts for only 5% of lesser toe deformities. It may be a single toe occurrence but is more commonly seen in multiple toes, especially the second, third, and fourth toes. The exact cause of mallet toe is unknown, but it is attributed to the increased length of the affected toe.³⁵

These conditions usually develop because of muscle imbalance initiated by compensatory mechanisms. Three mechanisms are identified: flexor stabilization, flexor substitution, and extensor substitution. The first two mechanisms concern the long toe flexor muscles, and extensor substitution concerns the EDL muscle.^{32, 34, 35}

Extensor substitution can produce both claw toes and classic hammer toes. This mechanism is more common than flexor substitution but less common than flexor stabilization. Extensor substitution produces excessive digital contraction during the swing phase of gait. Because the EDL muscle has a mechanical advantage, this overactivity causes a functional imbalance with the lumbrical muscles. The MP joints are hyperextended during swing phase and heel-strike and as the condition progresses, may remain in that position during weight bearing.^{32, 34, 35}

Extensor substitution occurs when the EDL muscle attempts to provide more than its

fair share of dorsiflexion effort. This muscle does not become effective as a dorsiflexor of the foot until it has accomplished its easier function of extending the MP joint. If the latter movement is unopposed by adequate lumbrical muscle action, this extended toe positioning occurs with every step. Any condition that plantar flexes the forefoot, such as anterior pes cavus or ankle equinus, can initiate a cycle of increasing distortion of toe position. Primary lumbrical muscle weakness or chronically increased tension of the flexor digitorum longus muscle can be responsible. A painful forefoot that causes the individual to lift the foot in a flat manner and avoid forefoot pressure at the end-of-stance phase disproportionately loads the EDL muscle.³²⁻³⁵ Wearing ill-fitting or tight shoes appears to be a major contributing factor to disuse atrophy of the lumbrical muscles and failure of their normal development in childhood.

Hypertrophy or exostosis at the 1st metatarsocuneiform joint, due to osteoarthritis or “turf toe,” may cause foot irritation by a shoe and hypertrophy of the EHL tendon as it crosses this region. Such chronic microtrauma to the tendon may also produce tendinitis, pain, thinning of the tendon, and possibly rupture.^{36,37}

5. CORRECTIVE ACTIONS

The long toe extensor muscles are functionally active during walking. Patients with highly irritable TrPs who need to reduce loading the muscle should wear light, closed-toe shoes. Shoes with heavier toe boxes (eg, steel toed shoes) should be avoided. Alternatively, if shoes are too tight, adaptive shortening of the long toe extensor muscles could be created and, in turn, could contribute to stiffness of the joints of the foot and ankle. Hallux valgus (bunion), seen more commonly in women who wear fashionable footwear,³⁸ may alter the angle of pull of the EHL muscle. If an individual lacks hip flexion strength or mobility, the ankle may dorsiflex higher throughout the swing phase to allow for toe clearance.

Maintaining a position of pulling the toes up for an extended period of time while driving, as is required by some steeply angled automobile accelerator pedals, causes sustained shortening of the EDL and EHL muscles that can activate and perpetuate TrPs in these muscles. The use of cruise control provides the opportunity for the driver to change foot position and obtain periodic relief from immobility. When seated for a prolonged period of time, the ankle pump exercise stretches the long toe extensor muscles as well as the soleus muscle and usually provides welcome relief.

In general, the leg muscles feel better if the ankle is maintained in a neutral position throughout the night; therefore, adjusting the patient’s sleeping posture may be necessary. This position is facilitated by having the bed sheets at the foot of the bed untucked to reduce external force into excessive plantar flexion (see Figure 65-6). Using a pillow between the legs and knees in side-lying to place the foot and ankle in a neutral position may also be beneficial. Patients with irritable TrPs should avoid lying on the affected side because the pressure from the bed may perpetuate TrP activity.

Individuals who walk or run for exercise are encouraged to use flat surfaces instead of uneven ground such as uneven bricks, cracks, grass, or sand. Additionally, laterally slanted

surfaces such as the edge of a crowned road or a slanted beach should be avoided.

Self-pressure release for TrPs in the long toe extensor muscles can be performed with the heel of the unaffected side (Figure 68-4A), manually with the thumbs (Figure 68-4B), or with a TrP release tool (Figure 68-4C). Finding the sensitive spot with the heel, thumbs, or a tool light pressure (no more than 4/10 pain) is applied and held for 15 to 30 seconds or until pain reduces. This technique can be repeated five times, several times per day. Also, patients could perform self-massage along the length of the involved soft tissues to enhance soft-tissue mobility.

Figure 68-4. Trigger point self-pressure release of long toe extensor muscles. A, Using the heel of the opposite leg for extensor digitorum longus muscle. B, Using the thumbs for extensor hallucis longus muscle. C, Using a TrP release tool. Note: Each of these techniques can be utilized on either of the long toe extensor muscles.

In cases where the toe extensor muscles are adaptively shortened, self-stretching exercises should be incorporated. One way to stretch the EDL (Figure 68-5A) and EHL (Figure 68-5B) muscles is in a seated position with the involved leg crossed over the opposite thigh. In this position, one hand can passively move the toes into flexion, then gradually pull the ankle down toward plantar flexion until a stretch is felt on the top of the foot/ankle. The opposite hand can be used to stabilize the distal tibiofibular joint complex as needed. The patient should hold the stretch for up to 30 seconds and repeat this stretch four times.

Figure 68-5. Self-stretch. A, Extensor digitorum longus muscle. B, Extensor hallucis longus muscle.

In cases where muscle strength is impaired, individuals may strengthen the long toe extensor muscles in a variety of ways. To activate the EHL and EDL muscles in relative isolation, patients may lift all the toes off the ground without allowing ball of the foot to come off the ground—a task performed with minimal contribution from the tibialis anterior muscle because the ankle should stay stationary. Because these muscles work in conjunction with the tibialis anterior muscle, performing ankle dorsiflexion can also improve muscle performance.

Long Toe Flexor Muscles

Flexor Digitorum Longus and Flexor Hallucis Longus: “Clawtoe Muscles”

Thomas L. Christ, John Sharkey, and Joseph M. Donnelly

1. INTRODUCTION

The flexor digitorum longus (FDL) and flexor hallucis longus (FHL) muscles are located in the deep compartment of the posterior leg along with the popliteus and tibialis posterior muscles. Both the FDL and FHL muscles are innervated by the tibial nerve. They each function together to plantar flex the talocrural joint, invert the subtalar joint, support the longitudinal arch of the foot, and flex the metatarsophalangeal and interphalangeal joints. Trigger points (TrPs) in the FDL muscle primarily refer pain to the plantar surface of the forefoot, proximal to toes 2 to 5. Trigger points in the FHL muscle primarily refer pain to the plantar surface of the great toe and head of the 1st metatarsal. Symptoms often include pain on the sole of the forefoot and plantar surfaces of the toes that is noticed while walking. Activation and perpetuation of TrPs in the FDL and FHL muscles usually results from overload during weight-bearing activities such as beginning a walking or jogging exercise program or long-distance running without proper training. Differential diagnosis should include assessment for nerve irritation or entrapment (tibial nerve, L5 nerve root); FHL tendon dysfunction; hallux valgus; claw, mallet and hammer toe abnormality; medial tibial stress syndrome; and chronic exertional compartment syndrome. Corrective actions include education and assessment of proper footwear, activity modification, modification of sitting and sleeping postures, TrP self-pressure release, and self-stretching exercises.

2. ANATOMIC CONSIDERATIONS

The two long (extrinsic) toe flexor muscles share the deep posterior compartment of the leg with the tibialis posterior and popliteus muscles.¹

Flexor Digitorum Longus

The thinly veiled FDL muscle is the smaller of the two muscles and originates below the

soleal line, just medial to the tibialis posterior muscle from the medial aspect of the posterior tibia and the tibialis posterior fascia.¹ The muscle is narrow at its proximal attachment and widens as it descends in the leg. The fibers of this pennate muscle converge on the tendon that passes behind the medial malleolus in a groove shared with the tendon of the tibialis posterior muscle, passing deep to the flexor retinaculum but in a separate compartment and in a separate synovial sheath. The tendon crosses the medial aspect of the sustentaculum tali of the calcaneus, and as the tendon approaches the navicular bone and passes into the sole of the foot, it crosses superficial to the FHL tendon, from which it receives a strong tendinous slip.¹ At approximately midsole, the flexor accessories (quadratus plantae) muscle joins the FDL tendon that then divides into four tendons, each of which passes through an opening in the corresponding tendon of the flexor digitorum brevis muscle. The four tendons insert into the base of the distal phalanges of digits 2 to 5 (Figure 69-1).

Figure 69-1. The FDL muscle (dark red) originates proximally just below the soleal line of the posterior tibia and travels distally posterior to the medial malleolus and through the

flexor retinaculum into the sole of the foot where it divides into four tendons, each attaching to the distal phalanges of digits 2 to 5. The FHL muscle (light red) attaches proximally to the interosseous membrane and the intermuscular septa and extends distally passing between the medial and lateral sesamoid bones to insert into the distal phalanx of the great toe.

The FDL muscle has a smaller cross-sectional area than the FHL muscle and similarly maintains a short fiber to muscle length ratio (0.16 ± 0.09).² Variations are common. The FDL muscle may be more or less divided into separate fasciculi for the individual toes.³ One of the more common anomalous muscles of the leg is the flexor accessorius longus digitorum muscle that spans from the fibula or tibia to the tendon of the FDL muscle or to the flexor accessories (quadratus plantae) muscle and may send slips to the FHL and tibialis anterior muscles.^{1, 4-6} A sesamoid bone may develop in the tendon of the FHL muscle where it passes over the talus and the calcaneus.³

Flexor Hallucis Longus

The FHL muscle is a strong, large, multiarticular muscle contained within the deep posterior compartment of the leg. This pennate muscle is located distal and lateral to the FDL and tibialis posterior muscles. The FHL muscle sits predominantly over the posterior surface of the lower two-thirds of the posterior fibula attaching proximally to the interosseous membrane and to the intermuscular septa shared with associated muscles on both sides of it. The fibers of this muscle continue to converge on its tendon as it crosses the posterior surface of the lower end of the tibia. The tendon then crosses the posterior surface of the talus and the inferior surface of the sustentaculum tali of the calcaneus—deep to the tendon of the FDL muscle. Marginally, distal to the common tendon sheath, the lateral aspect of the FHL tendon attaches by two slips to the medial two tendons of the FDL muscle, forming a conjoined tendon. At this juncture, both tendons merge to attach to the cupola of the foot's arch by the knot of Henry or the common tendon sheath and binds to the medial surface of the navicular.

In the sole of the foot, the FHL tendon courses forward between the two heads of the flexor hallucis brevis muscle, passing between the medial and lateral sesamoid bones under the metatarsophalangeal joint to insert into the base of the terminal phalanx of the great (first) toe¹ (Figure 69-1).

According to Friederich and Brand⁷ (and later confirmed by Kura et al⁸ and Ward et al²), the cross-sectional area of the FHL muscle is the largest of all the short and long toe flexor muscles. Ward et al² also demonstrated that the FHL muscle presents a short fiber length to muscle length ratio (0.20 ± 0.5).

The dense fibrous fascia located within the compartments of the leg act to provide both connection and disconnection by means of fascial (septal) thickening. The deep fasciae take the form of interweaving, interlacing fibers, creating continuity through the various aponeuroses, sheaths, and epimysium surrounding and enveloping the muscle fibers and

the associated neurovascular structures. Connective tissue is continuous from the skin and superficial fascia (sub cutis) to the deep fascia (profundus), providing a continuity that allows the expression of muscle fibers (ie, force production) to have a direct effect locally and at some distance. The translation of muscular forces into mechanical expression (such as movement) and physiologic activity (such as cellular metabolism) occurs by means of force transmission.⁹

2.1. Innervation and Vascularization

The tibial nerve, with specific spinal nerve contribution, innervates all the superficial and deep muscles of the posterior compartment of the leg. The FDL muscle receives innervation from the level L5 and S1 spinal nerves, and the FHL muscle receives innervation from the level L5, S1, and S2 spinal nerves. The FDL muscle receives its vascularization from ever-smaller branches of the posterior tibial artery entering its lateral side. Several branches of the fibular artery supply the muscle belly of the FHL muscle, whereas the tendon is supplied by the arteries of the ankle and foot.

2.2. Function

The FDL and FHL muscles act together in plantar flexion of the metatarsophalangeal and interphalangeal joints. During the swing phase of gait, both of these muscles assist in plantar flexion and inversion of the foot. During mid-to-late stance of gait, these muscles stabilize the foot to ensure mediolateral balance and to maintain stability of the longitudinal arches of the foot. During forefoot push-off, these muscles pull the toes into flexion, decelerating passive dorsiflexion of the distal phalanges. The FHL muscle contributes to plantar flexion at the ankle and inversion at the subtalar joint. The FDL muscle flexes the distal phalanx of each of the four lesser toes, whereas the FHL muscle flexes the distal phalanx of the great toe.

The small fiber length to muscle length ratio of both the FDL and FHL muscles proposes an architectural design favoring isometric function of these muscles.² This hypothesis has been supported both in vivo and with cadaveric specimens. Hofmann et al¹⁰ used a robotic dynamic activity simulator to replicate gait in cadaveric lower extremities while measuring the FDL and FHL tendon excursions during the stance phase of gait. Both muscles showed minimal tendon length excursions, suggesting isometric functions. Peter et al¹¹ supported this conclusion in vivo by using ultrasound to measure FHL fascicle length at different gait speeds and found that the FHL fascicle length is relatively constant throughout the stance phase of gait, regardless of speed.

This relatively isometric nature of the FDL and FHL muscles may be due to their role in stabilizing the arches of the foot. The FDL and FHL muscles are active from the mid-stance to the push-off phase of gait as the body's center of mass rotates over the arch of the foot. Researchers found that force under the great toe increased when gait speed increased from increased FHL muscle activity, but no significant changes in fascicle length were noted. These data support the notion that, as walking speed increases, the reliance on the

FHL muscle to maintain the longitudinal arch also increases.¹² Isometric contractions also require less energy output than eccentric or concentric contractions; therefore, the nature of the FDL and FHL muscles' isometric function may also conserve energy.¹⁰

The FDL and FHL muscles are activated during the stance phase and into the push-off phase of gait.^{13,14} Zelik et al¹⁴ showed a sequential order of lower extremity muscle activation during the gait cycle that works proximally to distally. The FHL and FDL muscles reach their peak activation 3% to 11% later in the gait cycle than the gastrocnemius and soleus muscles and 25% earlier than the ankle dorsiflexor muscles in normal linear gait.

2.3. Functional Unit

The functional unit to which a muscle belongs includes the muscles that reinforce and counter its actions as well as the joints that the muscle crosses. The interdependence of these structures is functionally reflected in the organization and neural connections of the sensory motor cortex. The functional unit is emphasized because the presence of a TrP in one muscle of the unit increases the likelihood that the other muscles of the unit will also develop TrPs. When inactivating TrPs in a muscle, one must be concerned about TrPs that may develop in muscles that are functionally interdependent. Box 69-1 grossly represents the functional unit of the FHL and FDL muscles.¹⁵

Box 69-1 Functional unit of the flexor hallucis longus and flexor digitorum longus muscles

Action	Synergists	Antagonists
Plantar flexion	Gastrocnemius Soleus Tibialis posterior Fibularis longus	Tibialis anterior Extensor digitorum longus Extensor hallucis longus Fibularis tertius
Subtalar inversion	Tibialis anterior Tibialis posterior	Fibularis longus Fibularis brevis Fibularis tertius
1st toe flexion	Flexor hallucis brevis	Extensor hallucis longus Extensor hallucis brevis
2nd-5th toe flexion	Flexor digitorum brevis Flexor digiti minimi brevis Interossei Flexor accessorius (Quadratus plantae)	Extensor digitorum longus Extensor digitorum brevis Lumbricals Interossei

3. CLINICAL PRESENTATION

3.1. Referred Pain Pattern

Typically, with FDL and FHL TrPs, patients will report pain in the foot and ankle, including the great toe. Pain and other sensations are reported on the sole of the foot as well as the plantar surfaces of the smaller digits and great toe. Trigger points in the FDL muscle refer pain and tenderness primarily to the middle of the plantar forefoot, proximal to the four lesser toes and, sometimes, with spreading to the toes (Figure 69-2). Occasionally, these TrPs refer pain to the medial side of the ankle and calf; however, they do not refer pain to the heel. Thus, when patients report that the sole of the forefoot is painful and tender, clinicians must consider the calf as a source of the patient's symptoms. Trigger points in the FHL muscle refer pain intensely to the plantar surface of the great toe and the head of the 1st metatarsal (Figure 69-2). Pain may occasionally radiate proximally for a short distance on the plantar surface but does not extend to the heel or leg.

Figure 69-2. Referred pain pattern of TrPs. A, Flexor digitorum longus muscle (dark red). B, Flexor hallucis longus muscle (light red).

3.2. Symptoms

Patients with TrPs in the FDL and/or FHL muscles typically report that their feet hurt when they walk. A chief report is pain that occurs in the sole of the forefoot and on the plantar surfaces of the toes especially with weight-bearing activities. Although pain in the foot may result from a problem within the foot itself, this is not always the case. Extrinsic and intrinsic foot muscles can be painful as a direct or indirect result from insults to neural, fascial, visceral, or other tissues. Symptoms of pain or other sensations in the feet can be a direct result of pelvic organ dysfunction or low back pathology. Pathology other than TrPs should always be ruled out. Custom inserts (orthoses) to reduce stress on the foot are useful in managing foot pain. Patients may also report a feeling of cramping in the toes or calf. Trigger points in the long extrinsic toe flexors may occasionally cause painful contraction of these muscles similar to the calf cramps of gastrocnemius TrPs. However, toe flexor “cramping” is more likely to be caused by TrPs of the intrinsic flexors of the toes.

3.3. Patient Examination

After a thorough subjective examination, the clinician should make a detailed drawing representing the pain pattern that the patient has described. This depiction will assist in planning the physical examination and can be useful in monitoring the progression of the patient as symptoms improve or change. The type, quality, and location of the pain should be carefully assessed, and the utilization of standardized outcome tools is imperative when examining patients with lower extremity dysfunctions.

Observation of static and dynamic posture is essential given the role of the FDL and FHL muscles in postural stability and gait. The toes should be examined for any abnormalities such as claw toe, hammer toe, and hallux valgus. These abnormalities should be assessed to determine if they are flexible or rigid and then addressed appropriately. The presence of deviations, such as ankle equinus, pes planus, or pes cavus, should be noted. The patient should be observed walking barefoot, with the clinician noting any relevant gait deviations such as early excessive pronation, excessive pronation at mid-stance (pes planus), or late pronation during push-off. Excessive flexion of the toes during the stance and push-off phases of gait may indicate joint hypomobility of the foot and ankle as well as muscle imbalances. At heel-off, the FDL, FHL, and tibialis posterior muscles contract to supinate the hindfoot and midfoot, creating a rigid lever for propulsion. If the calcaneus does not move into inversion at heel-off, tibialis posterior and/or FDL muscle weakness may be indicated.

A collapse of the medial longitudinal arch, or a midfoot posture with forefoot abduction, is commonly observed with tibialis posterior muscle dysfunction as discussed in Chapter 67. This deviation may lead to excessive overload and abnormal tensile loading of the extensor digitorum longus and extensor hallucis longus muscles. Measures such as the navicular drop test¹⁶ and the windlass mechanism¹⁷ should be assessed in standing as a predictor of dynamic function of the foot. Functional testing such as double- and single-leg squat will allow a quick assessment of hip and knee control, as well as a quick assessment of talocrural, subtalar, and midfoot range of motion. Timed single-leg stance with eyes open

and closed will give a quantitative measure of balance and will allow the clinician to observe foot and ankle strategies related to balance and control.

The patient's feet should be examined for muscular imbalances, and passive physiologic and accessory motion should be tested in the talocrural, subtalar, midtarsal, and forefoot joints. Assessment for great toe and first ray range of motion in dorsiflexion is vital, because limitation in this motion may cause abnormal pronation of the foot during the propulsive phases of gait, placing an abnormal tensile load on the FDL and FHL muscles.

Examination should include the distal phalanges of all toes for flexion weakness, as described by Kendall and McCreary.¹⁸ Weakness of the FDL and FHL muscles affects flexion of the distal phalanx of the lesser toes, whereas weakness of the flexor digitorum brevis muscle affects flexion of the middle phalanx in the lesser toes. Maximum flexion effort of the great toe or four lesser toes with the foot in the plantar flexed position is likely to be particularly painful for the patient with TrPs in the corresponding flexor muscle. Passive extension range of motion of the great toe is restricted with FHL muscle involvement,¹⁹ and passive extension of the four lesser toes is restricted when the FDL muscle has TrPs.

The patient's shoe may show a wear pattern characteristic of an abnormal foot structure or evidence of excessive wear. Indications of excessive wear are as follows: asymmetry between the two shoes, cracks between the midsole and edge of the shoe, a definite lean of the shoe either inward or outward when set on a level surface, loss of the sole pattern in sports shoes, and a flattened or expanded heel pattern of the shoe.

3.4. Trigger Point Examination

Trigger points can form at any point along the length of the FDL and FHL muscles.

Palpation for TrPs in the FDL and FHL muscles is achieved by placing the patient in a prone or side-lying position, with the leg to be treated supported appropriately. For palpation of TrPs in the FDL muscle, the patient lies on the involved side and the clinician uses cross-fiber flat palpation to exert pressure between the tibia and the soleus/gastrocnemius muscles on the medial side of the leg (Figure 69-3A).

Figure 69-3. Cross-fiber flat palpation for TrPs. A, Flexor digitorum longus muscle. B, Flexor hallucis longus muscle.

An alternate method is performed with the knee flexed to 90° and the foot plantar flexed so that the gastrocnemius muscle can be pressed posteriorly away from the tibia to expose the FDL muscle for more effective palpation. The clinician first exerts pressure toward the back of the tibia and then laterally against the FDL muscle belly with a cross-fiber flat palpation technique.

For examination of TrPs in the FHL muscle, the patient lies prone and the clinician uses cross-fiber flat palpation, applying deep pressure at the junction of the middle and lower thirds of the calf, just lateral to the midline, against the posterior aspect of the fibula (Figure 69-3B). The pressure of palpation must be projected through the soleus muscle, as well as through the thick aponeuroses that becomes the achilles tendon. Tenderness can be attributed to the FHL muscle only if the clinician is sure that the overlying muscles are free of TrPs.

For clinicians with appropriate training, safe use of a solid filiform or injection needle, from the lateral or medial aspect of the muscles, makes these structures more easily accessible and identifiable through reproduction of their referred pain patterns.

4. DIFFERENTIAL DIAGNOSIS

4.1. Activation and Perpetuation of Trigger Points

A posture or activity that activates a TrP, if not corrected, can also perpetuate it. In any part of the FHL or FDL muscles, TrPs may be activated by unaccustomed eccentric loading, eccentric exercise in an unconditioned muscle, or maximal or submaximal concentric loading.²⁰ Trigger points may also be activated or aggravated when the muscle is placed in a shortened and/or lengthened position for an extended period of time. FDL and FHL TrPs are activated by overload during weight-bearing activities. When initiating a walking or running exercise program, individuals should gradually ease into the exercise routine. Excessive frequency, intensity, and/or duration in the early stages of a weight-bearing exercise program may result in overload and, consequently, TrP development in the untrained FDL and FHL muscles. Acute overload, such as running a half marathon without proper training, can also lead to TrP development. Additionally, TrPs can be activated, and are then perpetuated, by running or jogging on uneven ground or on laterally slanted or cantilevered surfaces. Clinically, common ballet foot postures such as relevé, during which the individual maintains extreme angles of ankle plantar flexion, require excessive isometric contractions of the FDL and FHL muscles, and these can lead to muscle overload and TrP development.

Therapeutic success involves controlling perpetuating factors such as poorly fitted orthotics that can lead to irritation of soft tissues overlying the arch of the foot at the knot of Henry. High-demand forceful repetitive actions in positions of extreme ankle plantar flexion and metatarsophalangeal flexion and extension are recognized as contributing factors in musculotendinous overload, typically resulting in TrPs and tendinosis.

When the foot excessively pronates (because of a hypermobile midfoot, flexible pes valgus deformity, muscular imbalance, or some other cause), the FDL and FHL muscles

can become overloaded and develop TrPs, especially if the tibialis posterior muscle is dysfunctional. These muscles may also become overloaded in an individual with a high-arched, supinated foot with associated triceps surae muscle weakness.

Trigger points are more often than not the result of a functional adaptation due to impairment in joint mobility or muscle performance. Impaired mobility of the joints of the foot can perpetuate TrPs in these muscles. A common mistake committed by joggers and runners is to continue using a shoe after it has developed excessive wear on the sole and heel. Loss of cushioning and flexibility produces excessive strain on the joints and muscles, including the long flexor muscles of the toes. Walking and running on soft sand, especially barefoot, heavily loads the FDL muscle and can perpetuate, or activate, TrPs in this muscle.

4.2. Associated Trigger Points

Associated TrPs can develop in the referred pain areas caused by TrPs.²¹ Therefore, musculature in the referred pain areas for each muscle should also be considered. The muscles most likely to have associated TrPs, when one finds them in the long toe flexors, are muscles of the functional unit including the tibialis posterior, extensor hallucis longus and brevis, and extensor digitorum brevis muscles. The short (intrinsic) toe flexors, the flexor hallucis, and digitorum brevis muscles may also develop associated TrPs as part of the functional unit and because they are in the referred pain area of the muscles. Additionally, the adductor hallucis and flexor accessories (quadratus plantae) muscles can develop TrPs because the muscles are located in the referred pain area of the FHL and FDL muscles.

4.3. Associated Pathology

Injury and insult can occur along the entire FHL tendon. A common source of insult is repetitive, high-demand forces exceeding physiologic parameters resulting in tendinopathy or stenosing tenosynovitis. Hallux trigger or claw toe is a common sign of stenosing tenosynovitis of the FHL tendon. Tendon adhesions with accompanied nodules develop within the tendon sheath, thus reducing the ability of tendon gliding. Tendinopathy, a less-associated inflammatory condition in the leg, can involve partial tears of the deeper internal tissues leading to mucinoid degradation and nodule development.²²

Spontaneous rupture of the FHL tendon can occur during overload without evidence of previous disease or injury.²³ Even though surgical repair does not always restore function of the great toe, the authors concluded that, in cases of laceration or rupture, surgical repair seems justified.²³

Classic hammer toe, mallet toe, and claw toe deformities are presented in Section 4.3 in Chapter 68. Flexor stabilization most commonly occurs when the long flexor muscles of the toes attempt to stabilize the osseous structures of the foot in the presence of a flexible pes planus (flat foot) deformity. Pronation of the subtalar joint allows hypermobility and unlocking of the midtarsal joint, which, in turn, leads to hypermobility of the forefoot.²⁴ The long toe flexor muscles then act earlier and longer than in normal gait.²⁵ Instead of stabilizing the forefoot, this abnormal activity usually overpowers the smaller intrinsic

lumbrical and interosseous muscles, as well as the flexor accessories (quadratus plantae) muscle. Loss of flexor accessories (quadratus plantae) muscle function allows adductovarus deviation of the fifth toe and possibly of the fourth toe. Flexor stabilization is the most common etiology of hammer toes.^{24, 26}

Flexor substitution develops when the triceps surae muscles are weak and the deep posterior and lateral leg muscles try to substitute for this weakness. This substitution occurs in a high-arched and supinated foot in the late-stance phase of gait when the flexors have gained mechanical advantage over the interossei muscles; it usually produces clawing (total flexion) of all toes without adductovarus of the fourth and fifth toes. If triceps surae muscle strength is inadequate for push-off, this action readily leads to a hammer toe syndrome.²⁶

Flexor substitution is the least common of the three mechanisms (flexor stabilization, flexor substitution, and extensor substitution) that can produce claw toes and hammer toes.²⁴ Extensor substitution is reviewed under Section 4.3 in Chapter 68.

Toe curling may result from spasticity following traumatic brain injury or any cerebrovascular accident. Simply releasing the FHL and FDL tendons provided satisfactory relief in only about one-fourth of 41 feet. Additional release of the flexor digitorum brevis tendon often achieved a more functional result.²⁷ Kwon and DeAsla²⁶ describe a technique utilizing a flexor to extensor transfer for correction of a flexible hammer toe deformity.²⁶

Hallux valgus is more commonly known as a “bunion” and is the most common forefoot deformity, affecting women more than men. The cause of hallux valgus is thought to be attributed to ill-fitting shoes, genetic predisposition, pronated feet, and asymmetry of the bones and joints of the feet.²⁸ Bunions are typically caused by an imbalance between both extrinsic and intrinsic muscles of the great toe and forefoot and ligamentous structures in the great toe and forefoot.²⁹ There may be subluxation of the 1st metatarsophalangeal joint with an associated medial deviation of the proximal and distal phalanx of the great toe leading to arthritic changes in the joint.³⁰ This angulation can change the angle of pull on the FHL muscle and overload it, leading to the formation of TrPs, thus increasing pain in the region of the great toe.

Bouché and Johnson³¹ suggest that medial tibial stress syndrome is due to a “tenting” of the tibial fascia resulting from eccentric contraction of the deep leg flexor muscles including the gastrocnemius, soleus, tibialis posterior, FDL, and FHL muscles. In a pilot study using cadaveric specimens, these researchers demonstrated a linear increase in tension applied to the tibialis posterior, FDL, and soleus tendons and strain on the tibial fascia. Because the tibial fascia inserts directly into the medial tibial crest, the repetitive eccentric contractions of these muscles to prevent excessive pronation at the midtarsal and subtalar joints during the stance phase of gait may cause the medial tibial stress syndrome pathology. A follow-up study by Brown³² found that in all of the studied 22 cadaveric legs, the FDL muscle was attached to the middle third of the posterior tibia, and in all but one specimen, the soleus muscle attached to the middle third of the posterior tibia, the common site of pain in medial tibial stress syndrome (MTSS).

Garth and Miller³³ examined 17 athletes who presented for treatment of incapacitating

pain and soreness located posteromedially along the middle third of the tibia (over the attachment and belly of the FDL muscle). Symptoms were provoked and aggravated by repetitive weight bearing. Similar symptoms may be diagnosed as shin splints, MTSS,³³ and chronic exertional compartment syndrome.³⁴ Seventeen asymptomatic athletes served as controls. The symptomatic athletes consistently demonstrated a mild claw toe deformity of the second toe, with abnormal displacement of its arc of motion toward extension of the metatarsophalangeal joint, as well as weakness of the lumbrical muscles. It appears as if the relatively stronger FDL muscle became overloaded because of inadequate metatarsophalangeal joint stabilization due to lumbrical muscle weakness that resulted in clawing of the lesser toes rather than in effective stabilization. Symptoms were relieved by a treatment regimen consisting of toe flexion exercises, reduced athletic activity, and metatarsal and arch pads to compensate for the weak lumbrical muscle action.³³

Exertional compartment syndromes of the leg are a common form of overuse injury. Compartment syndromes are characterized by increased pressure within a muscular compartment sufficient to compromise the circulation of the muscles within it. The increased pressure obstructs venous outflow, which causes further swelling and more pressure. If prolonged, the resultant ischemia can lead to necrosis of the muscles and nerves within the compartment. When following a traumatic injury, it is vitally important that this condition be recognized immediately and managed properly to avoid possibly catastrophic consequences. Anterior compartment syndromes are recognized more commonly, followed by lateral, deep posterior, and superficial posterior compartment syndromes.^{35,36} Deep posterior chronic exertional compartment syndrome is discussed in Section 4.3 of Chapter 67.

5. CORRECTIVE ACTIONS

Individuals with TrPs in the FDL or FHL muscles may benefit from adopting sitting or standing postures that place the ankle in some degree of plantar flexion. While seated, an individual can sit with the knees in 50° or 60° of flexion, allowing the foot to contact the floor for lower extremity support, while providing ankle plantar flexion to place more slack on the long toe flexor muscles.

In general, the leg muscles feel better if the ankle is maintained in a neutral position throughout the night; therefore, adjusting the patient's sleeping posture may be necessary. This position is facilitated by having the bed sheets at the foot of the bed untucked to reduce external force into excessive plantar flexion (see Figure 65-6). Using a pillow between the legs and knees in side-lying to place the foot and ankle in a neutral position may also be beneficial.

Individuals with TrPs in the FDL and/or FHL muscles should wear comfortable shoes that have adequate shock absorption and flexibility of the sole, especially under the ball of the foot. New shoes should be tested at the time of purchase to ensure they have enough space in the toe box to allow for an insert, as needed. Worn-out shoes and those with poor flexibility of the distal sole must be replaced. An extremely stiff sole that prevents extension

of the metatarsophalangeal joint of the great toe should be avoided. Also, high heels and stiletto heels should be avoided completely (see Chapter 77).

If patients with TrPs in the FDL or FHL muscles walk or run for exercise, initial management should focus on inactivating TrPs, correcting anatomic and biomechanical imbalances, and improving the stamina of deconditioned muscles such as those invested into the iliotibial band. If these measures are inadequate, runners should be encouraged to substitute non-weight-bearing activities, such as rowing, swimming, or bicycling. Running should resume on a flat, even surface, initially with limited distance that progresses by increments within tolerance. If the only running surface available is slanted from side to side, such as a road, the individual should run out and back on the same side of the road so that the foot and the ankle are getting an equal distribution of extrinsic forces.

FDL or FHL TrP self-pressure release can be performed in the seated position on the edge of the bed or floor with the knee in 90° of flexion to allow gravity to move the gastrocnemius and soleus muscles out of the way. Manual TrP self-pressure release of the FDL muscle can be performed with the thumb on the undersurface of the tibia (Figure 69-4). Finding the most tender spot along the posterior surface of the tibia, light pressure (no more than 4/10 pain) should be gently applied below the muscle bulk of the gastrocnemius muscle (Figure 69-4A). A TrP self-release tool should be used with caution because of the proximity of the bone (Figure 69-4B). For self-pressure release of the FHL muscle, pressure is applied on the undersurface of the outer part of the leg, over the fibula (Figure 69-5). Finding the sensitive spot with the thumb, light pressure (no more than 4/10 pain) should be applied and held for 15 to 30 seconds or until pain reduces. These techniques may be repeated five times, several times per day. Also, patients may perform self-massage along the length of the involved soft tissues to enhance soft-tissue mobility.

Figure 69-4. Self-pressure release of TrPs in the flexor digitorum longus muscle. A, Manual release with thumb. B, TrP release tool.

Figure 69-5. Self-pressure release of TrPs in the flexor hallucis longus muscle.

In cases where the long toe flexor muscles are adaptively shortened, self-stretching exercises may be helpful. One way to stretch the FDL (Figure 69-6A) and FHL muscles (Figure 69-6B) is in a seated position with the involved leg crossed over the opposite thigh. In this position, one hand can passively move the toes into extension, and with distal extension sustained, gradually move the ankle toward dorsiflexion, until a stretch on the back of the foot/ankle is felt. The opposite hand can be used to stabilize the distal tibiofibular joint complex as needed. The stretch is held for up to 30 seconds and repeated four times.

Figure 69-6. Self-stretch. A, Flexor digitorum longus muscle. B, Flexor hallucis longus muscle.

Intrinsic Muscles of the Foot

“Sore Foot Muscles and Viper’s Nest”

Jeffrey Gervais Ebert

1. INTRODUCTION

There are approximately 20 relatively small muscles that make up the intrinsic muscles of the foot, depending on anatomic variations and classifications. Although each muscle has its own particular action, many of the intrinsic foot muscles work collectively to help support and stabilize the foot, especially during gait. Trigger points (TrPs) in these muscles often result in plantar foot pain. Activation and perpetuation of TrPs in the intrinsic foot muscles often result from an acute overload due to walking or running over soft or uneven terrain, from ill-fitting footwear, or from structural issues within the foot. Differential diagnosis should include assessment for plantar heel pain due to plantar fasciitis or entrapment of the lateral plantar nerve, structural issues including navicular drop or hallux valgus, and metatarsalgia. Corrective actions should include education regarding proper sleeping position, elimination of positions and activities that cause recurrent overload of the muscle, TrP self-pressure release, self-stretch exercises, and strengthening exercises.

2. ANATOMIC CONSIDERATIONS

The intrinsic muscles of the foot include flexors, located on the plantar aspect of the foot, and extensors, located on the dorsum of the foot. The plantar muscles are customarily divided into four groups or layers, from superficial to deep. The first, and most superficial, layer consists of the abductor hallucis, abductor digit minimi, and flexor digitorum brevis muscles. The second layer includes the flexor accessorius (quadratus plantae) muscle and the four lumbrical muscles. The third layer contains the flexor hallucis brevis, adductor hallucis, and flexor digiti minimi brevis muscles. The fourth, and deepest, layer consists of the plantar and dorsal interosseous muscles. The dorsally located extensor muscles include the extensor digitorum brevis and extensor hallucis brevis muscles.¹

Plantar Muscles

First Layer

The abductor hallucis muscle originates primarily from the flexor retinaculum but also from the medial aspect of the calcaneal tuberosity and the plantar aponeurosis. It inserts, along with the medial tendon of the flexor hallucis brevis muscle, onto the medial aspect of the base of the proximal phalanx of the great toe (Figure 70-1B). In some instances, fibers are attached to the medial sesamoid bone of the great toe.¹

Figure 70-1. A, The dorsal intrinsic muscles of the foot. B, The first, and most superficial, layer of the plantar intrinsic muscles of the foot.

The flexor digitorum brevis muscle originates via a narrow tendon from the medial aspect of the calcaneal tuberosity and from the central part of the plantar aponeurosis. It divides into four tendons, each of which enters tendinous sheaths along with the tendons of the flexor digitorum longus muscle, which lie deep to them. They ultimately insert onto the shafts of the middle phalanges of the 2nd through 5th digits (Figure 70-1B).¹

The abductor digiti minimi muscle originates from both processes of the calcaneal tuberosity and from the plantar aponeurosis. Its tendon lies in a groove on the plantar

surface of the base of the 5th metatarsal and inserts, along with the flexor digiti minimi brevis muscle, onto the lateral side of the base of the proximal phalanx of the fifth toe (Figure 70-1B).¹

Second Layer

The flexor accessorius (quadratus plantae) muscle consists of two heads, with the long plantar ligament located deeply between them. The larger medial head originates from the medial surface of the calcaneus. The flat and tendinous lateral head originates from the calcaneus distal to the lateral process of the tuberosity and from the long plantar ligament. The muscle inserts into the flexor digitorum longus tendon at the point where it divides into its four tendons (Figure 70-2A). In some instances, this muscle may be absent.¹

Figure 70-2. A, The second layer of the plantar intrinsic muscles of the foot. B, The third layer of the plantar intrinsic muscles of the foot.

The lumbrical muscles (numbered beginning at the medial side of the foot) are four small muscles that arise from the terminal flexor digitorum longus tendons. Their tendons pass distally on the medial sides of the lateral four toes and insert into the dorsal digital expansions on the proximal phalanges (Figure 70-2A).¹

Third Layer

The flexor hallucis brevis muscle originates from two locations. A lateral branch of its tendon originates from the medial aspect of the plantar surface of the cuboid and from the adjacent part of the lateral cuneiform. The medial tendon branch has an attachment that is

continuous with the lateral division of the tendon of the tibialis posterior muscle. The muscle belly itself also divides into medial and lateral parts, the tendons of which are attached to the sides of the base of the proximal phalanx of the great toe. The medial attachment blends with the tendon of the abductor hallucis muscle and the lateral attachment with that of the adductor hallucis muscle (Figure 70-2B).¹

The adductor hallucis muscle consists of two heads: oblique and transverse. The oblique head originates from the bases of the 2nd, 3rd, and 4th metatarsals and from the sheath of the tendon of the fibularis longus muscle. The transverse head originates from the plantar metatarsophalangeal ligaments of the third, fourth, and fifth toes and from the deep transverse metatarsal ligaments between them. The oblique head is further divided into medial and lateral portions. The medial portion blends with the lateral part of the flexor hallucis brevis muscle and is attached to the lateral sesamoid bone of the great toe. The lateral part attaches to the transverse head, the base of the proximal phalanx of the great toe, and to the lateral sesamoid bone of the great toe² (Figure 70-2B). The oblique head is significantly larger than the transverse head,³ and the transverse portion of the adductor hallucis muscle is sometimes absent.⁴

The flexor digiti minimi brevis muscle originates from the medial aspect of the plantar surface of the base of the 5th metatarsal and from the tendon sheath of the fibularis longus muscle. It inserts onto the lateral aspect of the base of the proximal phalanx of the fifth toe (Figure 70-2B). Periodically, some of its deeper fibers extend to the lateral part of the distal half of the 5th metatarsal, forming what is sometimes described as a separate muscle known as the opponens digiti minimi muscle.¹

Fourth Layer

The dorsal interosseous muscles are located between the metatarsals. They consist of four bipennate muscles, each originating by two heads from the adjacent metatarsals. The first inserts onto the medial aspect of the base of the proximal phalanx of the second toe. The remaining three insert onto the lateral aspect of the proximal phalanges of the second, third, and fourth toes (Figure 70-3A).¹

Figure 70-3. The fourth, and deepest, layer of the intrinsic muscles of the foot. A, Dorsal interosseous muscles. B, Plantar interosseous muscles.

There are three plantar interosseous muscles. Unlike the dorsal interosseous muscles, these muscles are located under the metatarsals rather than between them, and each muscle is attached to only one metatarsal. They are unipennate. They originate from the bases and medial aspects of the 3rd, 4th, and 5th metatarsals, and they insert onto the medial aspect of the bases of the proximal phalanges of the third, fourth, and fifth toes (Figure 70-3B).

Dorsal Muscles

The extensor digitorum brevis muscle is a thin muscle that originates from the distal aspect of the superolateral surface of the calcaneus, from the interosseous talocalcaneal ligament, and from the inferior extensor retinaculum. It runs distally and medially across the dorsum of the foot. The tendon of the most medial portion of the muscle crosses the dorsalis pedis artery superficially to insert onto the dorsal aspect of the base of the proximal phalanx of the great toe. This slip, which is rather distinct from the rest of the muscle, is actually considered to be the extensor hallucis brevis muscle. The remaining three tendons are considered a part of the extensor digitorum brevis muscle and attach to the lateral aspects of the extensor digitorum longus tendons for the second, third, and fourth toes (Figure 70-1A). There is much variation associated with the extensor digitorum brevis muscle, including accessory slips from the talus and navicular, an extra tendon running to the 5th digit, or a lack of one or more tendons.¹

2.1. Innervation and Vascularization

Plantar Muscles

First Layer

The abductor hallucis muscle is innervated by the medial plantar nerve from the S1 and S2 nerve roots. It receives its blood supply from the medial malleolar network, the medial calcaneal branches of the lateral plantar artery, the medial plantar artery (directly and via superficial and deep branches), the first plantar metatarsal artery, and the plantar arterial arch. The flexor digitorum brevis muscle is also innervated by the medial plantar nerve from the S1, S2 nerve roots and is supplied by the lateral and medial plantar arteries, the plantar metatarsal arteries, and the plantar digital arteries of the lateral four toes. The abductor digiti minimi muscle is innervated by the lateral plantar nerve from the S1, S2, S3 nerve roots and is supplied by the medial and lateral plantar arteries, the plantar digital artery, branches from the deep plantar arch, the fourth plantar metatarsal artery, and the arcuate and lateral tarsal arteries.¹

Second Layer

The flexor accessorius (quadratus plantae) muscle is innervated by the lateral plantar nerve from the S1, S2, S3 nerve roots and is supplied by the medial and lateral plantar arteries and the deep plantar arch. The first lumbrical muscle is innervated by the medial plantar nerve, and the remaining lumbrical muscles are innervated by the deep branch of the lateral plantar nerve from the S2, S3 nerve roots. All of the lumbrical muscles are supplied by the lateral plantar artery and deep plantar arch and by four plantar metatarsal arteries.¹

Third Layer

The flexor hallucis brevis muscle is innervated by the medial plantar nerve from the S1, S2 nerve roots and is supplied by the medial plantar artery, the first plantar metatarsal artery, the lateral plantar artery, and the deep plantar arch. The adductor hallucis muscle is innervated by the deep branch of the lateral plantar nerve from the S2, S3 nerve roots and is supplied by the medial and lateral plantar arteries, the deep plantar arch, and the first through fourth plantar metatarsal arteries. The flexor digiti minimi brevis muscle is innervated by the superficial branch of the lateral plantar nerve from the S2, S3 nerve roots and is supplied by the arcuate artery, the lateral tarsal arteries, and the lateral plantar artery.

Fourth Layer

The first three dorsal interosseous muscles are innervated by the deep branch of the lateral plantar nerve from the S2, S3 nerve roots. The fourth is innervated by the superficial branch of the lateral plantar nerve, also from the S2, S3 nerve roots. The dorsal interosseous

muscles are supplied by the arcuate artery, the lateral and medial tarsal arteries, the first through fourth plantar arteries, the first through fourth dorsal metatarsal arteries, and the dorsal digital arteries of the lateral four toes. The first two plantar interosseous muscles are supplied by the deep branch of the lateral plantar nerve from the S2, S3 nerve roots, and the third is innervated by the superficial branch of the lateral plantar nerve (S2, S3). The plantar interosseous muscles are supplied by the lateral plantar artery, the deep plantar arch, the second through fourth plantar metatarsal arteries, and the dorsal digital arteries of the lateral three toes.¹

Dorsal Muscles

The extensor digitorum brevis and extensor hallucis brevis muscles are innervated by the deep fibular nerve from the L5, S1 nerve roots and are supplied by the fibular artery, the anterior lateral malleolar artery, the lateral tarsal arteries, the dorsalis pedis artery, the arcuate artery, the first through third dorsal metatarsal arteries, the proximal and distal perforating arteries, and the dorsal digital arteries of the first four toes.

2.2. Function

Many of the intrinsic muscles of the foot, particularly the plantar muscles, work collectively, along with the extrinsic muscles of the foot, to aid in effective gait by maintaining medial longitudinal arch height,⁵⁻⁹ controlling the extent and speed of arch deformation,¹⁰ and assisting in dynamic postural control.^{9,11-13} Contrary to previous belief, Kelly et al have shown that intrinsic foot muscles are also active during quiet stance.¹¹ The intrinsic foot muscles that demonstrate the most involvement in maintaining foot stability during gait and during static and dynamic posture include the abductor hallucis, abductor digiti minimi, flexor digitorum brevis, flexor hallucis brevis, flexor accessorius (quadratus plantae), lumbrical, and interosseous muscles.^{9,11}

In addition to this collective function, each muscle has its own individual action(s). These individual actions, along with specific contributions to foot static and dynamic stability, if known, are described as follows:

Plantar Muscles

First Layer

The abductor hallucis muscle creates abduction, and often flexion, of the great toe at the metatarsophalangeal joint.¹ The abductor hallucis muscle is particularly important, along with the extrinsic tibialis posterior muscle, for supporting and elevating the medial longitudinal arch.^{6,8,14} The flexor digitorum brevis muscle flexes toes 2 to 5 at their proximal interphalangeal joints. It performs this action equally effectively regardless of ankle joint position.¹ The abductor digiti minimi muscle acts on the fifth toe by, despite its name, flexing it at the metatarsophalangeal joint more than it abducts it.¹

Second Layer

The flexor accessorius (quadratus plantae) muscle creates pure flexion of digits 2 to 4 from the posteromedial pull of the flexor digitorum longus muscle.^{15,16} This action can be performed regardless of the ankle position.¹ It is also believed that the flexor accessorius muscle is a muscle that acts as a “truss” for the longitudinal arches by actively resisting bending forces during ambulation.¹⁵ The lumbrical muscles help maintain interphalangeal joint extension of digits 2 to 4.¹

Third Layer

The flexor hallucis brevis muscle, as its name implies, flexes the great toe at the metatarsophalangeal joint.¹ The adductor hallucis muscle assists with flexion of the metatarsophalangeal joint of the great toe. It also works to stabilize the metatarsal heads.¹ The flexor digiti minimi brevis muscle flexes the metatarsophalangeal joint of the fifth toe.¹

Fourth Layer

The dorsal interosseous muscles abduct digits 2 to 4. They also contribute to flexion of the metatarsophalangeal joint and extension of the interphalangeal joints of digits 2 to 4.¹ The plantar interosseous muscles adduct digits 3 to 5, and they flex the metatarsophalangeal joints and extend the interphalangeal joints of the same digits. Together, the dorsal and plantar interosseous muscles also stabilize the tarsometatarsal joints late in the stance phase of gait, contributing to foot rigidity at push-off.¹⁷

Dorsal Muscles

The extensor digitorum brevis muscle aids in extension of digits 2 to 4 via the extensor digitorum longus tendons. The extensor hallucis brevis muscle aids in extension of the great toe. The recruitment pattern of these muscles during ambulation has been shown to vary significantly among individuals, and their contribution to additional functions in the foot remains, for the most part, unknown.^{18,19}

2.3. Functional Unit

The functional unit to which a muscle belongs includes the muscles that reinforce and counter its actions as well as the joints that the muscle crosses. The interdependence of these structures is functionally reflected in the organization and neural connections of the sensory motor cortex. The functional unit is emphasized because the presence of a TrP in one muscle of the unit increases the likelihood that the other muscles of the unit will also develop TrPs. When inactivating TrPs in a muscle, one must be concerned about TrPs that may develop in muscles that are functionally interdependent. Box 70-1 grossly represents the functional unit of the plantar intrinsic foot muscles and Box 70-2 represents the functional unit of the dorsal intrinsic foot muscles.²⁰

Box 70-1 Functional unit of the plantar intrinsic foot muscles

Action	Synergists	Antagonists
Toe flexion 2-5	Flexor digitorum longus	Dorsal interossei 2-4 Extensor digitorum longus Extensor digitorum brevis
Great toe flexion	Flexor hallucis longus	Extensor hallucis longus Extensor hallucis brevis

Box 70-2 Functional unit of the dorsal intrinsic foot muscles

Action	Synergists	Antagonists
Toe extension 2-5	Extensor digitorum longus Lumbricals	Flexor digitorum longus Flexor digitorum brevis Flexor digiti minimi brevis Abductor digiti minimi Flexor accessorius (quadratus plantae)
Great toe extension	Extensor hallucis longus	Flexor hallucis longus Flexor hallucis brevis Abductor hallucis

3. CLINICAL PRESENTATION

3.1. Referred Pain Pattern

With the possible exception of the dorsal and plantar interosseous muscles, the intrinsic muscles of the foot do not refer pain proximally to the foot.²⁰ Although referral patterns for many muscles of the body have been studied extensively, very few published reports exist that document the referred pain patterns of the intrinsic foot muscles. Much of what does exist comes from the original work of Janet G. Travell, MD and David G. Simons, MD.

Plantar Muscles

First Layer

The abductor hallucis muscle refers pain primarily to the medial aspect of the heel, with some extension to the posteromedial heel and along the medial longitudinal arch²⁰ (Figure

70-4). The abductor digit minimi muscle refers pain to the plantar aspect of the 5th metatarsal head, occasionally extending onto the lateral aspect of the distal forefoot²⁰ (Figure 70-5A). The flexor digitorum brevis muscle refers pain to the plantar surface of the foot over the 2nd to 4th metatarsal heads. It can sometimes refer pain to the 5th metatarsal head as well²⁰ (Figure 70-5B).

Figure 70-4. Referred pain patterns (red), in the right abductor hallucis muscle (shown in dark red). Solid red shows essential referred pain zones; stippled red areas show spillover zones.

Second Layer

The flexor accessorius (quadratus plantae) muscle tends to refer pain to the plantar aspect of the heel²⁰ (Figure 70-6). A referred pain pattern for the lumbrical muscles has not been well established but is believed to follow a pattern similar to that of the interosseous muscles (see Figure 70-8).²⁰

Third Layer

The flexor hallucis brevis muscle refers pain to the plantar and medial aspects of the 1st

metatarsal head. It can occasionally extend to all of the great toe and part of the second toe²⁰ (Figure 70-7B). Good reported that the flexor hallucis brevis muscle (along with some contribution from the flexor digitorum brevis muscle) was found to be responsible for more than half of the 100 cases of patients with painful feet due to muscle-related pain.²¹ The adductor hallucis muscle refers pain to the plantar aspect of the 1st through 4th metatarsal heads, with the transverse head sometimes causing a sensation of numbness and/or swelling over the same region²⁰ (Figure 70-7A). A referred pain pattern for the flexor digiti minimi brevis muscle has not been well established but is believed to follow a pattern similar to that of the abductor digiti minimi muscle (see Figure 70-5A).²⁰

Figure 70-5. A, Referred pain pattern (red) in the right abductor digit minimi muscle (shown in light red). B, Referred pain pattern (red) in the right flexor digitorum brevis muscle (shown in dark red). Solid red shows essential referred pain zones; stippled red areas show spillover zones.

Figure 70-6. Referred pain pattern (red) in the right flexor accessorius (quadratus plantae) muscle. Solid red shows essential referred pain zones; stippled red areas show spillover zones.

Figure 70-7. A, Referred pain patterns in the oblique and transverse heads of the right adductor hallucis muscle. B, Referred patterns in the flexor hallucis brevis muscle. Solid red shows essential referred pain zones; stippled red areas show spillover zones.

Fourth Layer

The dorsal and plantar interosseous muscles are believed to produce similar pain referral patterns.²⁰ Typically, TrPs in an interosseous muscle refer pain primarily to the side of the digit to which the tendon is attached, along with referral to the dorsal and plantar aspects of the foot along the corresponding metatarsal²⁰ (Figure 70-8). The first dorsal interosseous muscle can sometimes produce tingling in the great toe.²⁰ Kellgren discovered potential pain referral of the interosseous muscles into the lateral ankle and calf.²²

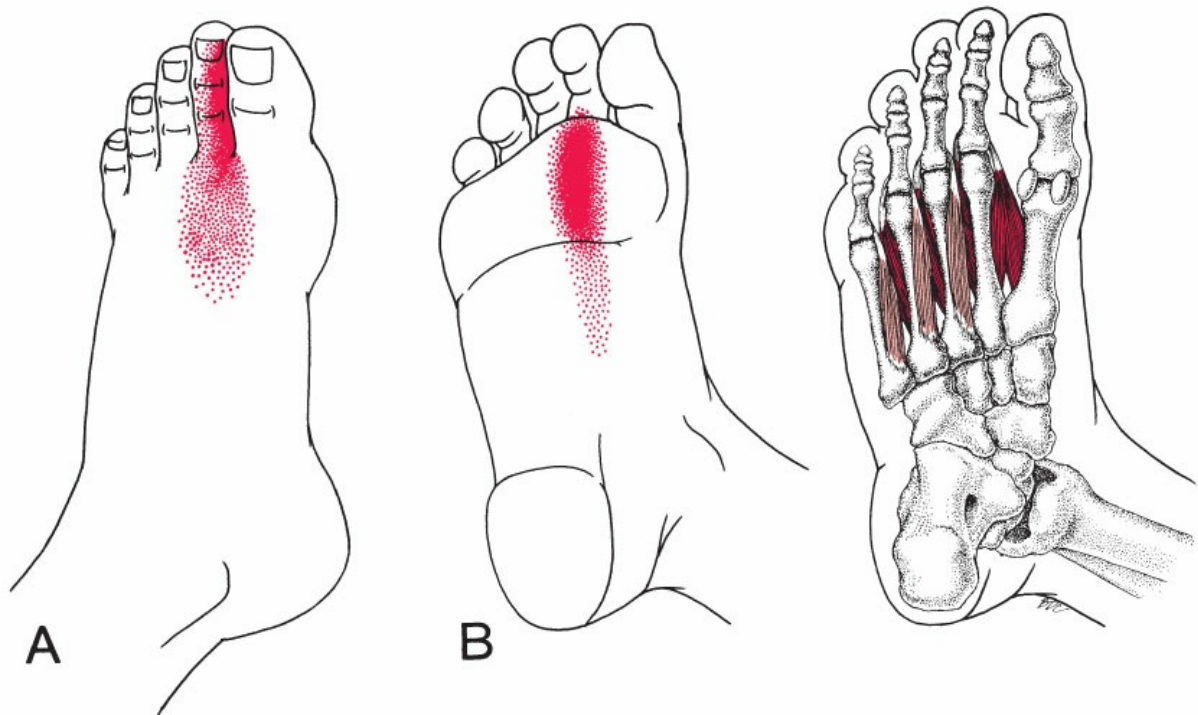

Figure 70-8. Referred pain pattern in the right first dorsal interosseous muscle. A, Dorsal view. B, Plantar view. Solid red shows essential referred pain zones; stippled red areas show spillover zones.

Dorsal Muscles

The combined referred pain pattern of the extensor digitorum brevis and extensor hallucis brevis muscles is to the dorsal aspect of the midfoot²⁰ (Figure 70-9). The extensor digitorum brevis muscle can also refer pain to the area over the medial longitudinal arch.²³

Figure 70-9. Referred pain patterns in the right extensor digitorum brevis and extensor hallucis brevis muscles. Solid red shows essential referred pain zones; stippled red areas show spillover zones.

3.2. Symptoms

Patients with TrPs in the abductor hallucis brevis, flexor digitorum brevis, and abductor digiti minimi muscles often report having very sore feet.²⁰ Typically, they have experimented with a variety of different shoe types and shoe inserts. Inserts are often uncomfortable because they press against the areas of muscle pain. Some of these patients may also report having “fallen arches” or “flat feet.” They may have a limited range of ambulation, and they might even exhibit a limp due to pain and soreness in their feet.

In addition to the symptoms described previously, patients with TrPs in the muscles of the deeper layers of the foot may have significant walking limitations resulting from pain. They may report numbness in the foot and a sensation of swelling. Some patients even report the feeling of a “bunched-up” sock under the foot causing them to check inside their shoe. Trigger points in the interosseous muscles may also contribute to a hammer toe deformity as their function to extend the proximal and distal interphalangeal joints may be inhibited.

3.3. Patient Examination

After a thorough subjective examination, the clinician should make a detailed drawing representing the pain pattern that the patient has described. This depiction will assist in planning the physical examination and can be useful in monitoring the progression of the patient as symptoms improve or change. The type, quality, and location of the pain should be carefully assessed, and the utilization of standardized outcome tools is imperative when examining patients with ankle and foot dysfunctions.

For proper examination of the ankle, foot, and intrinsic foot muscles, the clinician should observe the patient during ambulation, both with and without shoes. The clinician should note any sign of excessive supination or pronation. A patient with TrPs in the deeper muscles of the forefoot may be unable to hop on the involved foot.

Passive range of motion should be examined in the foot and all of the toes as TrPs often painfully restrict range of motion when the involved muscle is stretched. If pain limits flexion of the great toe and/or the lesser toes, the extensor hallucis brevis and/or extensor digitorum brevis muscle(s) may be adaptively shortened or as a result of TrPs in these muscles.²⁴ If pain limits passive extension of the 5th digit, the abductor digiti minimi muscle may be shortened due to TrPs. Painful limitation of passive extension of digits 2 to 4 may be the result of adaptive shortening of the flexor digitorum brevis muscle or as a result of the presence of TrPs.²⁴ Similar findings with passive extension of the great toe at the proximal phalanx may implicate the flexor hallucis brevis and/or abductor hallucis brevis muscle(s).²⁴

Palpation is important to help establish whether the pain is potentially referred from TrPs or joint structures in the foot. Because chronic TrPs can result in pain at the attachment sites of a muscle, patients with TrPs in the intrinsic toe flexor muscles are likely to be tender to palpation at the anterior aspect of the calcaneus where the plantar fascia attaches.

Joint mobility, including accessory motions, of the ankle, hindfoot, midfoot, forefoot, and phalanges should be examined for restriction or for hypermobility. Careful biomechanical examination should be performed for structural deviations such as hindfoot varus/valgus, forefoot varus/valgus, pes equinus, long 2nd metatarsal, pes cavus, hallux valgus, and hammer or claw toes. The presence and thickness of calluses should be noted, and the patient's shoes should be examined for abnormal wear patterns that may indicate altered foot mechanics.

Strength of involved muscles and active contraction in the shortened position are also often limited by pain. Examination of strength of great toe metatarsophalangeal flexion is performed by stabilizing the forefoot and resisting flexion at the proximal phalanx, which tests the flexor hallucis brevis muscle and, to a degree, the abductor hallucis and adductor hallucis muscles. Strength examination of the interosseous and lumbrical muscles is performed by resisting the patient's effort to extend the interphalangeal joints of digits 2 to 5, while stabilizing the metatarsophalangeal joints with the foot in 20° to 30° of plantar flexion.^{24, 25}

The dorsalis pedis and posterior tibial pulses should be palpated to assess the status of arterial circulation. The skin and nails should be examined for lesions, and the skin of the foot should be examined for color, temperature, and edema. Patients' feet should be screened for insensation with a 5.7 Semmes Weinstein monofilament as an early indicator of diabetes mellitus.

Any patient with painful intrinsic foot muscles, especially if associated with inflammation of the 1st metatarsophalangeal joint, should be examined for gout or other arthritides.

3.4. Trigger Point Examination

Examination of TrPs of the intrinsic muscles of the foot is most easily accomplished by positioning the patient in prone, supine, or long sitting, with the patient's feet just off the end of the examination table.

Plantar Muscles

First Layer

Trigger points in the first layer of intrinsic muscles of the plantar aspect of the foot are usually examined by cross-fiber flat palpation against underlying structures. The flexor digitorum brevis muscle lies deep to the thick plantar aponeurosis, potentially requiring deeper palpation (Figure 70-10A). The abductor hallucis muscle is a remarkably thick muscle for its size. This thickness makes its deeper fibers relatively inaccessible and may require strong, deep cross-fiber flat palpation rather than gentler cross-fiber flat palpation to elicit pain from deeper TrPs (Figure 70-10B). Typically, the abductor digiti minimi muscle is most effectively examined through cross-fiber pincer palpation along the length of the muscle at the lateral edge of the sole of the foot (Figure 70-10C). The clinician should explore both distal to, and proximal to, the base of the 5th metatarsal for taut bands and TrP pain.

Figure 70-10. Palpation of the first layer of plantar foot muscles. A, Cross-fiber flat palpation of the flexor digitorum brevis muscle. B, Cross-fiber flat palpation of the abductor hallucis muscle. C, Cross-fiber pincer palpation of the abductor digiti minimi muscle.

Second Layer

Deep palpation must be utilized to examine the flexor accessories (quadratus plantae) muscle for TrPs. The clinician must apply enough pressure to palpate deep to the plantar aponeurosis, with the toes slightly extended (Figure 70-11A). Local areas of pain are often detectable, but the clinician will likely not feel a taut band in this muscle. The lumbrical muscles are palpated with the interosseous muscles (Figure 70-11B).

Figure 70-11. Palpation of the second layer of plantar foot muscles. A, Cross-fiber flat palpation of the flexor accessorius muscle (quadratus plantae). B, Lumbrical muscles.

Third Layer

The flexor hallucis brevis muscle is largely covered by the plantar aponeurosis; therefore, the medial head of this muscle is best palpated by cross-fiber flat palpation through the thinner skin along the medial edge of bottom of the foot. A TrP in this head of the muscle may be palpable against the underlying 1st metatarsal. Trigger points in the lateral head must be examined for pain by deep palpation through the plantar surface of the foot. The clinician must be careful not to mistake the tendon of the abductor hallucis muscle for a taut band in the flexor hallucis brevis muscle. The adductor hallucis muscle is examined by first abducting the great toe to create a stretch in the muscle. It is then palpated through the plantar aponeurosis in the distal forefoot, just proximal to the metatarsal heads. Taut bands are rarely palpable, but pain can be elicited (Figure 70-12B and C). The flexor digiti minimi brevis muscle can rarely be differentiated from the abductor digiti minimi muscle and is palpated at the same time using the same technique (Figure 70-10C).

Fourth Layer

The dorsal and plantar interosseous muscles are palpated using both hands to gently separate adjacent metatarsals and apply a stretch to the muscles. The dorsal interosseous muscles are palpated with the finger of one hand and counter pressure to the plantar surface

of the foot with a finger of the other hand (Figure 70-12D). Pain in the plantar interosseous and lumbrical muscles can be elicited by deep palpation through the plantar aponeurosis against counter pressure to the dorsal aspect of the foot (Figure 70-12E). It is usually possible to palpate taut bands of TrPs in a dorsal interosseous muscle against its adjacent metatarsal bone, eliciting a local twitch response. One cannot differentiate between palpation of the lumbrical and plantar interosseous muscles through the plantar aponeurosis.

Figure 70-12. Cross-fiber flat palpation of the third layer of plantar foot muscles. A, Flexor hallucis brevis muscle. B, Adductor hallucis muscle. C, Adductor hallucis muscle (transverse head). D, Dorsal interosseous muscles. E, Plantar interosseous muscles.

Dorsal Muscles

The extensor digitorum brevis and extensor hallucis brevis muscles are palpated on the dorsal aspect of the foot using flat palpation, but the overlying tendons of extrinsic foot muscles can sometimes complicate the examination (Figure 70-13).

Figure 70-13. Cross-fiber flat palpation of dorsal intrinsic foot muscles. A, Extensor digitorum brevis muscle. B, Extensor hallucis brevis muscle.

4. DIFFERENTIAL DIAGNOSIS

4.1. Activation and Perpetuation of Trigger Points

A posture or activity that activates a TrP, if not corrected, can also perpetuate it. In any part of the intrinsic foot muscles, TrPs may be activated by unaccustomed eccentric loading, eccentric exercise in an unconditioned muscle, or maximal or submaximal concentric loading.²⁶ Trigger points may also be activated or aggravated when the muscle is placed in a shortened and/or lengthened position for an extended period of time.

Tight-fitting shoes and shoes with an inflexible sole can restrict toe movement, which can lead to overload of the intrinsic foot muscles and activate TrPs in them. Once activated, the continued use of restrictive footwear perpetuates the TrPs. A similar pattern can occur following a fracture of the foot or ankle bones, especially when prolonged immobilization is involved. Trigger points in the interosseous muscles are more likely to be activated and perpetuated by footwear that is too short (see Chapter 77).

Injuries to the foot intrinsic muscles in the form of trauma, such as bruising, banging, stubbing the toes, and falling, can initiate TrPs in them. Although pronation of the foot during the early stance phase of gait is normal, excessive pronation can activate and perpetuate TrPs in the intrinsic foot muscles if not corrected. Patients with a Morton foot structure or other structural causes of excessive pronation, for instance, may develop TrPs in the abductor digiti minimi and abductor hallucis muscles.

Impaired mobility of the joints of the foot, in the form of either hypermobility or hypomobility, can perpetuate TrPs of the intrinsic foot muscles that cross the involved joints. Hypomobility in the 2nd, 3rd, and 4th tarsometatarsal joints is a common potential source of TrP activation and perpetuation in the foot intrinsic muscles.²⁷

Additional examples of activities that can perpetuate TrPs in the intrinsic foot muscles include walking or running in soft sand, over uneven terrain, or on sloped surfaces, as well as sitting in a wheeled office chair on a slippery surface, requiring one to overload the toe flexors by repeatedly pulling the chair close to the desk with one's feet.

4.2. Associated Trigger Points

Associated TrPs can develop in the referred pain areas caused by primary TrPs.²⁸ Therefore, musculature in the referred pain areas for each muscle should also be considered.

Trigger points in the extensor digitorum brevis and extensor hallucis brevis muscles are typically associated with TrPs in the corresponding long toe extensor muscles. Trigger points in the abductor hallucis muscle tend to coincide with those in the nearby deep intrinsic muscles, resulting in soreness throughout the entire foot, particularly the distal plantar surface. Similarly, flexor digitorum brevis TrPs are often associated with those in the long toe flexor muscles and, occasionally, with the deeper flexor hallucis brevis muscle. Conversely, the abductor digiti minimi muscle tends to appear as a single-muscle syndrome, usually as the result of ill-fitting shoes. The interosseous muscles are another example of muscles that present as single-muscle myofascial pain syndrome.

4.3. Associated Pathology

Several conditions exist that can potentially mimic the pain associated with TrPs in the intrinsic muscles of the foot or that can lead to and/or exacerbate TrPs in those muscles.

Plantar heel pain is a rather common source of pain, with a prevalence rate estimated at 3.6% to 7.5%.^{29–31} Plantar heel pain primarily affects middle-age and older adults³⁰ and is believed to account for roughly 8% of running-related injuries.³²

There are several factors and mechanisms believed to contribute to plantar heel pain, including reduced ankle dorsiflexion range of motion, obesity, and prolonged standing.^{33,34} There is some evidence that TrPs can also be involved in plantar heel pain. Trigger points have been found to be prevalent in some intrinsic muscles of the foot in patients with plantar heel pain, including the abductor hallucis and flexor digitorum brevis muscles.³⁵ Furthermore, two intrinsic foot muscles, the abductor hallucis and flexor accessorius (quadratus plantae) muscles, have referred pain patterns at and around the plantar aspect of the heel.²⁰

An additional cause of plantar heel pain is entrapment of the first branch of the lateral plantar nerve, also known as Baxter nerve or the inferior calcaneal nerve.^{36,37} Entrapment of this nerve can occur as it passes between the abductor hallucis muscle and the medial border of the flexor accessorius (quadratus plantae) muscle,³⁸ potentially resulting in plantar heel pain, paresthesia, and even weakness and atrophy of the abductor digiti minimi muscle.^{37,39}

Structural issues or injuries in the foot can often lead to pain that can potentially mimic pain associated with TrPs. Pain in the great toe such as that seen with bunion and sesamoiditis is consistent with the referred pain pattern of the flexor hallucis brevis muscle. Turf-toe, an injury of the 1st metatarsal phalangeal joint resulting from hyperextension of the joint, can result in pain that is consistent with TrPs in the first dorsal interosseous muscle⁴⁰ as well as the flexor hallucis brevis muscle. Metatarsalgia shares pain symptoms consistent with TrPs in the flexor digitorum brevis muscle.

Certain conditions, such as pes planus or navicular drop as seen with tibialis posterior dysfunction, may or may not result in pain, but are typically associated with dysfunction of several muscles in the foot and ankle, including intrinsic foot muscles. Dysfunction in these muscles that support the medial longitudinal arch could result in overuse injuries related to excessive pronation⁸ such as plantar fasciitis,⁴¹ hallux valgus,⁴² medial tibial stress syndrome,⁴³ tibialis posterior tendinopathy,⁴⁴ achilles tendonitis,⁴⁵ and patellofemoral pain syndrome.⁴⁶ Intrinsic foot muscles involved in supporting the medial longitudinal arch include the abductor hallucis, flexor hallucis brevis, flexor digitorum brevis, abductor digiti minimi, and the interosseous muscles.⁹

5. CORRECTIVE ACTIONS

Patients experiencing plantar foot pain as a result of TrPs in the intrinsic muscles of the foot can take several actions to try to address their symptoms. Because TrPs can cause a shortening of involved muscles, care should be taken to discourage positions that promote a shortened position of these muscles. When sleeping, patients should be sure to untuck the bedsheets from the foot of the bed to help minimize the foot and ankle plantar flexion positioning caused by tight bedding (see Figure 65-6).

Patients should be sure to select footwear that is appropriate. There should be plenty of room in the front, or toe box, of the shoe. For plantar pain related to TrPs, it is important to have room for the toes to move up and down within the shoe. For great toe and 1st metatarsal pain related to TrPs, it is also important that there is at least some room for the toes to move from side to side. Shoes should have a flexible sole and should be well cushioned. Patients with TrP-related pain should avoid shoes with heels and/or pointed toes as much as possible (see Chapter 77).

Various products are available at relatively low cost that may prove beneficial for certain conditions. Off-the-shelf shoe orthoses with arch support can sometimes be helpful for patients with TrP-related plantar pain by reducing stress on involved muscles. For patients with TrPs in the adductor hallucis muscle related to a bunion deformity, a toe spacer may be beneficial to prevent shortening of the muscle and perpetuation of the TrP (Figure 70-14). Metatarsal pads may be helpful for patients with forefoot plantar pain related to TrPs.

Figure 70-14. Toe spacer for trigger points in the adductor hallucis muscle related to a bunion.

There are exercises and soft-tissue mobilization techniques that patients with plantar foot pain related to TrPs in the intrinsic foot muscles can try. Stretching of the gastrocnemius and soleus muscles of the calf can increase the amount of ankle dorsiflexion and thereby lessen the stress applied to the involved muscles during walking and running. There are multiple methods to perform this stretch (see Figures 65-8 and 66-11).

Extending the great toe in order to put a stretch on the plantar fascia and the flexor hallucis brevis muscle can be helpful as well. Combining this stretch while performing a deep stroking massage of the plantar fascia and short toe flexors can be even more beneficial (Figure 70-15A). Other self-pressure release techniques include placing a golf ball under the foot and applying as much body weight through the lower extremity as tolerated while rolling the ball over tender areas in the intrinsic muscles on the plantar aspect of the foot. A modification of this technique involves filling a textured soda bottle and freezing it. The patient then rolls the bottle under the foot (Figure 70-15B). The texture and contour of the bottle address the TrPs in much the same way as the golf ball technique, and the ice can help ease the patient's discomfort. Additional techniques can be performed in standing to stretch the plantar foot intrinsic muscles (Figure 70-16A) and the plantar fascia (Figure 70-16B).

Figure 70-16. Self-stretch of foot intrinsic muscles and plantar fascia. A, Toe flexors. B, Plantar fascia.

Specific exercises that have been shown to strengthen several of the intrinsic foot muscles exist. The short-foot exercise is performed by trying to accentuate the arch of the foot while the foot is on the ground but without flexing the toes⁴⁷ (Figure 70-17A). This exercise is effective for targeting the abductor hallucis, flexor accessorius (quadratus plantae), and abductor digiti minimi muscles.^{47,48} The first-toe extension exercise is performed by extending the great toe, while keeping all remaining toes in contact with the ground⁴⁷ (Figure 70-17B). This exercise targets the flexor digitorum brevis muscle as it works to keep toes two through five on the ground, while the great toe extends.⁴⁷ The second-to-fifth-toe extension exercise targets the abductor digiti minimi, flexor hallucis brevis, and adductor hallucis muscles and is performed by extending the second through fifth toes, while keeping the great toe in contact with the ground⁴⁷ (Figure 70-17C). The toes-spread-out exercise is effective for targeting the abductor hallucis, interosseous, lumbrical, and adductor digiti minimi muscles.^{47,49} This exercise is performed by first extending all toes and then abducting all toes while simultaneously flexing the first and fifth toes and maintaining extension of the second through fourth toes⁴⁷ (Figure 70-17D).

Figure 70-17. Exercises to strengthen the intrinsic muscles of the foot. A, Short-foot exercise. B, First-toe extension exercise. C, Second-to-fifth-toe extension exercise. D, Toes-spread-out exercise. E, Towel scrunches.

Another exercise commonly performed to try to strengthen the intrinsic foot muscles is toe curling. This exercise can be performed using a variety of techniques, including picking up marbles with the toes and grasping a towel with the toes in an effort to “scrunch” the towel (Figure 70-17E).

Clinical Considerations of Leg, Ankle, and Foot Pain

Jeffrey Gervais Ebert, Stella Fuensalida-Novos, and César Fernández De Las Peñas

1. ANKLE SPRAIN—ANKLE INSTABILITY

1.1. Overview

Ankle sprains represent one of the most common lesions of the leg. Doherty et al¹ found a higher incidence of ankle sprains in women than in men, and in children and adolescents than in adults. The sport category with the highest incidence of ankle sprain was indoor/court sports, and lateral ankle sprain was much more prevalent than medial ankle sprain.¹ Acute ankle sprains are often described according to the severity of the injury and classified as grade I, II, or III depending on the extent and severity of ligament damage (grade I is the least involved and grade III the most severe type of injury).² Conservative management is the initial treatment option for ankle sprains; however, the most appropriate treatment strategy is unclear. A recent meta-analysis revealed significant immediate benefits of joint mobilization for improving dynamic balance and weight-bearing ankle dorsiflexion range of motion in patients with ankle sprains; however, long-term effects are still unknown.³ Another recent meta-analysis found strong evidence for nonsteroidal anti-inflammatory drugs (NSAIDs) and early mobilization and moderate evidence for exercise and manual therapies for improving pain and function in acute ankle sprain.⁴

It should be considered that ankle sprains may be a self-limited condition in around 50% of individuals; however, when symptoms continue after an ankle injury, mostly associated with lateral ankle sprains, patients are commonly diagnosed as having ankle instability. Chronic ankle instability has been defined as the presence of persistent postacute symptoms such as occasional swelling, impaired strength, instability, and impaired balance responses for greater than 6 months following the initial ankle injury.⁵ Doherty et al⁶ identified an inability to complete jumping and landing tasks within 2 weeks of a first-time lateral ankle sprain, poorer dynamic postural control, and lower self-reported function 6 months after a first-time lateral ankle sprain as being predictive of eventual chronic ankle

instability. Functional ankle instability can be defined as recurrent ankle sprains or ongoing sensations of the ankle giving way with normal ankle motion and the absence of objective joint laxity. Some studies have reported that manual therapy, including joint mobilization techniques, is effective for the management of ankle instability⁷⁻⁹; however, the quality of these studies is low.¹⁰

It seems that neuromuscular/proprioceptive interventions are the most appropriate for the treatment of ankle instability,¹¹ which suggests that the targeted structure for the management of ankle instability is the musculature. In fact, factors that contribute to functional ankle instability include muscle weakness, impaired muscle recruitment patterns, reduced ankle range of motion, balance deficits, and impaired joint proprioception. There is evidence demonstrating that subjects with ankle instability exhibit delayed fibularis muscle reaction time when compared with the contralateral uninvolved limb or a healthy control group.¹² These findings support a potential role of trigger points (TrPs) in the leg musculature in patients with ankle sprain or functional ankle instability.

1.2. Initial Evaluation of a Patient With Ankle Sprain

Initial examination of a patient with an ankle sprain starts with assessment of the injury mechanism because it can assist in determining the likelihood of the presence of a fracture. The Ottawa Ankle Rules were developed in 1992 to reduce the frequency of radiographic imaging following ankle sprain. These rules dictate that in the presence of a traumatic injury to the ankle, there is a need for an ankle radiographic series if a patient exhibits the following: (1) tenderness at the posterior edge or tip of the lateral malleolus, (2) tenderness at the posterior edge or tip of the medial malleolus, and/or (3) inability to bear weight both immediately postinjury and in the emergency room for four steps (including limping).¹³

Pain distribution or the presence of paresthesias can help differentiate comorbid conditions such as osteochondritis dissecans of the subtalar joint or ankle anterior impingement. Clinical examination of the ankle and foot should include palpation of the ligaments of the ankle and foot, passive and active ankle range of motion in both nonweight- and weight-bearing positions, assessment of passive physiologic movements of the ankle and foot joints, and specific orthopedic special tests. For instance, the anterior drawer test can be used for assessing the integrity of the anterior inferior tibiofibular ligament,¹⁴ whereas the medial talar tilt test can be used to assess the amount of talar inversion occurring within the ankle mortise, testing the integrity of the calcaneofibular ligament.¹⁵ Trigger points in the fibularis longus or fibularis brevis, tibialis anterior, gastrocnemius, and soleus muscles can be related to symptoms associated with ankle sprains or ankle instability. Finally, it is important to evaluate the stability of the entire lower extremity with functional tests such as single limb balance or the Star Excursion Balance Test.¹⁶

1.3. Trigger Points and Ankle Sprain

Trigger points in the fibularis muscles can refer pain to the lateral aspect of the ankle,

mimicking the symptoms experienced after an ankle sprain.¹⁷ Additionally, TrPs in these muscles could contribute to motor disturbances and delayed activation in the fibularis muscles found in individuals with functional ankle instability. Nevertheless, there are no epidemiologic studies published on this topic. Salom-Moreno et al¹⁸ found that subjects with functional ankle instability who received TrP dry needling into the fibularis longus muscle before application of a proprioceptive and strengthening exercise program exhibited better improvements in pain and function than those receiving proprioceptive and strengthening exercise program in isolation. The greatest benefits found with application of dry needling were in functional outcomes, supporting the hypothesis that TrPs in the fibularis muscles could be related to motor disturbances observed in these patients.¹⁸

2. TIBIALIS POSTERIOR TENDON DYSFUNCTION

2.1. Overview

The tibialis posterior muscle is one of the dynamic stabilizers active during the late midstance and push-off phases of gait.¹⁹ Therefore, tibialis posterior tendon dysfunction, also known as tibialis posterior tendinopathy, involves the progressive loss of this stabilization function. Although this condition can be present at any age, it is commonly seen in middle-aged women who are overweight.²⁰ It also tends to affect the athletic population, particularly runners and those involved in sports that require rapid changes in direction, such as basketball or soccer.²¹ The etiology of this syndrome includes inflammatory, degenerative, functional, and traumatic processes often secondary to systemic inflammatory diseases. Tibialis posterior tendon dysfunction secondary to chronic overuse and subsequent tendon degeneration occurs more frequently in late middle-aged women.²¹ Tibialis posterior tendon dysfunction has been described using a four-stage classification system ranging from mild signs and symptoms consistent with tendinopathy to a fixed hindfoot valgus deformity.^{22–24}

There is no agreement regarding the efficacy of conservative treatment approaches for tibialis posterior tendinopathy.²⁵ General recommendations include relative rest, pain medication, physical therapy, and walking cast or ankle foot orthosis in stage I, referral to an orthopedic surgeon in stage II, or surgical repair in stage III or IV.^{26,27} Exercises to strengthen the weakened tibialis posterior musculotendinous complex, albeit in the presence of painful tendon dysfunction, are strongly recommended.²⁷

2.2. Initial Evaluation of a Patient With Tibialis Posterior Tendon Dysfunction

In stage I, patients with tibialis posterior tendon dysfunction may report mild pain over the medial aspect of the ankle and along the path of the posterior tibialis tendon that is aggravated by activity. Physical examination reveals tenderness and possible swelling over the course of the tendon. Tendon length is typically normal.²⁸ In this stage, pathologic examination of the tendon reveals tenosynovial proliferation.²⁹ Additional findings may include normal foot and ankle alignment and mild weakness on a single-leg heel raise test.

No bony structural changes are expected on radiographic images.²⁸

In stage II, pain is moderate and typically becomes more debilitating, and swelling and tenderness with palpation are more pronounced. The posterior tibial tendon is lengthened, resulting in a pes planus deformity.²⁸ Pathologic examination indicates degenerative changes with longitudinal tears within the tendon.²⁹ There is significant weakness with a single-leg heel raise test, and there is a visible, yet mobile, valgus deformity of the hindfoot. The “too many toes” sign (sensitivity 65%-80%) is evident. Radiographs reveal forefoot abduction relative to the hindfoot, and a talonavicular subluxation is likely present.²⁸

In stages III and IV, the pain can become severe and may present over the lateral aspect of the ankle in addition to the medial aspect. There is pronounced lengthening and disruption of the tendon. Physical examination often reveals less swelling, but the deformity is more severe.²⁸ Pathologic examination indicates tendon disruption with visible tearing.²⁹ There is significant pain and weakness with a single-leg heel raise test. The hindfoot valgus and forefoot abduction deformities are now typically fixed, and the “too many toes” sign is still evident. Radiographs reveal the same changes seen in stage II along with degenerative changes in the subtalar, talonavicular, and calcaneocuboid joints.²⁸ Deltoid ligament insufficiency resulting in a lateral talar tilt indicates the progression to stage IV.²³ The 1st-metatarsal rise test, which has demonstrated excellent sensitivity, can also be used in the examination.

Examination of a patient with tibialis posterior tendon dysfunction, independent of the stage, should include postural analysis of gait behaviors and an exhaustive clinical evaluation of the lower extremity. Passive and active range of motion of the foot, ankle, knee, and hip, with or without overpressure should be included. Because the tibialis posterior tendon runs closer to the tibialis posterior nerve in the tarsal tunnel, a differential diagnosis with a potential neuropathy should include neurodynamic test of this nerve.³⁰ All musculature of the lower extremity should be palpated for the presence of TrPs, especially the tibialis posterior, tibialis anterior, gastrocnemius, and soleus muscles.

2.3. Trigger Points in Tibialis Posterior Tendon Dysfunction

Examination for the presence of TrPs is important with a potential diagnosis of tibialis posterior tendon dysfunction. There are several muscles whose TrPs refer pain to the medial ankle region, where tibialis posterior tendon dysfunction symptoms are most prevalent. Trigger points in the flexor digitorum longus muscle can refer pain to the medial aspect of the ankle.¹⁷ Abductor hallucis TrPs can also result in pain in the same region.¹⁷ Therefore, it is important to look for TrPs in these muscles as alternate sources of, or as contributors to, tibialis posterior tendon dysfunction pain.

Trigger points in the tibialis posterior muscle can, on occasion, refer pain symptoms along the course of its own tendon¹⁷; however, it is more likely a contributor to the development of tibialis posterior tendon dysfunction. The presence of TrPs in the tibialis posterior muscle can lead to medial arch collapse because of impaired function of the muscle.^{17, 31, 32}

3. TARSAL TUNNEL SYNDROME

3.1. Overview

Tarsal tunnel syndrome is an entrapment neuropathy of the posterior tibial nerve and/or one or more of its associated terminal branches, including the medial plantar, lateral plantar, and calcaneal nerves.^{33,34} The tarsal tunnel runs deep to the fascia and the flexor retinaculum, and within the abductor hallucis muscle, a nerve entrapment can occur at any of these points along the tunnel.³⁵ A particular cause of tarsal tunnel syndrome can be identified in 60% to 80% of cases, with the remaining ones being idiopathic.^{36,37}

Intrinsic factors that can cause tarsal tunnel syndrome include osteophytes, hypertrophic retinaculum tendinopathy, hypertrophy of the extensor hallucis brevis muscle, lipoma, ganglion cysts, venous varicosities, pseudoaneurysms,^{34,38} tumors, accessory muscles,^{39,40} and other space-occupying lesions. In addition, the fascial septa and the flexor retinaculum themselves have been identified as sources of entrapment.⁴¹ Entrapment of the lateral plantar nerve as it passes through the abductor hallucis muscle⁴² or between the abductor hallucis and flexor accessorius (quadratus plantae) muscles can result in plantar heel pain⁴³ and is often associated with, or mistaken for, plantar fasciitis.^{44,45} In fact, tarsal tunnel syndrome has also been associated with an accessory soleus⁴⁶ or flexor digitorum longus⁴⁷ muscle.

Extrinsic factors can include trauma, tight-fitting shoes, hindfoot varus or valgus, lower extremity edema, systemic inflammatory arthropathy, mucopolysaccharidoses, and diabetes.³⁴ The incidence of tarsal tunnel syndrome is unknown but is believed to occur primarily in adults and affects women more than men.^{48–50} Tarsal tunnel syndrome is a relatively rare condition with a variable presentation and symptom severity depending on the specific nerve(s) involved,⁵¹ and consequently, it can often be misdiagnosed if a clinician does not consider it a likely diagnosis.^{52,53}

3.2. Initial Evaluation of a Patient With Tarsal Tunnel Syndrome

Although specific symptoms of an entrapment neuropathy will vary based on the nerve(s) involved, patients with tarsal tunnel syndrome will typically report burning, tingling, and pain along the plantar aspect of the foot. Occasionally, pain can extend proximally to the medial aspect or midcalf region of the leg.^{54,55} Sensory changes are limited to the distribution of the terminal branches of the posterior tibial nerve. As a result, the dorsal aspect of the foot is not usually involved. Symptoms tend to worsen with walking, prolonged standing, or wearing high-heeled shoes, and patients will often report that their symptoms are worst at night. Symptoms are typically unilateral, so in patients with bilateral symptoms, underlying systemic illness and polyneuropathy should be ruled out.⁵⁴ Symptoms are often alleviated by rest and elevation of the leg.⁵⁶

Palpation and visual inspection should be utilized to locate soft-tissue masses on the tibial nerve course, varicosities, or hindfoot misalignment.⁵⁷ In severe or chronic cases,

muscles innervated by the tibial nerve, distal to the site of entrapment, may show atrophy and motor deficit, although these manifestations rarely interfere with function.^{52,57}

Patients may demonstrate a positive Tinel sign.⁵⁶ Neural tension with selective targeting of the tibial nerve can reproduce symptoms by positioning the foot and ankle in a combination of dorsiflexion and eversion.^{30,58–60}

Nerve conduction testing and electromyography (EMG) can be helpful in diagnosing tarsal tunnel syndrome^{61,62}; however, nerve conduction studies for this condition have a high false-negative rate, whereas EMG has been shown to have a high false-positive rate.⁶¹ Therefore, negative nerve conduction studies do not necessarily rule out a diagnosis of tarsal tunnel syndrome.^{37,56,62} Pain and paresthesia in the foot, a positive Tinel sign, and positive electrodiagnostic studies are considered strong indicators for the presence of tarsal tunnel syndrome when all three are present.^{63,64}

Clinicians should inquire about the presence of low back pain to help rule out a lumbar spine condition as a source of the patient's foot and ankle symptoms. Reflex testing and determining the distribution of sensory and motor deficits are essential in making a differential diagnosis.⁶⁵

Similarly to evaluating a patient with tibialis posterior tendon dysfunction, clinical examination of a patient with tarsal tunnel syndrome should include postural analysis of gait behaviors and an exhaustive clinical evaluation of the lower extremity. Passive and active range of motion of the foot, ankle, knee, and hip, with or without overpressure, should be included. Musculature of the leg and foot related to the tibial nerve, such as the tibialis posterior, gastrocnemius, soleus, abductor hallucis, flexor accessories (quadratus plantae) muscles, should be examined for the presence of TrPs.

3.3. Trigger Points in Tarsal Tunnel Syndrome

There is no epidemiologic study on tarsal tunnel syndrome and the presence of TrPs. Trigger point referral patterns themselves are not always implicated by the burning and tingling symptoms often reported by patients with tarsal tunnel syndrome.¹⁷ However, TrPs in the abductor hallucis muscle could mimic or contribute to the painful symptoms associated with a particular form of tarsal tunnel syndrome. Trigger points in the abductor hallucis muscle can contribute to shortening of the muscle and increase the likelihood of entrapment of the lateral plantar nerve as it passes through the abductor hallucis muscle or between abductor hallucis and flexor accessorius (quadratus plantae) muscles, potentially resulting in pain and paresthesias.⁴⁵ Trigger points in the tibialis posterior or soleus muscles could also contribute to potential entrapment of the tibial nerve through its course in the lower extremity.

4. PLANTAR HEEL PAIN OR PLANTAR FASCIITIS

4.1. Overview

Plantar fasciitis, also referred to as plantar fasciosis or plantar heel pain, consists of a sharp

pain at the insertion of the plantar fascia at the medial tuberosity of the calcaneus and along the medial border of the plantar fascia. Previously believed to involve inflammation of the plantar fascia aponeurosis, current evidence indicates that this condition is the result of microscopic degeneration of collagen with subsequent thickening of the plantar fascia caused by chronic overload.^{66–69} Pathologic changes within the foot intrinsic musculature, that is, atrophy of the abductor digiti minimi muscle⁷⁰ or forefoot intrinsic muscles,⁷¹ have also been reported in people with plantar heel pain.

Plantar heel pain affects 10% of the population at some point in their lifetime.⁷² It is the most common foot condition seen by healthcare practitioners⁷² and tends to affect middle-aged people who are sedentary. It is also commonly seen in people who engage in activities such as running and dancing that require significant ankle plantar flexion and metatarsophalangeal joint extension.⁷³ Several factors have been identified that put patients at greater risk for developing plantar heel pain. These include increased body mass index, particularly in a sedentary population,^{74–76} increased age, occupations requiring prolonged standing on hard surfaces,⁷⁷ reduced ankle dorsiflexion range of motion, reduced 1st metatarsophalangeal extension range of motion, prolonged standing,⁷⁵ and tightness of the calf and hamstring muscles.⁷⁸ Weakness or atrophy of the ankle plantar flexors and toe flexor muscles has also been observed in individuals with plantar heel pain.^{71,79–81}

Management of plantar heel pain is controversial because numerous interventions are used such as strapping, stretching, foot orthoses, shoe modifications, NSAIDs, corticoid injections, education, exercise, modalities, manual therapy, weight reduction, and laser therapy.^{82,83} A recent meta-analysis has found that TrP dry needling is effective for reducing pain compared with placebo in plantar fasciitis.⁸⁴ These findings would suggest that TrPs in the foot musculature can play a relevant role in this condition.

4.2. Initial Evaluation of a Patient With Plantar Heel Pain

Patients with plantar heel pain typically present with insidious pain at the insertion of the plantar fascia on the calcaneus and often report pain along the length of the plantar fascia medially. A classic symptom of plantar fasciitis is a pronounced increase in pain with the first step after a period of inactivity.^{72,85} The onset of plantar heel pain often coincides with a change in the type and level of activity or a change in footwear. As the condition progresses, these symptoms can become more severe and can impact the patient's ability to bear weight. According to the updated clinical practice guidelines from the Academy of Orthopaedic Physical Therapy of the American Physical Therapy Association, the signs and symptoms fitting the diagnosis of plantar heel pain or plantar fasciitis include the following: medial plantar heel pain with initial steps after inactivity, increased heel pain with weight-bearing activity, pain with palpation of the calcaneal insertion of the plantar fascia, reduced ankle dorsiflexion range of motion, an abnormal foot posture index score, a high body mass index in a nonathlete, a positive windlass test, and negative tarsal tunnel tests.⁷²

Although imaging is typically not necessary for diagnosis of plantar heel pain, diagnostic ultrasound may be useful in some cases.⁷² Diagnostic ultrasound can be used to

assess the thickness of the plantar fascia. A reduction in plantar fascia thickness has been linked to a reduction in plantar heel pain.^{68, 86}

Clinical examination of a patient with plantar heel pain should include palpation of the soft-tissue structures of the ankle and foot, passive and active ankle and foot range of motion in both nonweight- and weight-bearing positions, and evaluation of accessory motion of the ankle and foot joints. Trigger points in the soleus, gastrocnemius, quadratus plantae, abductor hallucis, and flexor digitorum brevis muscles are considered relevant for the management of plantar heel pain.⁸⁷

4.3. Trigger Points and Plantar Heel Pain

Trigger points are a significant potential source of or contributor to plantar heel pain, including those of several intrinsic and extrinsic muscles of the foot.¹⁷ Trigger points in the abductor hallucis muscle refer pain at or near the plantar aspect of the heel that can mimic plantar heel pain.¹⁷ Trigger points in the abductor hallucis muscle can result in entrapment of the lateral plantar nerve, which can also result in plantar heel pain.⁴⁵ Extrinsic foot muscles, including the tibialis posterior and flexor digitorum longus muscles, can also have TrPs that mimic pain associated with plantar heel pain.¹⁷

Trigger points in the gastrocnemius muscle not only have a referral pattern that includes the plantar heel region, but they can also mimic many of the “classic” signs and symptoms of plantar fasciitis very closely. Individuals with TrPs in the gastrocnemius muscle may report sharp pain along the plantar surface of the heel with weight-bearing activities, especially with the first few steps upon waking in the morning or after a prolonged period of nonweight bearing. In fact, treatment of TrPs in the gastrocnemius muscle was effective for the management of patients with plantar heel pain.⁸⁸ Saban et al⁸⁹ found that deep massage of the calf muscles, neural mobilization exercises, and a self-stretch program were also effective for plantar fasciitis. These results support the role of muscle TrPs in this condition.

Although they are not a direct source of plantar heel pain, TrPs in muscles that support the medial longitudinal arch and/or contribute to foot stability during gait, such as the flexor digitorum brevis muscle,⁹⁰ have been shown to be prevalent with many cases of plantar heel pain.^{91, 92} Trigger points in these muscles can lead to dysfunction that results in overuse injuries related to excessive pronation, including plantar heel pain.^{92, 93} Nevertheless, TrPs in the flexor accessorius (quadratus plantae) muscle would probably be the most relevant in plantar fasciitis because taut bands in this muscle can increase tension in the plantar fascia at the calcaneal tuberosity.¹⁷

5. METATARSAL STRESS FRACTURE

5.1. Overview

Repetitive loading of bone without sufficient opportunity for the bone tissue to adapt can result in structural changes and reduced ability to withstand loading at the site(s) of

maximal stress.^{94,95} Stress fractures of the metatarsals are one of the most common overuse injuries in athletes, making up nearly 4% of all sport-related injuries.⁹⁶ Metatarsal stress fractures account for nearly 10% to 20% of all stress fractures,^{97–101} and fractures of the 2nd and 3rd metatarsals comprise as many as 90% of metatarsal stress fractures.^{96,102,103} The 2nd through 4th metatarsals are the least resistant to bending stresses but sustain the highest peak loading forces during weight-bearing activity, especially running.^{101,104} The incidence of metatarsal stress fractures in women is 1.5 to 12 times greater than that in men.^{105–111}

5.2. Initial Evaluation of a Patient With Metatarsal Stress Fracture

Patients with metatarsal stress fracture often report a dull aching pain in the forefoot with weight-bearing activity and increased pain with palpation of the involved bone. There may be swelling and erythema in the surrounding soft tissue.^{112,113} Clinicians should examine patients for structural foot abnormalities such as pes cavus or hypomobility of the first ray.^{112,114} Misdiagnosis of arthritis or tendinopathy is common, so a careful history will typically reveal recent changes in the type, duration, and/or frequency of walking or running activity without a specific traumatic event.¹¹³ Early diagnosis is important to prevent progression to a complete fracture.¹¹⁵

Radiography in the early stages of metatarsal stress fracture may not reveal pathology. It can take 3 to 6 weeks following the initial fracture before any findings will be evident on a radiograph.¹¹⁶ Early diagnosis of stress fracture is often based on magnetic resonance imaging, which is expensive.¹¹⁷ More recently, diagnostic ultrasound has shown good reliability for early diagnosis of stress fracture at a significantly lower cost.¹¹⁵

Once the fracture has been stabilized, clinical examination of the hindfoot and forefoot joint passive accessory movements, with and without overpressure, should be conducted. Further, palpation of the intrinsic foot muscles, such as the dorsal interosseous and lumbrical muscles, is also recommended.

5.3. Trigger Points and Metatarsal Stress Fracture

Trigger points can produce pain that refers to the plantar aspect of the forefoot and mimics the symptoms associated with metatarsal stress fracture. Intrinsic foot muscles associated with this pain referral pattern include the flexor digitorum brevis, flexor digitorum longus, flexor hallucis brevis, extensor digitorum brevis, abductor hallucis, abductor digiti minimi, and the interosseous muscles.¹¹⁸ Extrinsic foot muscles that can create pain at or around the metatarsal heads include the extensor hallucis longus, tibialis posterior, flexor digitorum longus, and flexor hallucis longus muscles.¹¹⁸

6. MORTON NEUROMA

6.1. Overview

Morton neuroma is a benign but painful mechanical entrapment neuropathy involving a common digital nerve in the forefoot.¹¹⁹ Its name is a misnomer as it is not a true neuroma but rather a fibrosis of the perineurium.¹²⁰ Morton neuroma most commonly occurs between the 3rd and 4th metatarsals.¹²¹ No data currently exist regarding the prevalence of Morton neuroma in the general population; however, women are affected more often than men.^{121, 122} The average age of those affected is between 45 and 50 years old.¹²² It can occur bilaterally but rarely involves more than one site within the same foot.¹²¹ Approximately one-third of people who have a Morton neuroma are asymptomatic, with the likelihood of pain increasing as the size of the fibrous tissue formation increases.¹²³

Although the exact cause of Morton neuroma is unknown, several factors have been described that may contribute to the condition. It is believed, in part, to affect women more than men because women's shoes more often have a tight-fitting toe box and/or high heels.¹²⁴ Runners and dancers are more prone to the condition because of hyperextension of the metatarsophalangeal joints and repetitive trauma to the metatarsals.¹²⁴ Age-related structural changes are believed to increase the risk of developing a Morton neuroma.^{125, 126} Biomechanical factors such as overpronation, pes cavus, and equinus deformity are often associated with the condition. It is proposed that overpronation causes forefoot instability during gait, resulting in excessive traction and strain of the plantar digital nerves.¹²⁷ Pes cavus and equinus deformity are believed to be a factor because of the increased strain on the plantar fascia and transverse intermetatarsal ligament.¹²⁸ A Cochrane review concluded that there is insufficient evidence to determine the effectiveness of either surgical or nonsurgical interventions for Morton neuroma.¹²⁹

6.2. Initial Evaluation of a Patient With Morton Neuroma

Patients with Morton neuroma often report the insidious onset of a burning pain in the ball of the foot, worsened by activity and tight footwear and relieved by rest.^{123, 130} The pain is occasionally described as dull and cramping with brief episodes of sharp pain, or it may be described as numb and tingly.¹²¹ Patients may report a sensation of having a small rock in their shoe when walking.¹³⁰

Several examination procedures can help reach a diagnosis of Morton neuroma. Reproduction of the patient's symptoms with direct pressure applied at the 3rd intermetatarsal space is indicative of the condition, especially if combined with compression of the five metatarsal heads together.¹¹⁹ If a click is elicited during compression of the metatarsal heads, this is known as Mulder sign and is also indicative of Morton neuroma.^{119, 121, 131, 132}

Although usually unnecessary, imaging in the form of magnetic resonance^{123, 131, 133} or ultrasonography^{119, 134–136} has shown good validity and reliability data for the diagnosis of Morton neuroma. Utilization of a nerve block has been advocated for diagnosis. If the block provides symptom relief, it is considered indicative of Morton neuroma.^{132, 137, 138}

Clinical examination of the hindfoot and forefoot joint passive accessory movements,

with and without overpressure, should be conducted. Further, palpation of the intrinsic foot muscles, such as the dorsal interosseous and lumbrical muscles, is also recommended.

6.3. Trigger Points and Morton Neuroma

Trigger points of several muscles can result in pain in the forefoot and metatarsal region, as in the case of pain experienced with Morton neuroma. The muscle(s) involved depend on the exact symptom location. Intrinsic foot muscles associated with this pain referral pattern are the flexor digitorum brevis, flexor digitorum longus, flexor hallucis brevis, extensor digitorum brevis, abductor hallucis, abductor digiti minimi, and the interosseous muscles.¹⁷ Extrinsic foot muscles that can create pain at or around the metatarsal heads are the extensor hallucis longus, tibialis posterior, flexor digitorum longus, and flexor hallucis longus muscles.¹⁷

7. HALLUX VALGUS

7.1. Overview

Hallux valgus, one of the most common structural deformities of the foot, is a lateral displacement of the great toe.^{139–141} It is a progressive, irreversible condition¹⁴² involving lateral, or valgus, displacement of the great toe with a medial, or varus, displacement of the 1st metatarsal.^{139, 142–144} Hallux valgus deformity also usually involves an overgrowth of bone—called exostosis—and other tissue that forms on the dorsomedial aspect of the 1st metatarsal head, commonly known as a “bunion.”^{143, 145} It is believed to affect 12% to 70% of the general population,^{140, 146, 147} with a larger prevalence in women (as much as 30%-58%) than in men.^{146, 148} It is especially prevalent in women during the third through sixth decades of life.^{139, 140}

There is no single definitive cause for hallux valgus; rather, there exist a multitude of factors involved in the development of the deformity.^{139, 142} These factors include tight or high-heeled footwear,^{139, 149} abnormalities in foot anatomy and/or foot mechanics,^{150–152} leg length discrepancy,¹³⁹ inflammatory conditions,^{153, 154} occupational demands,¹³⁹ and genetics.^{155–157}

7.2. Initial Evaluation of a Patient With Hallux Valgus

Diagnosis of hallux valgus is based largely on visual inspection, as the deformity is typically evident on observation. Patients with hallux valgus will typically report pain over the dorsomedial aspect of the 1st metatarsophalangeal joint and often present with callus formation or bunion deformity.^{139, 158} Patients may also report pain where the great toe and second toe overlap, or they may experience midfoot pain.¹⁵⁸ Additional alignment issues or structural deformities may also be observed, including pronation of the great toe, lateral shift of the sesamoid bones, medial arch collapse,^{143, 145} and leg length discrepancy.¹³⁹ Patients should be examined for intrinsic foot muscle weakness, as this is

believed to play a role in the development and/or exacerbation of hallux valgus.^{159,160} In addition, TrPs of the great toe can be involved.¹¹⁸

A thorough history should include questions about footwear, because shoes with a narrow toe box or high heels can increase the progression of hallux valgus.¹⁴⁹ The clinician should also inquire about occupational requirements¹³⁹ and family history of foot problems.^{139,155-157}

Clinical examination of the hindfoot and forefoot joint passive accessory movements, with and without overpressure, should be conducted. Further, palpation of the intrinsic foot muscles, such as dorsal interosseous and lumbrical muscles, is also recommended.

7.3. Trigger Points and Hallux Valgus

Several muscles can refer pain to the region of the great toe and 1st metatarsal head. The flexor hallucis longus, flexor hallucis brevis, tibialis posterior, first dorsal interosseous,¹⁷ and tibialis anterior muscles¹¹⁸ have all been implicated in pain in this region. Trigger points in the intrinsic muscles of the foot, such as the abductor hallucis muscle, can result in weakness or dysfunction of those muscles. As mentioned earlier, this type of dysfunction may be involved in the development or progression of hallux valgus.^{159,160}

In addition, according to Travell & Simons, ill-fitting footwear can activate or perpetuate TrPs in muscles of the foot.¹⁷ Given the link between tightly fitting or high-heeled shoes and the development or exacerbation of hallux valgus,¹⁴⁹ it is important to strongly consider the role of footwear when it comes to pain at or around the great toe.

8. SESAMOIDITIS

8.1. Overview

Sesamoiditis is a condition involving pain and inflammation of the sesamoid bones of the first ray of the foot and their associated peritendinous structures.¹⁶¹⁻¹⁶³ It most commonly affects the medial sesamoid and is often associated with a previous history of trauma.^{161,163} The prevalence of this condition is higher in teenagers and young adults,^{162,164} and it is most commonly seen in dancers and runners. Prevalence rates for dancers are unknown, but for runners, sesamoid disorders, in general, make up 12% of great toe injuries, 4% to 9% of foot and ankle injuries, and 1.2% of all running-related injuries.¹⁶⁵⁻¹⁶⁷

Factors that may predispose individuals to sesamoiditis include a cavus foot posture with a plantar flexed first ray, asymmetry between medial and lateral sesamoid size, rotational malalignment, and enlargement of both sesamoids.¹⁶² Footwear, particularly high-heeled shoes, can contribute to this condition.¹⁶⁴

8.2. Initial Evaluation of a Patient With Sesamoiditis

Patients with sesamoiditis will report pain localized under the 1st metatarsal head during weight-bearing activity. Patients will often recall a single incident that started their

symptoms, but some cases will not be associated with a traumatic event.¹⁶¹ Patients will typically experience pain with direct palpation of the sesamoids and the plantar aspect of the 1st metatarsophalangeal joint,^{164, 168} and crepitus may be felt along the distal path of the flexor hallucis longus tendon.^{165, 169} Because of the proximity of the sesamoid bones to the flexor hallucis longus tendon, palpation alone cannot be relied on to make a definitive diagnosis.¹⁶¹ Motion at the 1st metatarsophalangeal joint is often painful and limited,^{164, 168} and patients may exhibit swelling around the joint. Plantar flexion and dorsiflexion strength of the great toe are likely to be reduced. In some cases, callus formation may be present under the sesamoids.¹⁶⁴ Patients should be assessed for postural or alignment issues such as pes cavus and a plantar flexed first ray.¹⁶²

True sesamoiditis does not result in radiographic changes, which can be helpful in distinguishing it from other sesamoid pathologies such as fracture or osteochondritis.^{161, 162}

Clinical examination of the hindfoot and forefoot joint passive accessory movements, with and without overpressure, should be conducted. Further, palpation of the intrinsic foot muscles, such as dorsal interosseous and lumbrical muscles, is also recommended.

8.3. Trigger Points and Sesamoiditis

Trigger point involvement for sesamoiditis is quite similar to that of hallux valgus,¹⁷ and the flexor hallucis longus, flexor hallucis brevis, tibialis posterior, first dorsal interosseous, and tibialis anterior muscles need to be considered.¹¹⁸

As mentioned in the hallux valgus section, ill-fitting footwear can activate or perpetuate TrPs in muscles of the foot, resulting in pain in the region of the great toe.¹⁷ Consequently, it is important to consider the role of footwear when it comes to pain at or around this region (see Chapter 77 Footwear Considerations).

Treatment Considerations for Myofascial Pain and Dysfunction

Trigger Point Injection and Dry Needling

Joseph M. Donnelly, Lynne M. Fries, Corine S. Cicchetti, and César Fernández de las Peñas

1. INTRODUCTION

Two different treatment methods use the insertion of needles to inactivate trigger points (TrPs): wet needling and dry needling (DN). Wet needling refers to the injection of a substance into a TrP through a hypodermic needle, whereas DN refers to the insertion of a filiform needle into a TrP without the introduction of any substance. Both needling therapies can effectively manage myofascial pain, but it seems that DN results in increased postneedling soreness in some muscles.¹ Generally, Simons et al² recommend TrP injections (TrPI) of a local anesthetic without corticosteroid and no adrenalin. Effective treatment using either TrPI or DN depends on mechanical disruption and inactivation of the active loci in the TrP.¹ Under particular circumstances, the injection of Botulinum toxin A (Botox A) has been proposed. Inactivation of TrPs by injecting Botox A depends on its specific pharmacologic effect on the motor endplate and may be an effective solution for those patients with myofascial pain who are not responsive to TrPI with local anesthetics or DN.

A single TrPI or DN treatment should be defined as the needling of one TrP site, despite the number of times some solution has been deposited within that one TrP site. One TrP site has a highly variable number of active loci that must be inactivated, and all of the loci in one TrP can be needled with one skin penetration. Using a nonmyotoxic local anesthetic or DN, many needle movements within the TrP site are normally required. When a local anesthetic is used, clinicians should inject only a small amount (<1 mL) at any one location within the TrP site. The clinician must obtain twitch responses from all of the remaining active loci in that TrP in order to ensure effective treatment.

Some clinicians depend on the injection of large amounts of extremely myotoxic drugs like Botox A or concentrated long-acting local anesthetics in the general vicinity of a point of tenderness, hoping to inactivate TrPs. When myotoxic drugs are considered unavoidable for injection of TrPs, it is much better to inject small amounts precisely where the

contracture knots of the TrPs are located. Selective injection of small amounts of these substances wherever the needle elicits a local twitch response (LTR) in a TrP is much less damaging to the muscle as a whole, and is just as effective as a large amount.

When documenting TrPI or DN, clinicians should specify the muscle needled, any adverse event, and the postneedling outcomes in regard to pain, activity limitations, and participation restrictions. These outcomes will be directly related to postneedling care which should include instruction in proper resting and sleeping postures, activity modification, self-stretching exercises, and a carefully preplanned therapeutic exercise prescription. Section 5 of each of muscle chapter of this textbook contains vital information for patient self-management to improve the efficacy of manual therapy, TrPI, or DN treatments. Manual therapy, TrPI, or DN used in isolation will typically not result in an effective therapeutic outcome for the patient.

2. MANUAL THERAPY OR NEEDLING THERAPY

The decision whether to treat TrPs by manual therapy, TrPI, or DN depends strongly on the training and skill of the clinician. Ideally, all approaches should be equally available to the patient and used when indicated. In fact, some studies conducted in the cervical spine reported no differences between manual therapy of upper trapezius active TrPs.³⁻⁵ Manual methods are noninvasive, adaptable for the patient to use for self-treatment, and can be used to release multiple TrPs at the same time in one muscle or a group of TrPs in several muscles that function synergistically. Manual therapy may also address the associated articular (joint) dysfunctions that could be activating or perpetuating the TrPs. However, manual methods are more likely to require several treatments, and the benefit of treatment may not be as fully apparent for a day or two, when compared with TrPI or DN. Manual methods are specifically indicated when the TrP is acute, when the goal is to train the patient in methods of home self-management, when the patient is needle-shy or has needle phobia, or when the TrPs in the muscle belly are not readily accessible to TrPI or DN.

One well-performed TrPI or DN treatment can fully inactivate TrPs quickly, which is reassuring to both the patient and the clinician. Identification and needling of active TrPs can produce impressive results. Success depends strongly on the recognition of the referred pain pattern, accuracy of the clinician's palpation, and the ability to direct the needle accurately. This accuracy depends strongly on the precision with which the TrPs are localized and on the manual skill of the clinician.

Trigger point injection or DN is indicated when a few TrPs remain that are unresponsive to manual methods, when skilled manual TrP therapy is not available, when there are only a few relatively acute TrPs and the treatment time is limited, and when the patient has hyperuricemia and symptoms of gout. Needling can be helpful when the muscle cannot be directly stretched for mechanical reasons or when stretch should be limited because of hypermobility.

Patients with both fibromyalgia and myofascial TrPs are much more sensitive to painful therapeutic techniques than are patients with TrPs without fibromyalgia. Clinically,

patients with both conditions could respond to TrPI or DN, but they do not respond as well as patients with myofascial TrPs alone.⁶

It is a serious mistake to judge the efficacy of TrP treatment by manual methods or by needling if the clinician was not adequately trained and experienced in the techniques used for the muscles and dysfunction treated. When patients give a history of being treated for TrPs without benefit, careful questioning makes it clear that treatment was given without adequate manual examination for TrPs or was not performed in a manner that one would expect to be effective. One of the main reasons for treatment failure, seen clinically, is the lack of postneedling treatment care and instructions or failure to recognize or address systemic perpetuating factors (see Chapter 4).

3. WET NEEDLING OR DRY NEEDLING

Clinicians may consider the potential risks and benefits of utilizing TrPI with solutions versus application of DN techniques. Trigger point injections are administered using hypodermic needles, a hollow needle through which a solution is injected at the TrP site.

Local anesthetics, corticosteroids, and neurolytics are substances commonly used in pain management⁷ and are also used in solutions for TrP management. Trigger point injection involves depositing approximately 0.2 mL of solution at the TrP.² Some studies have used larger volumes up to several milliliters. For example, Ay et al⁸ used 2 mL of 1% lidocaine injection for comparison with DN in conjunction with exercise and found no significant differences between the groups relative to pain level, cervical range of motion, and depressive mood; both groups benefited.

Hypodermic needles used for TrPI have a beveled, cutting edge. Filiform needles have a conical point. This difference should be considered when treating areas close to visceral anatomy such as pleural, vascular, or neural structures. The use of a noncutting needle may reduce the risk of laceration of these tissues that could lead to complications such as bleeding, pneumothorax, or nerve injury. DN may be preferable if injecting close to a nerve to avoid possible anesthetic block. Also, the use of DN prevents inadvertent intervascular deposition of treatment solution. It is prudent to aspirate, especially in the vicinity of large vessels, prior to injecting to assess that the needle has not entered a vessel. Accurate injection at deep sites, near neurovascular structures, or in patients who are obese may be improved by the use of ultrasonic or electromyography (EMG) guidance.^{9,10}

As with DN, the goal is to accurately locate and deactivate the TrP loci. Obtaining LTRs is similarly desirable. Mechanical disruption of the TrPs is effective by DN as well as needling in conjunction with TrPI of solution. Good technique and provocation of an LTR are important in obtaining a positive result, whether using DN or TrPI of a local anesthetic.¹¹ Nevertheless, the topic of the LTR during DN is currently under debate.¹²

Myofascial pain often has a chronic component, frequently requiring serial treatments. Clinicians may adjust their approach, including needle or solution options, at subsequent sessions to assess the best individualized treatment approach. Adequate treatment adjustment trials are appropriate prior to determining that TrPI or DN is not effective for a

particular patient as long as effective postneedling care and home self-management is employed.

Practical considerations may also drive the decision to use DN rather than TrPI solutions. Some clinicians may not have the option to utilize injection therapy within professional licensing parameters. Reimbursement issues and price point of supplies may also bias the clinician's choice.

Studies of TrPI have been limited by heterogeneity of subject groups and small sample sizes. Pain is complex, and multiple factors can affect fluctuations in pain intensity, quality-of-life measures, and perceived relief. Limited high-quality randomized controlled trials (RCTs) are available for review. A majority of the studies available involve treatment of the neck and upper quadrant.¹³ Additional research would be helpful in assessing optimal treatment approach and response to specific patient types. Huang and Liu¹⁴ found that abdominal muscle TrPI with lidocaine 2 weeks prior to menstruation yielded improvement in primary dysmenorrhea. However, no comparison with DN treatment was included in this study.¹⁴

There is little consensus regarding the superiority of either DN or TrPI. A meta-analysis demonstrated that both wet needling and DN were effective for neck and shoulder myofascial pain without clear differences between the needling therapies.¹³ Another systematic review found no differences between DN and wet needling using lidocaine after treatment or at follow-up intervals of 1 month or at 3 to 6 months.¹⁵ Nevertheless, some studies showed evidence that lidocaine injection may be more effective for pain reduction than DN at 4 weeks.^{16,17} An older randomized, double-blind crossover study compared the use of 0.5% bupivacaine, 1% etidocaine, or physiologic saline. Pain categories measured prior to treatment and 15 minutes, 24 hours, and 7 days after treatment indicated the use of the local anesthetic injections to be preferable over saline.¹⁸ Although the sample size was small ($n = 15$), the crossover component of this study limits heterogeneity of the comparison groups and compares response of different treatment solutions on the same patients.¹⁸

In clinical practice, patients are generally treated with more than one session. A double-blinded study of individuals with episodic tension-type headache compared TrPI using saline to 0.5% lidocaine and compared single injection with a series of five injections.¹⁹ The results indicated that repeated lidocaine injections showed improvement at 2, 4, and 6 months, but only the group treated with a series of lidocaine injections showed significant changes at 6 months, suggesting multiple lidocaine injections may be more effective than a single treatment.¹⁹ Treatment frequency and duration may be factors to consider when reviewing comparative studies.

4. SELECTION OF NEEDLE GAUGE

The clinician must determine an appropriate needle gauge and length to access the target tissue. Choice may vary greatly, from 30-gauge $\frac{1}{2}$ in to treat the anterior border of the upper trapezius to ultrasound-guided 20-gauge 3.5-in spinal needle to address the

piriformis muscle. In thick subcutaneous muscles, such as the gluteus maximus or paraspinal muscles, a 21-gauge, 5-cm (2-in) hypodermic needle, or 0.30 × 50 mm filiform needle is usually necessary. For TrPI or DN technique, the needle should be long enough to reach the TrP without inserting the needle to its hub. A 21-gauge, 6.4-cm (2.5-in) hypodermic needle or a 0.30 × 60 to 75 mm filiform needle is generally long enough to reach TrPs in the deepest muscles, such as the gluteus minimus, quadratus lumborum, and psoas muscles. The spinal needle is not as effective for TrP injection as the hypodermic type needle because the spinal needle may push the TrP aside, rather than penetrating it because of its flexibility and diamond-shaped tip.

It would seem intuitive that a smaller gauge needle would be less painful for the patient. When initiating TrPI, patients will often ask, “how big is the needle?” Some authors, including Simons, hypothesize that a larger gauge allows for more accurate localization and improved mechanical disruption in treatment of TrPs with TrPI or DN. There is limited data on response as related to needle gauge. Yoon et al²⁰ measured treatment efficacy comparing 21, 23, and 25 gauge hypodermic needles in individuals with TrPs in the upper trapezius muscle followed up to 14 days after treatment. All the groups improved and, interestingly, there was no difference in the pain perception of injection needle size. Nevertheless, although no difference in pain relief scores was noted, 21 or 23 gauge needles were more effective in SF-36 health survey scores.²⁰

A knowledge of anatomy, the depth of target tissue, and the clinical status of the patient are all factors to be considered by clinicians when choosing needle gauge and length for TrPI or DN. Larger gauge needles may offer less flexibility and possibly more accurate localization and treatment of TrPs. Muscles that are deep or in close proximity to neurovascular structures may best be accessed utilizing ultrasound guidance. Consideration may be given to using a smaller gauge in patients being treated with capillary fragility, platelet disorders, or anticoagulant agents such as warfarin or novel oral anticoagulants.

Coagulopathy may be inherent or medically induced and should be included in patient evaluation prior to embarking on TrP management by invasive techniques, such as needling or even with some manual therapy techniques. It is prudent for patients on warfarin to check for current monitoring and stability of international normalized ratio (INR) within range. Consider consultation with the patient’s hematologist in the setting of coagulopathy, such as platelet dysfunction. Also, consider the anatomy of the target site to assess that the treatment area is readily compressible (hemostasis) to limit bruising or bleeding.

Clinically, a 30-gauge needle is effective for TrPI with the effect of obtaining LTR and clinical response with less bleeding noted. A 30-gauge needle has a nominal outer diameter of 0.30 mm that corresponds to a fairly common filiform needle diameter choice for use in DN techniques. Ga et al²¹ compared the efficacy of treatment with a 0.30 mm DN compared to TrPI using 0.5% lidocaine administered 25-gauge needle in elderly patients. Although the with a 25-gauge needle has a greater diameter, there was no significant difference in postinjection soreness or in improvement of cervical range or motion or myofascial pain.

5. CLINICAL GUIDELINE FOR APPLICATION OF NEEDLING THERAPIES

Prior to performing any needling technique (TrPI or DN), the clinician should consider patient positioning, medical history with regard to possible increased bleeding tendency, needle selection, proper cleansing, painless skin penetration, and the value of preinjection blocks.

The patient should be positioned in recumbence (supine, semisupine, side-lying, prone, or semiprone) for any TrPI or DN technique to avoid falling associated with psychogenic syncope. When the patient sits on a chair or is standing, needle therapies can be hazardous in susceptible individuals.^{22,23} Recumbence also facilitates manual palpation of the TrPs because the patient is typically more comfortable and relaxed. It is also easier to adjust muscle tension so that the bands containing TrPs stand out in a background of relaxed muscle fibers.

Trigger point injection and DN are not sterile techniques. The area to be needled should be properly cleaned with alcohol or soap and water. The needles used are sterile, single use, and disposable. Nevertheless, there is an ongoing debate whether disinfection of the skin or the use of gloves is necessary or not, and guidelines vary in different countries and regions.^{24,25}

Some patients are afraid of the skin pain caused by needle penetration. This fear of the needle is usually acquired in childhood and creates obstacles to the therapeutic alliance.²⁶ Most patients find the sharp skin pain more threatening than the deep aching and more severe pain of the needle contact with the TrPs. The skin pain is avoidable with the use of cold anesthesia for TrPI or in the case of DN holding the tube firmly against the patient's skin prior to tapping the needle through the skin.

In adults, vapocoolant spray can provide cold anesthesia^{27,28} to effectively block nerve conduction when the skin temperature falls to 10°C (50°F). After carefully disinfecting the skin with alcohol, vapocoolant spray is applied from a distance of about 45 cm (18 in) for 5 or 6 seconds, and then the needle is inserted quickly after the spray has evaporated leaving the skin dry.^{26,29} For young children who dislike the sudden cold impact of the vapocoolant jet stream, a sterile, fluffy, small cotton ball is saturated with vapocoolant until it is dripping wet. The wet cotton is held *lightly* against the skin for about 10 seconds and then removed. At the instant the skin dries, the needle is inserted painlessly.

Three less reliable, but more convenient, techniques that can be combined are to (1) insert the needle *very quickly* through the skin with a flick of the wrist or with a very firm tap with a DN, (2) place the skin under tension so that the additional tension of the needle penetration is hardly noticeable (this can be done by the clinician strongly spreading the fingers apart against the skin and inserting a needle between them), and (3) increase skin tension by pinching a fold of the skin between the thumb and fingers and inserting the needle through the tightly folded skin. When the skin has been cleansed with an alcohol wipe, a film of liquid alcohol can remain for seconds. If the needle is inserted through the wet alcohol, it produces a stinging sensation because the needle carries some of it into the

skin. This can be avoided by simply waiting until the alcohol dries. The particular technique used is less important than the communication to the patient that the clinician cares and knows how to insert the needle painlessly.

Prior to TrPI or DN, the patient should be warned that successful needle contact with TrPs may produce a flash of distant pain and likely will cause the muscle to twitch. The patient should be asked to note where that pain is felt, permitting an accurate description afterward of the pattern of pain referred by the TrPs. In this way, the clinician can confirm the referred pain pattern of that TrP, and the patient can realize the connection between the pain and the TrP in that muscle (pain recognition or not). This reassures both the clinician and the patient as to the importance of inactivating it. Patients learn to welcome this painful harbinger of a successful TrPI or DN treatment and future relief.

A preinjection block may be used prior to the TrPI procedure. It is now well established that even brief exposure to considerable pain can cause neuroplastic changes in the spinal cord that tend to enhance sensitization and pain. For patients who are particularly pain-sensitive, or who have found the pain produced by needle encounter with TrPs seriously distressing, a preinjection block can be helpful. This procedure must be adopted with due caution. It is described in detail by Fischer³⁰ who presents two methods: one involves diffuse infiltration of a local anesthetic proximal to the area to be injected and the other involves infiltration of the entire TrP area with a local anesthetic before needling individual active loci. It is important, if a clinician does these infiltrations, to use 0.5% procaine because of its lower myotoxicity, its relative innocuousness if a vessel were accidentally injected, and the more rapid recovery of normal nerve function.³⁰

Although there are a number of alternate TrPI and DN techniques now in use, the following precision technique is the one that was presented by Simons et al.² It is a basic technique that is applicable to TrPs in any muscle location that can be reached with a needle.

Localization of a TrP is done mainly by the practitioner's sense of feel, assisted by patient expressions of pain, and by visual observation of LTRs.

The two methods of palpation (cross-fiber flat or pincer palpation) are utilized to identify TrPs. The more precisely the TrP is localized, the more effective the needling technique will be. When flat palpation is used to locate the TrP for needling, its position can be confirmed precisely by pushing the nodular TrP back and forth between two fingers (Figure 72-1A and B). The TrP can be fixed for needling by pinning it down midway between the index and middle finger tips (Figure 72-1C). This identifies for the clinician the plane that passes through the TrP perpendicular to the skin. The needle can be aimed and directed half way between the fingers precisely in that plane and angled to whatever depth is necessary to reach the TrP. The needle should be considered as an extension of the clinician's finger; the clinician, therefore, palpates the TrP with the tip of the needle and penetrates it. When pincer palpation is used to locate the TrP, the degree of tension placed on the muscle fibers can be fine-tuned by varying the distance that the muscle is pulled away from underlying tissues. The nodule is located by rolling sequential portions of the taut band between the clinician's digits (Figure 72-2). For needling, the TrPs are held

tightly between the thumb, index, and middle fingertips; the needle is typically directed toward the TrPs; and the clinician's fingers on the underside of the tissue. The needling procedures for both flat and pincer palpation should be conducted similar to manual palpation techniques for the identification of TrPs.

Figure 72-1. Cross-sectional schematic drawing of flat palpation to localize and hold the TrP (dark red spot) for TrP injections or dry needle. A and B, Use of alternating pressure between two fingers to confirm the location of the palpable TrP. C, Positioning of the TrP half way between the fingers to keep it from sliding to one side during the needling.

Figure 72-2. Cross-sectional schematic drawing showing cross-fiber pincer palpation of a taut band (black ring) at a TrP (red spot). Cross-fiber pincer palpation is used for muscles (light red) that can be picked up between the digits, such as the sternocleidomastoid, pectoralis major, and latissimus dorsi muscles. A, Muscle fibers surrounded by the thumb and fingers in a pincer grip. B, Hardness of the taut band felt clearly as it is rolled between the digits. The change in the angle of the distal phalanges produces a rocking motion that improves discrimination of fine detail. C, The palpable edge of the taut band is sharply defined, as it escapes from between the fingertips, often with a local twitch response.

For TrPI or DN of TrPs when employing any method of palpation, the muscle fibers of the taut band are placed on sufficient stretch to take up any slack but not enough stretch to cause additional pain. This tautness is necessary to help hold the TrP in position. If the muscle is slack, there is a tendency for the dense contracture knots of the TrP to slide to one side as the needle tip encounters them.

To needle TrPs in superficial layers of muscle close to the skin, the needle tip can be brought precisely to the TrP by first carefully locating TrP with the finger and then, after inserting the needle subcutaneously, pressing it against the finger through the skin to accurately localize the TrPs. Finally, the needle tip is directed into the TrP by means of this “tactile vision” provided by palpating both the needle and the TrP at the same time.

The same technique is useful for TrPI or DN in the area of the muscle opposite the needling site when using a pincer grasp. The location of the needle and the TrP can be identified by palpation as the needle approaches the skin after penetrating most of the muscle.

Trigger point injection or DN TrPs is a full-time job for both hands of the clinician. The needling hand is busy placing the needle and controlling the plunger of the syringe for TrPI. The palpating hand constantly maintains hemostasis and often must fix the TrP to help the needle penetrate it. It also must be ready to detect any palpable LTRs. Hemostasis is important. Local bleeding irritates the muscle, causes postinjection soreness, and can produce unsightly ecchymosis. Ecchymosis is usually preventable; when it occurs, only time eradicates it.

To prevent bleeding, the fingers of the palpating hand of the clinician should be spread apart, maintaining tension on the skin (Figure 72-3A) to reduce the likelihood of subcutaneous bleeding where the needle has penetrated during TrPI. Bleeding is considered a minor adverse event when performing DN. Also, during TrPI or DN, the fingers exert pressure around the needle tip to provide hemostasis in deeper tissues. When the angle of the needle is changed, the direction of the pressure changes with it. The pressure should be applied throughout the needling procedure. As the needle is withdrawn, one finger slides over the track of the needle and instantly applies pressure where the needle was. If visible bleeding develops, prolonged hemostasis and a cold pack should be applied and the patient is warned of a possible “bruised” spot.

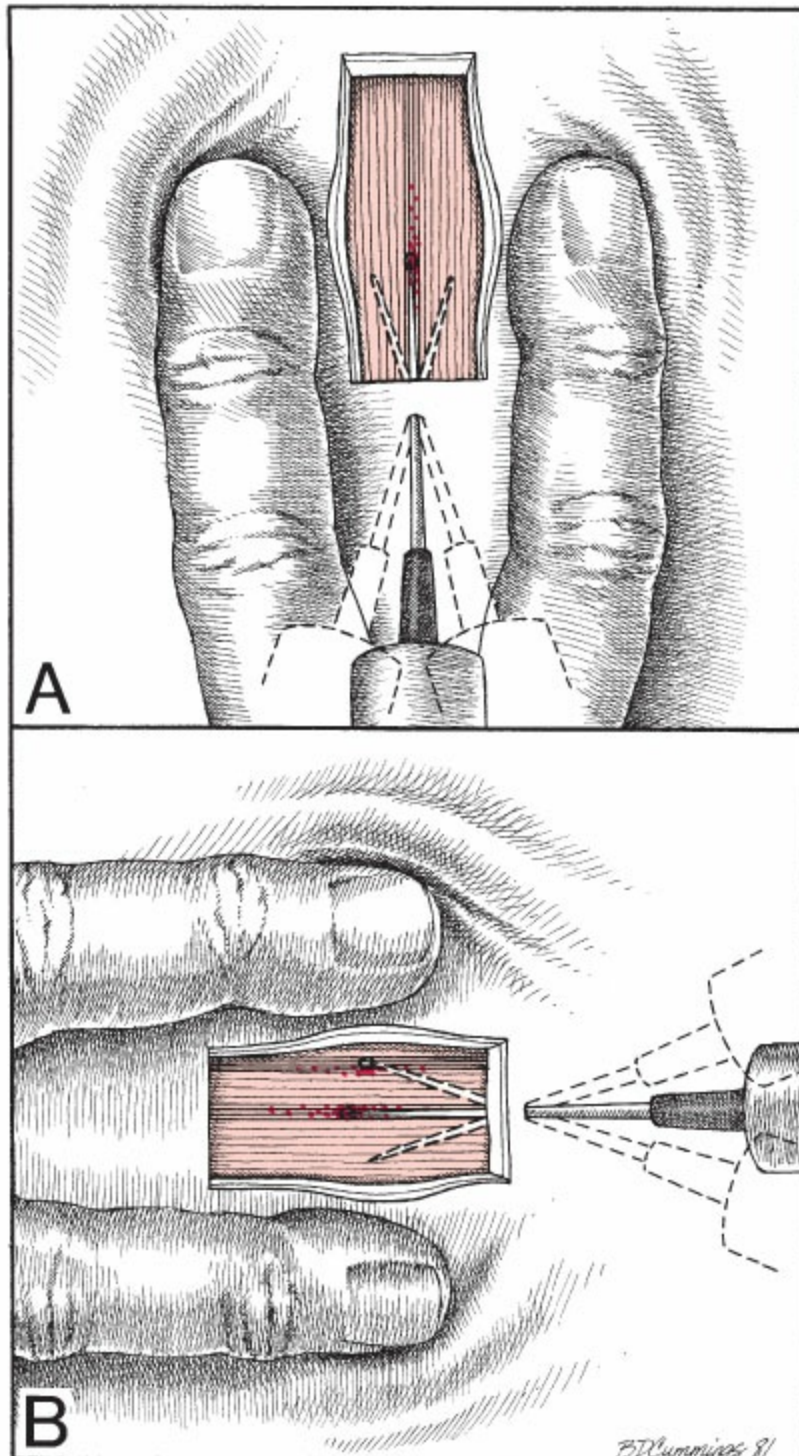

Figure 72-3. Schematic top view of two approaches to the flat needling of a TrP area (dark red spot) in a palpable taut band (closely spaced black lines). A, Needling away from fingers, which have pinned down the TrP so it cannot slide away from the needle. Dotted outline indicates additional probing to explore for additional adjacent TrPs. The fingers are pressing downward and apart to maintain pressure for hemostasis. B, Needling toward the fingers, with similar finger pressure. Additional TrPs are often found in the immediate vicinity by probing with the needle.

Blindly probing an area of diffuse tenderness where there is no palpable band or muscle attachment is futile. Such an area is most likely to be a pain reference zone, not TrPs. Injecting a local anesthetic in the reference zone may temporarily reduce the referred pain, but it does not eliminate the cause of the pain.

The importance of distinguishing between TrPs in the muscle belly, the myotendinous junction, or enthesis when TrPI or DN is applied was illustrated (Figure 72-4) by Fischer.³⁰ The precision required to penetrate the TrP with a needle is a skill that requires practice. When using flat palpation, as illustrated in Figures 72-1C and 72-3A and B, the needle is inserted between the fingers that have located the TrPs. The needle penetrates the skin 1 to 2 cm away from the TrP so that it can approach it at an acute angle of about 30° to the skin. Adequate tension of the muscle fibers is required to penetrate the TrP. The needle should explore both the deep and superficial fibers of the muscle. For TrPI, the syringe may be held between the fingers of the injecting hand, and thumb pressure used against the plunger, which is the method shown in most of the figures illustrating injection in this chapter. Thumb pressure on the plunger slowly introduces small amounts of 0.5% procaine solution as the needle advances within the muscle. This ensures that the procaine is present to relieve pain at the instant that the needle tip encounters an active locus of the TrP. The filiform needle can be easily redirected with the needling hand to induce and eradicate all the LTRs in the area.

Figure 72-4. Diagrammatic representation of preneedling sites (open circles), and needling sites (solid circles) of local anesthetic in relation to the TrP (large broken circle). The taut band is represented by the enclosed stippled area. This diagram distinguishes the mid-muscle belly TrP within the broken circle from the myotendinous junction and at the

attachment of the tendon to the bone. Each of these three TrP regions can be identified by the individual spot tenderness and anatomic locations. No rationale is apparent for needling the part of the taut band that lies between solid circles numbers 7 to 10. Reproduced with permission from Fischer AA. New approaches in treatment of myofascial pain: myofascial pain—update in diagnosis and treatment. *Phys Med Rehabil Clin North Am*. 1997;8(1):153-169.

The clinician should avoid inserting the needle to the hub where the needle is most likely to break off. Some additional depth of penetration can be safely obtained by compressing the skin and subcutaneous tissues with the palpating hand if needed. Once the skin and subcutaneous tissues have been compressed, the clinician should maintain the compression until the needle is withdrawn.

The dense contracture knots in TrPs often feel, to the practitioner, as if the needle tip has encountered hard rubber that is resistant to penetration and tends to slide to one side, as described by Gold and Travell many years ago. Using the needle as a probe, the TrP sometimes feels like a dense globule, 2 to 3 mm in diameter; resistance to penetration helps identify it.³¹ Occasionally, when the needle makes contact with the TrP, it may feel “gritty.” Adequate tension of the muscle helps stabilize the position of the TrP to permit precise penetration by the needle, especially for deep TrPs that cannot be easily fixed in position by manual palpation.

If an LTR and referred pain were elicited from the TrP prior to TrPI or DN, then both should be observed when the needle penetrates the TrP during the procedure. Hong³² showed that when needle penetrations of a TrP produced LTRs, they were much more likely to result in subsequent pain relief than penetrations that did not elicit an LTR. Following effective needling, most TrP characteristics should have minimized or disappeared. The taut band is more relaxed following effective needling and may no longer be distinguishable by manual palpation. Nevertheless, the topic of the LTR during DN is currently under debate.¹²

Sometimes a cluster of TrPs are present in one part of the muscle. This fact is often recognized when the muscle is initially palpated for TrPs. When one of these TrPs has been inactivated, the area is peppered in a fan-like manner or in a full circle³² in an effort to ensure that all remaining TrPs in the group are inactivated, as illustrated in Figure 72-3B. Following each probing movement, the needle tip must be withdrawn to the subcutaneous tissue and redirected before the next movement. When this probing search of the region is completed, the site is palpated for any remaining spots of tenderness. If another one is found, it is accurately localized with the fingers and needled. All potential tender spots in that region should be eliminated before withdrawing the needle through the skin, if possible. Box 72-1 describes a general guideline for TrPI or DN procedures. Boxes 72-2 and 72-3 identify absolute contraindications and precautions to TrPI or DN, respectively. Box 72-4 lists caveats from Travell and Simons regarding TrPI or DN.

Box 72-1 General guidelines for TrP injection or dry needling

- Palpate and identify anatomic landmarks
- Palpate the taut band with cross-fiber flat or pincer palpation
- Identify the TrP and fix with either a pincer grasp or flat palpation
- Needle with straight in and out motions
- Elicit a local twitch response (or referred pain)
- Draw the needle back to the subcutaneous tissue and re-redirect the needle to treat other TrPs in the same or nearby areas
- Provide hemostasis immediately upon withdrawal of the needle
- Apply a postneedling intervention for reducing postneedle soreness

Box 72-2 Contraindications to TrP injection or dry needling

- Inadequately trained practitioner
- Needle phobia
- Cognitive impairment
- Patient's unwillingness to be treated
- Patient's inability to give consent
- Local skin lesions
- Local or systemic infections
- Needling directly over implants

Box 72-3 Precautions to TrP injection or dry needling

- First trimester of pregnancy
- Vascular disease
- Abnormal bleeding tendency (anticoagulant therapy, thrombocytopenia)
- Compromised immune system
- Intercostal area
- Needle aversion

Box 72-4 Travell and Simons caveats for TrP injection or dry needling

By NEVER aiming the needle at an intercostal space, the clinician avoids the distressing complication of a *pneumothorax*. As a resident, Dr Travell found in her early experience of doing many pleural taps for pleural effusions, that patients consistently reported a salty taste in the mouth whenever the pleura was punctured. The patient might say,

“Oh, I can taste the solution.” When the lung is punctured and collapses, dyspnea, cough, and chest pain characteristic of a pneumothorax follow.

A needle is prone to break where it attaches to the hub. The needle should never be inserted solidly to its hub because of the difficult situation that would ensue should it break off at the hub and disappear under the skin. Recovering the needle can be a time-consuming, frustrating process for the clinician. A long enough needle should be used, or the skin compressed around it, to ensure that some of the needle projects above the skin surface.

The location of the needle tip can readily be misjudged when using a long slender needle. It is especially important to insert the needle straight and avoid any side pressure that might bend the needle.

When the tip of a needle contacts the bone, the impact frequently curls the tip to produce a “fishhook” burr that feels “scratchy” and drags as the needle is drawn through tissues; it causes unnecessary bleeding and pain and the needle should be replaced immediately. It is especially important to avoid using such a barbed needle for TrPI or DN TrPs in muscles like the scalene that lie near nerve trunks.

Hong³² introduced two needling techniques: one was a safer way to hold the syringe and the other was a different way to perform the injection itself, that is DN. When a clinician injects a TrP in locations that pose a hazard should the patient make a sudden unexpected movement (such as a startle reaction, sneeze, and/or cough), Hong^{11,32} recommends a way to hold the syringe that is safer than the usual way. His technique ensures that the syringe will move with the patient and not enter an unintended tissue, and that the finger on the plunger of the syringe will move with the syringe and not cause an accidental injection. The hand holding the syringe must be firmly supported by the patient’s body; this is readily accomplished with his technique, as illustrated in Figure 72-5. The syringe is held between the thumb and lesser fingers, and the plunger is depressed with the index finger. This technique is particularly valuable when injecting over the lung or when the needle is directed toward major arteries or nerves.

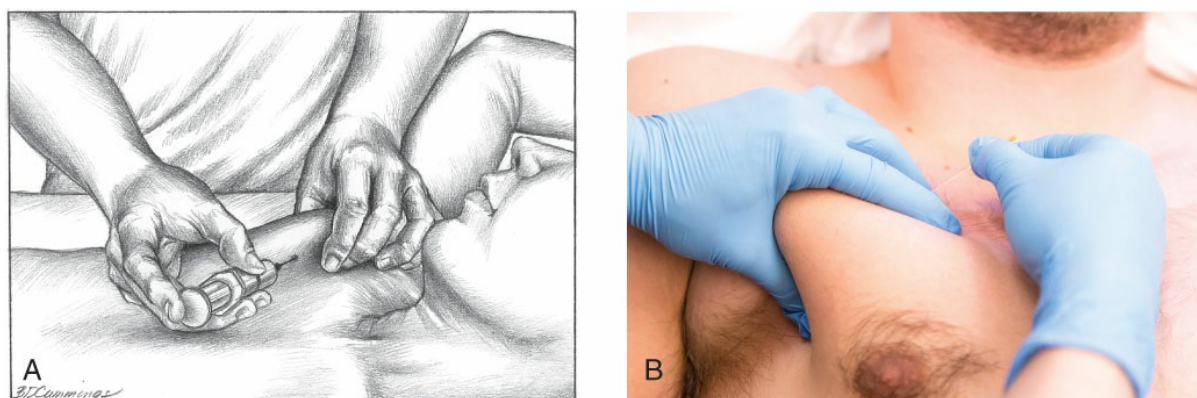

Figure 72-5. Trigger point injection using a technique for holding the syringe that minimizes the danger of accidentally inserting the needle farther than intended if the patient makes a

sudden unexpected movement. A, Drawn from an original photograph, courtesy of John Hong, MD who first described this method. Hong C-Z. Myofascial trigger point injection. *Crit Rev Phys Med Rehabil.* 1993;5:203-217. B, Similar technique shown for dry needling.

6. NUMBER OF NEEDLING SESSIONS

Note the definition of one injection at the beginning of this chapter. The number of TrP sites that need to be injected per visit and the number of visits required are strongly dependent on the patient's condition and the practitioner's skill and judgment. To date, no medical specialty has adopted the diagnosis and treatment of myofascial TrPs as an official part of the training program, nor have *specialty* standards of training and practice been established for this diagnosis. The *International Association for the Study of Pain* has published recommended standards of TrP training.³³

Active myofascial TrPs with no long-lasting perpetuating factors or additional tissue damage due to mechanical injury to other structures should resolve with one or two needling sessions. This estimate is especially true if the patient has been provided with adequate self-management techniques, which are discussed in Section 5 of each muscle chapter. When initial TrP therapy is delayed and symptoms have not subsided with time, the longer the period of delay before starting TrP therapy, the higher the number of TrPI or DN techniques that will be required over a longer period of time.³⁴ Some chronic TrP problems could involve several injections over a span of months of treatment. In this situation, the primary guideline is that the period of relief from TrP pain and dysfunction should become progressively longer with successive TrPI or DN treatments, and the patient should be performing a self-management program between sessions.

When a patient demonstrates multiple active TrPs in functionally related muscles, there is a distinct advantage to inactivating them as a group. Thus, 5 or even 10 needling treatments at one visit may be appropriate but could be more than tolerable. Because a properly performed and effective needling treatment produces an LTR that is often associated with considerable pain, there is a limit as to how many painful injections should be performed at one visit given the patient's emotional and autonomic distress level.

The presence of unrecognized perpetuating factors (see Chapter 4) will lead to unnecessary TrPI or DN. The presence of associated joint dysfunctions that need manipulation can cause poor response to needling and prompt recurrence of the TrP activity. After appropriate treatment of the joint(s), one or two more TrPI or DN sessions should resolve the problem. The presence of concurrent fibromyalgia will increase the number of needling sessions required and can justify recurrent TrPI or DN every 6 to 8 weeks because fibromyalgia acts as a perpetuating factor that has no cure. Inactivating TrPs can provide significant pain relief for many of these patients.

7. Postneedling Procedures

Postneedling-induced soreness is thought to be a consequence of the neuromuscular damage generated by needling insertions into the muscle.³⁵ The presence of postneedling

soreness can be associated with a possible reluctance to receive further needling therapy by the patient, generating patient dissatisfaction and reduction in treatment adherence. In fact, it is highly recommended to advise the patient about the presence of soreness after any needling therapies.³⁶ Therefore, postneedling procedures should always be implemented into a multimodal treatment approach.

Postural education and positioning, activity modification, self-stretch, and neuromotor retraining following TrPI or DN is an integral part of that treatment. Immediately following TrPI or DN, hemostasis should be applied for a minimum of 30 seconds or longer, the patient should actively move each muscle needled through its full range of motion three to five times, reaching its fully tolerable shortened and fully tolerable lengthened position during each cycle. The muscle usually feels stiff toward the end of full stretch range of motion on the first cycle, less on the second, and begins to feel comfortable through its full range by the third to fifth cycle. It is important that the patient move the muscle slowly to explore the end range of motion for additional release. It is also vital that the patient is able to activate the muscles that have been needled volitionally to improve motor control. An ice pack immediately following the TrPI or DN procedure, stretch,³⁷ manual compression,³⁸ or low-load eccentric exercise³⁹ can be helpful in reducing postneedling soreness and enhancing recovery.

The postinjection stretch is important because it helps to again equalize sarcomere lengths throughout the length of the affected muscle fibers, which relieves the abnormal tension and can eliminate the palpable taut bands.³⁷ Voluntary movement also relieves residual stiffness at full range of motion, helps the patient appreciate the improved range of motion, and provides the patient stretches that will be incorporated in the home management program. Additionally, this range-of-motion activity establishes the patient's conscious awareness of normal function in that muscle, while reprogramming the cerebellum to incorporate the newly restored full-range capability of the muscle into the patient's daily activities. Establishing a home exercise prescription for the patient following TrPI or DN is vital for treatment success.

Lewit⁴⁰ noted muscle soreness after DN and after TrPI with a local anesthetic but made no mention of applying heat or cold as part of the treatment. The postinjection soreness, per se, is not unfavorable if the patient's related pattern of referred pain has been relieved. In fact, some clinicians consider postneedling soreness as a "natural" or "positive" effect indicating that TrP inactivation has been effectively achieved. However, it is wise to let the muscle recover completely from postinjection soreness, which ordinarily lasts at most 48 to 72 hours independent of the postneedling intervention used,³⁷⁻³⁹ before needling its TrPs again. Soreness can also be caused by ineffectually needling close to, but not into, TrPs.

If two or three treatments of TrPI or DN fail to eradicate the TrPs in a muscle, repeated TrPI or DN is rarely the answer. The perpetuating factors that are causing recurrence of the TrPs must be identified and managed (see Chapter 4). Box 72-5 lists possible reasons for failure of TrPI or DN to effectively treat the myofascial pain and dysfunction caused by TrPs.

Box 72-5 Possible reasons for failure of TrP injection or dry needling

1. Disregarding perpetuating factors is probably the most important reason for failure
2. Needling a latent TrP, not an active TrP
3. Needling the area of referred pain and referred tenderness, not the TrPs, therefore providing incomplete or temporary relief
4. Failure to needle the TrP itself
5. Inappropriate needle gauge
6. Injecting a solution with an irritating or allergenic bacteriostatic preservative
7. Inadequate hemostasis followed by irritation of the TrP due to local bleeding
8. Overlooking other active or associated TrPs that are contributing to the patient's pain
9. Failure to provide postneedling care including hemostasis, full stretch range of motion, postural and positioning instruction, activity modification, and neuromotor retraining
10. Failure to establish a home exercise prescription that includes intensity, frequency, and duration of the home management program

WET NEEDLING: TRIGGER POINT INJECTIONS

1. LOCAL ANESTHETICS

This discussion is an overview summary in the use of the TrPI solutions for treatment of myofascial pain and TrP dysfunction. Certainly, more specific and extensive research, scientific detail, and clinical opinion are available than can be addressed within the confines of this chapter.

A variety of solutions and combinations have been utilized in TrPI. Local anesthetics have been the most common solution utilized. Lidocaine, bupivacaine, and procaine are most frequently used local anesthetics for TrPI. Simons et al² were of the opinion that DN is as effective, but it results in greater postneedling soreness than treatment with the injection of a local anesthetic.^{2, 11} In fact, Simons et al² recommended using small amounts of solution, a few 10ths of a mL at any single location.

Many patients have chronic pain and are candidates to receive serial injections in clinical practice. It is common to make alterations in treatment approach relative to needle and solution choice to identify the optimal response for an individual patient. Treatment approach may also be adjusted for changes in the patient's presentation, such as in episodes of exacerbation or alteration in pain distribution.

Local anesthetics have a favorable safety profile when appropriately administered, mostly in the doses and concentrations used in TrPI. Mechanism of action for local anesthetics involves blockade of nerve conduction by reversibly binding to sodium

channels, thus preventing depolarization. Duration of action is determined by protein binding capacity to the sodium channel receptors. Onset, duration, and maximum doses are referenced within Table 72-1. For patients with multiple areas requiring treatment, a lower concentration of local anesthetic may allow more areas to be safely injected.

Table	72-1	Classification and Uses of Local Anesthetics				
	Clinical Uses	Usual Concentration (%)	Usual Onset	Usual Duration (h)	Maximum ^a Single Dose (mg)	Unique Characteristics
Aminoesters						
2-Chloroprocaine	Infiltration PNB Epidural	1 2 2-3	Fast Fast Fast	0.5-1.0 0.5-1.0 0.5-1.5	1000 + EPI 1000 + EPI 1000 + EPI	Lowest systemic toxicity Intrathecal route may be neurotoxic
Procaine	Infiltration PNB Spinal	1 1-2 10	Fast Slow Moderate	0.5-1.0 0.5-1.0 0.5-1.0	1000 1000 200	Used for different spinal

^aMaximum single dose is affected by many factors; this is only a guide.

EPI, epinephrine; IV, intravenous; PNB, peripheral nerve block.

Modified from Barash PG, Cullen BF, Stoelting RK. *Handbook of Clinical Anesthesia*. 2nd ed. Philadelphia, PA: Lippincott; 1993:206-207; Dreyer S, Beckworth W. Commonly used medications in procedures. In: Lennard TA, Vivian D, Walkowski S, Singla A, eds. *Pain Procedures in Clinical Practice*. 3rd ed. Philadelphia, PA: Elsevier-Saunders; 2011:5-12.

Local anesthetics fall in to the biochemical category of ester or amide, as determined by the linking bond of the substance. Lidocaine and bupivacaine are commonly used local anesthetics that fall under the amide group. Amide local anesthetics are metabolized in the liver. This mechanism may be a consideration in patients with impaired hepatic function, although the volumes and concentrations of local anesthetics used for TrPI are not large and can be adjusted for patient condition. Procaine is an ester local anesthetic. Ester local anesthetics are hydrolyzed and rapidly metabolized and, therefore, have lower toxicity. Rapid degradation reduces the potential for adverse reaction if inadvertently introduced intravascularly. Para-aminobenzoic acid is a metabolite that can act as an allergen in some patients, but rapid metabolism reduces the likelihood of reaction when used in TrPI. Metabolites of procaine are excreted in the urine.⁷ The half-life of local anesthetics may be prolonged in the setting of renal failure,⁴¹ but local anesthetics are routinely used for procedures in renal failure and patients requiring dialysis. The quantity and dilution of local anesthetics used in TrPI would generally not be a concern in patients with renal dysfunction.

True allergy to local anesthetics is rare, accounting for less than 1% of adverse reactions.^{42, 43} Some patients have sensitivity to the antimicrobial preservative methylparaben contained in multidose vials. Most allergic reactions to local anesthetic are type IV hypersensitivity and have small risk of anaphylaxis. Although allergy testing can be conducted to assess whether or not a specific patient is truly allergic to a local anesthetic, the lack of overwhelming data supporting superiority of wet needling may then predispose the clinician to opt for treatment with DN. A common adverse event that may occur with

any injection is a vasovagal reaction, usually secondary to needle insertion rather than to the administration of local anesthetics.

Myotoxicity of local anesthetics is another factor that may influence treatment decisions regarding the type of solution used or the option to use DN technique. The review by Zink and Graf⁴⁴ found that the intramuscular injection of local anesthetics frequently results in local myonecrosis, although significant skeletal muscle toxicity is a rare side effect. Myonecrosis persists for 24 to 48 hours until phagocytes invade the area. Intracellular dysregulation of Ca^{2+} appears to be an important element in myocyte injury. This effect is reversible and muscular regeneration occurs within 3 to 4 weeks. Muscle injury is noted to be least with use of procaine and most with bupivacaine. This effect appears to be dose and volume dependent as well as related to serial use.⁴⁴ Clinically, myotoxicity and resultant inflammation may be a consideration in patients who experience exacerbation within a few days of TrPI.

Some authors have proposed that the use of a local anesthetic may impair palpatory evaluation of response and treatment of remaining TrPs. Limiting volume and concentration of local anesthetic injected at each site is a consideration. Also, clinicians should seek to localize the site of injection through skilled palpation and elicit an LTR before injecting solution.

Lidocaine without the vasoconstricting agent epinephrine is the most common solution utilized in TrPI. It is readily available and is relatively inexpensive. Lidocaine toxicity may cause central nervous system and cardiovascular effects. Toxicity is rare and dose dependent. It has a relatively immediate onset and duration of action from 30 to 90 minutes. Lidocaine is a category B drug for pregnancy, but is excreted in breast milk.

When reviewing the literature, there is considerable variation in the dosing of lidocaine used for TrPI. Volumes studied may range from 0.2 to 2 mL and concentrations from 0.25% to 2%, factors that may limit comparison between these studies. Lidocaine may be diluted with sterile water to a concentration of 0.25%, and it has been shown to be equivocal or better in effect to concentrations of 0.50% or 1% in a single study.⁴⁵ Iwama and Akama⁴⁶ showed diluted lidocaine to be less painful and have a longer duration of relief in a study of comparative treatment of trapezius TrPs.

Lidocaine has a pH of 6.3 to 6.4. Some clinicians will buffer lidocaine using 8.4% bicarbonate solution at a ratio of 10:1, with the goal of reducing burning discomfort. Conflicting results are noted in the studies of intradermal lidocaine injection. Matsumoto et al⁴⁷ noted that buffered lidocaine significantly reduced discomfort when compared with 10:1 dilution with normal saline, whereas Zaiac⁴⁸ found lidocaine with epinephrine diluted at 10:1 ratio with normal saline to be less painful than buffering with lidocaine. These studies were intradermal rather than intramuscular.

A study of the tolerability of intramuscular injection using 1% lidocaine as a diluent for ceftriaxone administration versus buffered 1% lidocaine as a diluent demonstrated no difference in pain or discomfort associated with the injection.⁴⁹ If this information may be extrapolated to intramuscular TrPI, there would be little benefit to buffering lidocaine for

TrPI. Additional comparisons specific to comfort during TrPI would be helpful.

Procaine, similar to lidocaine, has a rapid onset and short duration of action. Procaine may have a lower myotoxicity effect and was the preferred local anesthetic recommended by Janet Travell, MD. Dr Travell recommended the use of the short-acting local anesthetic diluted to 0.5%, because a higher concentration showed no greater anesthetic effect.^{50,51}

Bupivacaine or ropivacaine are longer-acting local anesthetics that are sometimes used alone or in combination for TrPI. Duration of action may last several hours. A comparison of intramuscular injection showed pain related to injection to be less with ropivacaine when compared with bupivacaine; however, this application was not assessed specific to TrPI location.⁵² Bupivacaine is the more common product cited in clinical use and in research for TrPI. Ropivacaine is more frequently used for procedural anesthesia such as spinal anesthesia or nerve block. Although it may be tempting for patients and clinicians to view longer-acting anesthetics as more powerful or giving longer postinjection soreness relief, longer-acting anesthetics have not been shown to be clearly superior to shorter-acting products for TrPI. There is potential for longer postinjection sensory or motor block if injected closer to a nerve as well as increased myotoxicity.

Finally, clinicians have empirically made additions to TrPI solutions, sometimes on theoretic basis and anecdotal information. Therefore, demonstrated efficacy and potential risks should be assessed before including additives to TrPI solutions.

2. CORTICOSTEROIDS

Corticosteroids have both anti-inflammatory and immunosuppressive effects. They are probably the most common additive to TrPI, although no clear overall benefit has been observed. Simons et al² advocated against the use of long-acting steroids for use in TrPI. Steroid preparations with predominantly glucocorticoid activity rather than mineralocorticoid activity are used in pain management procedures (Table 72-2). Adverse effects of corticosteroid injection include facial flushing, depigmentation, and muscle atrophy. Local administration may produce systemic effects such as hyperglycemia in patients with diabetes. Potential risks should be included when considering this option for TrPI. Generally, corticosteroids can be mixed in the same syringe with local anesthetics. Betamethasone should not be mixed with local anesthetics containing methylparaben as a preservative because flocculation of the solution may result⁷ (Celestone Package insert).

Table 72-2 Comparison of Commonly Used Glucocorticoid Steroids ^a					
Agent	Anti-inflammatory Potency ^a	Salt Retention Property	Plasma Half-life (min)	Duration	Equivalent Oral Dose (mg)
Hydrocortisone (Cortisol)	1	2+	90	S	20

Cortisone	0.8	2+	30	S	25
Prednisone	4-5	1+	60	I	5
Prednisolone	4-5	1+	200	I	5
Methylprednisolone (Medrol, Depo-Medrol)	5	0	180	I	4
Triamcinolone (Aristocort, Kenalog)	5	0	300	I	4
Betamethasone (Celestone)	25-35	0	100-300	L	0.6
Dexamethasone (Decadron)	25-30	30	100-300	L	0.75

Adapted from Lennard TA. Fundamentals of procedural care. In: Lennard TA, ed. *Physiatric Procedures in Clinical Practice*. Philadelphia, PA: Saunders; 1995; Dreyer S, Beckworth W. Commonly used medications in procedures. In: Lennard TA, Vivian D, Walkowski S, Singla A, eds. *Pain Procedures in Clinical Practice*. 3rd ed. Philadelphia, PA: Elsevier-Saunders; 2011:5-12.

Results regarding the addition of corticosteroid to TrPI solution are mixed, and therefore, studies should be assessed for the inclusion of a control group. For example, an ultrasound-guided TrPI for piriformis syndrome performed using lidocaine was equivalent to injection using a combination of lidocaine and steroid.⁵³ Some studies have suggested benefit from the addition of steroid. A study of patients with headache compared treatment with DN, use of 0.25% lidocaine, and 0.25% lidocaine with 0.2 mL decadron 4 mg/mL.⁵⁴ Less postinjection discomfort and ingestion of rescue medication was noted in the group injected with a combination of a local anesthetic and corticoid.⁵⁴ On the contrary, cortisone injection directed toward the bursa for the treatment of greater trochanteric pain syndrome is a common procedure and did not prove superior to a series of DN TrP treatments.⁵⁵

A case report of treatment of serratus anterior muscle pain syndrome describes the use of 2% lidocaine and 0.5% bupivacaine and 1 mL (40 mg) triamcinolone with a total of 3 mL deposited at each site via ultrasound guidance to target muscle fibers at the TrPs, localized by palpation.⁵⁶ A small sample group was treated but showed a fairly robust response in seven of eight patients relative to medication use and pain scale at 3 months and beyond. This patient group was unique in that pain syndrome was triggered following surgical intervention. Also, no control group for treatment without steroid or with DN was involved.⁵⁶

Additional research may show benefit in particular patient types or anatomic locations. Positive steroid response may also be a factor that is concomitant rather than specific to addition to TrPI solution. Steroids are used in nerve blocks such as intercostal or greater

occipital neuralgia and TrPI in these areas may have overlapping effects. Steroids by oral or infusion route are often a component of headache exacerbation management. In reviewing the literature or case reports showing positive result from adding steroid to TrPI, consideration should be given to proximity of injections to nerve or systemic effects before concluding benefit from the addition to TrPI solution.

Serapin is a sterile aqueous solution of salts of the Pitcher plant (*sarracenia purpurea*). It has been used in injections for more than 50 years to treat pain of both muscular and neuropathic origin. Limited research is available on the use of serapin for myofascial pain, and most available information is old. A mechanism of action of selectively blocking C-fiber activity was proposed.⁵⁷ Bates⁵⁸ noted longer relief with injection of serapin when compared with novocaine or saline without sensory or motor block. No RCTs of its use in TrPI are noted at this time.

Clinically, serapin can be successfully used in a 50/50 combination with a local anesthetic to treat patients in exacerbation, with a significant component of aching pain or if limited response to local anesthetic alone. No adverse reactions to the addition of serapin to TrPI solution have been seen with this technique. Any improvement in response quality or duration is purely observational. Serapin is no longer available on the US market, and it is not certain when or if the product will be available.

Hyaluronate is a glycosaminoglycan found in the extracellular matrix, especially of soft connective tissues. Product forms are used for intraarticular viscosupplementation injections. Comparison was made of TrPI using 0.5% lidocaine with the same solution of lidocaine mixed with hyaluronidase 600 IU/mL. No significant differences at day 0, 4, 7, or 14 were reported. Patients receiving hyaluronidase showed less postinjection soreness on day 1.⁵⁹ Given the very limited benefit and associated cost, it would be difficult to recommend unless additional supportive data became available.

Dextrose solution has been used for proliferative injection techniques such as prolotherapy at concentrations ranging from 10% to 20% and in perineural injection treatment buffered at 0.5% in sterile water. A proposed mechanism for the use of dextrose in myofascial pain cites glycopenia as a potential trigger for C-fiber excitation, neurogenic inflammation, and neuropathic pain.⁶⁰ A single Korean study proposed dextrose as an energy supplement for impaired energy metabolism of the TrPs. In this study, comparison of the pain intensity and pressure pain thresholds showed lower scores indicating greater improvement at 7 days for the group treated with 5% dextrose water than for the one treated with 0.5% lidocaine or normal saline.⁶¹ More research would be needed before recommending the addition of dextrose to TrPI solutions.

Clinicians have added intramuscular vitamin preparations such as Vitamin B₁₂, D, or C to TrPI solutions. Although the assessment of overall health and nutritional status is an important consideration when addressing perpetuating factors for myofascial pain, there is no evidence to recommend the addition of vitamins (see Chapter 4).

The anti-inflammatory ketorolac is a nonsteroidal anti-inflammatory drug in the family of propionic acids, often used as an analgesic and antipyretic. Ketorolac acts by inhibiting bodily synthesis of prostaglandins. Approved use includes both intramuscular and

intravenous administration. Ketorolac may be utilized to treat pain exacerbations, including musculoskeletal pain. No RCT that is specific to the addition of ketorolac to TrPI solution is available.

Potential remains for other types of solution to be helpful additions to TrPI, such as 5-HT₃ receptor antagonists,⁶² tumor necrosis factor blockers,⁶³ or autologous serum conditioned for interleukin-1 receptor antagonists. Quality research would be needed before recommending additional solution components for routine clinical use.

3. NEUROTOXINS

The use of neurotoxins for the treatment of musculoskeletal pain has expanded⁶⁴ and requires mention, although a full review of this treatment intervention is beyond the scope of this text.

Botox is produced by *Clostridium botulinum*, an anerobic, gram-positive organism that can be found in soil and water. Botox, when injected, causes a degree of flaccid paralysis by blocking the release of acetylcholine at the presynaptic terminal of the neuromuscular junction. There are multiple neurotoxins designated as types A, B, C1, C2, D, E, F, and G. Table 72-3 is a summary of the neurotoxins that are Food and Drug Administration (FDA) approved. Botox is used to treat multiple painful conditions such as cervical dystonia and chronic daily migraine headaches. Its effects on the motor neurons are well known, causing a relaxation of hypertonic or spastic muscle. It has also been found to inhibit the release of neurotransmitters involved in pain transmission, such as glutamate and substance P.⁶⁵ A study performed on rats, showed significantly reduced glutamate release as well as reduced local edema and diminished signs of pain after peripheral injection of toxin. This may be the rationale for why Botox reduces pain in addition to its motor effects.⁶⁶

Table 72-3 Summary of FDA Approved Neurotoxins		
Molecular Name	Pharmaceutical Name	Type
Onabotulinum	Botox	A
Abobotulinum	Dysport	A
Incobotulinum	Xeomin	A
Rimabotulinum	Myobloc	B

From Davids HR. Botulinum toxin in pain management. <https://emedicine.medscape.com/article/325574-overview#a4>. Accessed August 31, 2017.

Muscle weakness can begin to take effect in 2 to 5 days, with maximum effect at about 2 weeks. As a result of the toxin's effect on the neuromuscular junction, the motor endplate fails and the nerve ending dies back. A new nerve ending sprouts from the residual axon, eventually forming the new neuromuscular junction. The neuromuscular junction is usually reestablished in approximately 3 months. Thus, Botox injections last for 3 months

on average.⁶⁷

The results reported in studies comparing the efficacy of TrPI with that of Botox are mixed. In reviewing the literature, the treatment response window studied often compared relatively short postinjection intervals. Given the neurotoxin duration of action, differences in response should have been evaluated 2 to 3 months from treatment rather than postinjection and at intervals of a few weeks after injection.^{67,68} The Cochrane review found only four trials comparing the effects of Botox A against placebo in individuals with myofascial pain. The results were controversial because three trials reported no statistically significant differences between Botox A and placebo for reducing pain.⁶⁸

A subset of individuals with chronic myofascial pain will have TrP reactivation despite repeated TrPI. This group of patients may be considered for botulinum injections. The injections can reduce the electrical activity of the TrPs and provide longer lasting response.⁶⁷ The method of identifying a locus for treatment may be different when evaluating for neurotoxin injection. Trigger point injection is directed by palpation, whereas evaluation for neurotoxin injection may be performed by needle EMG to appropriately identify and map out the muscles to be targeted. EMG mapping is generally used in the cervical region given the complexity of the anatomy. Manual palpation and clinical judgment are generally used in other regions of the body. Studies have shown that patients who have mapping studies tend to have a greater response to injections than those who do not.⁶⁹ Mapping may also include the use of ultrasound to evaluate deeper muscles that would ordinarily be avoided because of proximity to sensitive structures such as nerves, vessels, or pleura. Clinically, patients who have elevated activity of the muscles on testing tend to have better outcomes with neurotoxin injection than patients with minimal to no activity.

Neurotoxin injection may offer longer duration of relief of myofascial pain and may also offer a window of opportunity for rehabilitation efforts such as muscle reeducation, effective stretching, and postural correction. Longer duration of effect may also have negative consequences. Clinically, there are patients who tolerated TrPI well who experience significant exacerbation after neurotoxin treatment. Patients with underlying segmental or generalized hypermobility may be further destabilized by the weakness resulting from Botox injection. For example, shoulder pain may be worsened by a compromise of scapular stabilization by neurotoxin administration to treat TrPs at the medial scapular border.

Patients should be educated on the potential side effects from neurotoxin injections. As stated previously, the injections take about 2 weeks to begin taking effect. After 2 weeks, patients may notice a flare in the pain. If injecting neck muscles, they may also notice weakness in the neck with difficulty lifting the head up. Mild flu-like symptoms may also be reported. These side effects are self-limiting and should not last more than 2 weeks.

If a patient responds positively to neurotoxin injection, repeat injections should be considered at 3 months. If TrPs are deactivated and do not reactivate, patients may be able to stop treatment. Others may notice a return of symptoms after 3 months, requiring subsequent injections. Patients should be monitored after each injection to assess the need

for further treatment.

4. SUMMARY OF TRIGGER POINT INJECTIONS

There continues to be a significant degree of empirical evaluation regarding the practice and efficacy of TrPI. This area of study offers many potential research opportunities. Comparisons are needed of treatment in matched patient types, solutions, and additives, as well as optimal frequency and duration regimens.

As noted by Simons et al,² patients may report a history of treatment by TrPI without benefit. Patients may also report a history of significant pain or postinjection soreness with previous treatments. Clinicians who perform TrPI should be both well-trained and experienced. With more states and countries acknowledging that DN is within the scope of physical therapist practice, patients will have greater access to qualified clinicians for the treatment of myofascial pain and dysfunction.

As the available literature does not overwhelmingly demonstrate superiority of TrPI over DN or of a particular solution for injection, it ultimately falls to the clinician to choose the initial treatment approach and individualize to each patient. Concomitant health issues, body habitus, and anatomy of treatment target are all factors to be considered when determining needle choice, solution, and possibly guidance assistance such as ultrasound or EMG. A combination of wet needling and DN may also be used. Subsequent treatments may be adjusted pending the patient's response.

There may be some benefit in the use of local anesthetics relative to postinjection comfort and possibly several weeks to months out from treatment. Lidocaine or procaine may be used at 1% or diluted with normal saline or sterile water down to a 0.5% or even 0.25% concentration. Longer-duration local anesthetic such as bupivacaine may be used but has not shown greater effect and may increase the component of myotoxicity and potential for longer neural blockade. Higher-concentration solutions have generally not shown better effect. Volumes greater than a few 10th of a milliliter at each site are generally not indicated. Limiting concentration, volume, and delay in the injection of local anesthetic may better allow the practitioner to localize TrPs and elicit LTRs.

Additives to TrPI solutions have been used empirically by clinicians but have limited or no support in the literature. Corticosteroids may have benefit in some patient types, but there is insufficient research to outline recommendations for use. Steroids carry additional local and systemic risks, especially if the dosage is higher, with multiple injection sites or with repeated use. A trial may be reserved for patients not responding to TrPI using only local anesthetic.

The use of neurotoxins in the treatment of myofascial pain remains controversial. It is possible that we have not yet fully teased out which patients are most likely to respond to the use of neurotoxin administration or which individual's pain may be temporarily exacerbated by its use. Given the higher costs associated for neurotoxin solution and administration, the use of local anesthetic TrPI should likely remain the first choice of intervention.⁵⁴ Evaluation for the use of neurotoxin should be reserved for cases in which

response to TrPI or DN is limited or not of adequate duration. Positive response to the use of neurotoxin can reduce the frequency or eliminate the need for TrPI. Some patients benefit from the availability of TrPI between neurotoxin sessions to address the residual areas of myofascial dysfunction.

DRY NEEDLING

It is important to consider that filiform needles are used in acupuncture and DN. A discussion of the differences between both approaches is beyond the scope of this text. The American Physical Therapy Association defines DN as a “skilled intervention using a thin filiform needle (usually an acupuncture needle) to penetrate the skin that stimulates myofascial TrPs, muscles, and connective tissue for the management of neuromusculoskeletal disorders.”⁷⁰

Some authors have described different DN techniques. Probably the most expanded needling intervention is the one described by Hong.¹¹ Hong¹¹ described his “fast in, fast out” method of needling of a TrP that has been precisely located by palpation. The palpating finger should stay over or straddle the taut band in order to guide the needle insertion directly to the TrP area. The needle is held by the other hand. With the thin (27-gauge) needle remaining deep to the subcutaneous tissue, the muscle fibers of the TrP are explored with multiple needle insertions. The needle movement is rapid, “fast in” and “fast out.” Hong has modified the technique as originally described by including a pause of 2 or 3 seconds between insertions. The pause following each insertion permits time to consider the tissue textures traversed by the needle and where to redirect the needle, the time for the identification of an LTR, and the time to immediately inject anesthetic solution into the same needle track when a twitch occurs. The needle is inserted deep enough to fully penetrate the TrP and then is pulled back to the subcutaneous tissue layer but not out of the skin. If the clinician is performing TrPI, a drop of 0.5% procaine (or lidocaine) is injected into the taut band following every LTR that is detected by the feeling of needle tip movement (from the hand holding the syringe), by palpating the twitch contraction (with the palpating hand), or by seeing, if the muscle is superficial, the movement of a visible twitch. The local analgesic agent should be injected only if an LTR accompanies needle insertion.

This rapid technique avoids muscle fiber damage from LTRs. Experience during research studies showed that LTRs are elicited more frequently when the needle is moved quickly rather than slowly. The track of needle insertion is usually very straight and the needle is less likely to be deflected by the dense contracture knots when the needle is inserted at high speed. For this reason, this “fast in, fast out” technique is well suited to the use of filiform (acupuncture) needles. Hong¹¹ originally proposed that an LTR should be obtained during the application of the technique to be effective. However, how many LTRs are needed to obtain a positive outcome is still debatable. A recent study has found no clinical differences in pain depending on the number of LTRs obtained during DN in the upper trapezius muscle in patients with neck pain.⁷¹ Similarly, another study suggests that

the LTR may not be as necessary as Hong¹¹ described for a successful outcome because no difference at 1 week was observed between patients experiencing LTR and those not experiencing LTR.⁷² Discrepancies in the published studies have lead some authors to question the need of LTR during DN.¹²

Gunn⁷³ recommends identifying TrPs by spot tenderness in a taut band and then using DN techniques. He first identifies the TrPs as a spot of localized tenderness in a taut band and then identifies the precise skin location through which to insert the needle using a dermatometer (point finder or skin resistance detector). He then inserts the needle through this location to the TrP where he feels a “grabbing” sensation at the needle tip, which is often associated with aching pain, as the needle enters into the TrP area. Gunn⁷³ defined this TrP needling technique as Intramuscular Stimulation.

The effectiveness of DN in many conditions is supported by systematic reviews and meta-analysis. For instance, it has been concluded that TrP-DN is effective, at least in the short term, for the management of pain conditions in the upper⁷⁴ and lower⁷⁵ quadrants, neck-shoulder pain,¹³ low back pain,⁷⁶ and plantar heel pain.⁷⁷ An interesting meta-analysis found evidence suggesting that DN applied by physical therapists was superior to no treatment or sham, but it has been found to be equally effective as other physical therapy treatments for short- and mid-term follow-ups in individuals with musculoskeletal pain.⁷⁸ No clear evidence of long-term effects of DN is available. Nevertheless, the Canadian Agency for Drugs and Technologies in Health has accepted the use of DN following an appropriate clinical reasoning in the public health system.⁷⁹

The underlying mechanism by which DN exerts its therapeutic effects is not understood, and both mechanical and neurophysiologic mechanisms are proposed.^{80, 81} From a mechanical point of view, disruption of the integrity of dysfunctional endplates, increase of sarcomere length, and reduction of the overlap between actin and myosin filaments are proposed.¹ From a neurophysiologic point of view, DN may reduce both peripheral and central sensitization by removing the source of peripheral nociception (TrP), by modulating spinal efficacy in the dorsal horn, and by activating central inhibitory pain pathways. Likely, DN acts simultaneously at different levels in this process.⁸²

TRIGGER POINT INJECTION AND DRY NEEDLING PROCEDURES

1. HEAD AND NECK PAIN (SECTION 2)

Trapezius Muscle (Chapter 6)

Trigger point injection or DN of the upper trapezius muscle may be performed with the patient positioned in supine, side-lying, or prone. The middle and lower trapezius TrPs are best approached with the patient positioned in prone or side-lying on the unaffected side, whereas the upper trapezius muscle can be needled in supine and prone, depending on the TrP location. Different systematic reviews suggest that DN of the upper trapezius muscle is effective for reducing pain in individuals with mechanical neck pain.^{4, 13} The results are also

maintained at 6-month follow-up.⁸³ Further, the application of DN into an active TrP of the lower fibers of the trapezius muscle was also effective for reducing pain in individuals with mechanical neck pain.⁸⁴

Upper Trapezius Fibers (Figure 72-6)

For TrPI or DN of the upper fibers of the trapezius muscle, the patient should be positioned in supine or prone. If the patient is unable to assume these positions, the side-lying position can be utilized. The TrP is identified with cross-fiber pincer palpation and held firmly in a pincer grasp to lift the muscle away from underlying cervical structures and the apex of the lung. The needle is directed in an anterior-posterior (Figure 72-6A) or posterior-anterior (Figure 72-6B) direction. When the needle penetrates a TrP, the LTRs are typically quite strong and numerous.

Figure 72-6. Trigger point injection or dry needling technique for upper trapezius muscle fibers. A, Supine. The needle is directed from anterior to posterior. B, Prone. The needle is directed from posterior to anterior. Note that the muscle is pulled away from the apex of the lung and other structures.

Middle Trapezius Fibers (Figure 72-7)

For TrPI or DN of the middle fibers of the trapezius muscle, the patient is positioned prone. The TrP is identified with cross-fiber flat palpation and fixed on the underlying rib. The clinician identifies and blocks the intercostal spaces over and under the corresponding rib with the index and middle fingers of the palpating hand to avoid entering the lung field

(Figure 72-7). The needle is directed toward the TrP. If the intercostal space can't be identified, the needle can be inserted tangentially and superficially into the muscle from a lateral to medial direction.

Figure 72-7. Trigger point injection or dry needling technique for the middle trapezius muscle fibers. Note the blocking of the intercostal space to avoid penetration of the lung field.

Lower Trapezius Fibers (Figure 72-8)

For TrPI or DN of the lower fibers of the trapezius muscle, the patient is positioned prone. The TrP is identified with cross-fiber flat palpation and fixed on the underlying rib. The clinician identifies and blocks the intercostal spaces over and under the corresponding rib with the index and middle finger of the palpating hand to avoid entering the lung field (Figure 72-8). The needle is directed from a posterior to anterior direction toward the TrP. If the intercostal space can't be identified, the needle can be inserted tangentially and

superficially into the muscle from a lateral to inferomedial direction.

Figure 72-8. Trigger point injection or dry needling technique for the lower trapezius muscle fibers. Note the blocking of the intercostal space to avoid penetration of the lung field.

Sternocleidomastoid Muscle (Chapter 7) Figure 72-9

Sternocleidomastoid TrPs often react to injection therapy with headache and more local soreness than do other muscles, perhaps because of the multiplicity of TrPs, some of which remain active in spite of treatment, or because of the strong autonomic influences of its TrPs. The muscle on only one side can be needled during the first session. Any TrPs on the contralateral side should be needled only after any reaction to the previous TrPI or after DN has subsided and if the injected TrP sites showed substantial improvement.

For TrPI or DN of either division, the patient is positioned supine (Figure 72-9A and B) and the TrP is identified with a cross-fiber pincer palpation and fixed with a pincer grasp between the clinician's thumb, index, and middle fingers. The muscle is slackened by

tilting the ear toward the shoulder on the affected side with the face turned slightly upward and to the opposite side; a pillow may be placed under the shoulder of the affected side to lift the chest and further slacken the muscle. The course of the external jugular vein is outlined by blocking the vein with a finger just above the clavicle and the carotid artery is identified. When the mid-level of the muscle is being needled, the vein can be shifted either laterally or medially by the clinician's finger to avoid penetrating it.

Figure 72-9. Trigger point injection or dry needling of the right sternocleidomastoid muscle into the mid-region of the muscle belly, with the patient supine, head tilted toward the same side as the affected muscle, and the face turned away. A, Mid-portion of the sternal (superficial) division. B, Mid-portion of the clavicular (deep) division. C, Injection seen in anatomic cross-section, at the level of the 4th cervical vertebra. The clinician has grasped both divisions using pincer palpation and pulled the muscle away from the underlying neurovascular structures.

For TrPI or DN of the sternal and clavicular heads (Figure 72-9B), the entire muscle should be encompassed by the clinician's thumb and fingers and lifted off the underlying blood vessels, nerves, and scalene muscles (Figure 72-9C). The needle is directed toward the clinician's finger on the posterior aspect of the muscle and the needle direction is from anterior to posterior. A TrP in the proximal portion of the muscle can be needled with the needle inserted and directed toward the clinician's finger and the mastoid process.

A 22- to 27-gauge hypodermic needle (preferably 25-gauge), that is 3.8 cm (1.5 in) long or a 0.30 × 30 mm filiform needle, should be selected. Penetration of the needle into the TrP at the precise point of maximal tenderness is confirmed by an LTR and/or by local

pain with projection of the pattern of referred pain. Through a single skin puncture, multiple needling with a continuous injection of 1 or 2 mL of 0.5% procaine solution can be carried out until pain and LTR are no longer elicited by the needle.^{31,85} Usually, TrPs in the superficial, more medial sternal division are inactivated first (Figure 72-4A), followed by the TrPs in the deeper and more posterior clavicular division (Figure 72-9B).

Occasionally, during TrPI at or above the mid-level of the sternocleidomastoid muscle, the patient may describe numbness in the face, which involves tissue deeper than the skin. The patient can still feel light touch, heat, and cold, and may also feel a prickling pain in the angle of the jaw, cheek, and pinna of the ear. These symptoms may be due to anesthetic infiltration of the posterior branch of the greater auricular nerve that loops around and traverses the face from the sternocleidomastoid muscle. Depending on the solution, the sensation of numbness disappears in 15 or 20 minutes, as the local anesthetic effect dissipates.

Masseter Muscle (Chapter 8) Figure 72-10

If the immediate treatment response of masseter TrPs to manual release techniques is not satisfactory, TrPI or DN of the masseter TrPs usually inactivates them. Trigger point injection or DN is most accurately performed with the patient positioned supine and the mouth slightly opened. Trigger points are typically located with cross-fiber flat palpation; however, cross-fiber pincer grasp may also be used with one digit localizing the TrP from inside the mouth against the thumb outside the mouth (Figure 72-10A). Needling of the posterior (deep) fibers requires awareness of the location of the facial nerve. The needle is directed into the muscle belly.

Figure 72-10. Trigger point injection or dry needling of the masseter muscle. A, Mid-belly of the superficial portion, using pincer grasp. B, Posteriorly located deep portion of the muscle, using flat palpation to fix the trigger point against the underlying ramus of the mandible, avoiding the facial nerve.

When the TrP is clearly identified and fixed between the clinician's index and middle fingers, the needle should be directed specifically into the muscle belly with multiple insertions (peppering) performed without withdrawing the needle (Figure 72-10B). The clinician should note any LTR and pain reactions indicating that the needle accurately encountered the TrPs.

Masseter TrPs are sometimes injected intraorally by qualified clinicians. For intraoral injection, a short thin needle (25- or 27-gauge 1-in) is satisfactory.⁸⁶ Intraoral injection has the advantage that it does not require penetration of the parotid gland where the facial nerve is also located as the nerve penetrates the gland.⁸⁷ Intraoral DN is not recommended by the authors of this chapter.

Temporalis Muscle (Chapter 9) Figure 72-11

The patient is positioned supine with the head quarter-turned in the opposite direction from the side to be treated. The TrP is identified by cross-fiber flat palpation, one finger is placed on the temporal artery to continuously monitor its location; other fingers localize and fix the TrP (Figure 72-11). The needle is inserted perpendicular to the skin and angled tangentially toward the temporalis fossa. Simons et al² recommend 0.5% procaine without epinephrine for intramuscular injection.⁸⁶ The masseter and temporalis muscles are synergistic for elevation of the mandible and therefore may have TrPs concomitantly. Because the masseter muscle is the more powerful muscle of the two, it should be examined for TrPs first and treated prior to TrPI or DN of the temporalis muscle.

Figure 72-11. Trigger point injection or dry needling of the temporalis muscle (light red). The temporal artery (dark red) is avoided. A finger is placed on the artery to continuously monitor its location; other fingers localize a TrP.

Medial Pterygoid Muscle (Chapter 10) Figure 72-12

It is only possible to needle the inferior portion of the medial pterygoid muscle.⁵⁰ Trigger points in the medial pterygoid muscle can be identified by cross-fiber flat palpation with the patient in the supine position with the head tilted back. The inferior portion of the muscle is fairly accessible when approached from the medial aspect of the angle of the mandible. The needle is directed laterally and superiorly toward the angle and ramus of the mandible (Figure 72-12).^{1, 11}

Injecting this muscle intraorally is more effective and should be performed only by qualified clinicians who are familiar with intraoral injections. To inject the muscle intraorally, the TrP is located by palpation and injected directly through the pharyngeal wall, as illustrated by Gelb.⁸⁸ A hyperactive gag reflex must be suppressed to use the intraoral route.

Figure 72-12. Trigger point injection or dry needling technique for the medial pterygoid muscle.

Lateral Pterygoid Muscle (Chapter 11) Figures 72-13 and 72-14

The lateral pterygoid muscle requires more skill than usual to apply manual therapy techniques to effectively treat this muscle; therefore, TrPI or DN may be helpful. The approach permits TrPI or DN of TrPs in the muscle bellies of both divisions. Only intraoral injection can reach the anterior musculotendinous junction region of the inferior division.

Trigger point injection or DN of either division of the lateral pterygoid muscle requires a detailed knowledge of the anatomy because of the difficulty in palpating the muscle and because numerous nerves and vessels neighbor it, including the pterygoid plexus. The needle must be oriented by visualizing the relation of the muscle and its TrPs to surrounding structures.

The patient is positioned supine with the face parallel to the ceiling. For TrPI or DN of TrPs in the inferior division, the jaw must be opened 22 to 30 mm (about 1 in) or more in order to open the bony window sufficiently. The window is bounded by the zygomatic arch above, the mandibular (semilunar) notch below, the coronoid process in front, and the mandibular condyle behind (Figure 72-13A). The needle is inserted just anterior to the neck of the mandible and is directed toward the roots of the upper molar teeth (Figure 72-13A and B). The needle usually must penetrate both the masseter muscle and part of the temporalis tendon to reach the inferior division of the lateral pterygoid muscle. The pterygoid plate, to which this muscle attaches anteriorly, is to the left of the dotted line in Figure 72-13A.

Figure 72-13. Trigger point injection or dry needling technique for the inferior division of the left lateral pterygoid muscle (dark red). A, Lateral view of its anatomic relationships when the jaw is propped open. The dotted line marks the posterior margin of the pterygoid plate to which the inferior division attaches. The needle reaches the inferior division through the bony aperture bounded by the zygomatic arch above, the semilunar (mandibular) notch below, the coronoid process in front, and the condyle of the mandible behind. B, Dry needling of the inferior division of the lateral pterygoid muscle.

For TrPI or DN of TrPs in the superior division, the jaw is opened, the needle is inserted just anterior to the temporomandibular joint (TMJ), and it is directed upward and forward, deep to the zygomatic arch, as illustrated by Cohen.⁸⁶ The TrP can be reached only after the full depth of the masseter muscle has been penetrated and the needle tip reaches the region under the zygomatic arch (Figure 72-14). The sphenoid bone forms the floor of the space within which the muscle lies. Gently encountering this bone with the needle establishes the full depth of this muscle. In the absence of a history of allergic reactions to procaine, 0.5% procaine in isotonic saline may be used rather than a long-acting local anesthetic. This solution choice reduces the likelihood of adverse reactions. Even if a nerve or blood vessel is penetrated, the dilute procaine is rapidly degraded by procainesterase as the drug enters the bloodstream. Lidocaine (Xylocaine) 2% or mepivacaine (Carbocaine) 3% has been used successfully by others, but the latter requires special care to avoid intravascular injection and provides little or no advantage. Epinephrine-containing solutions should not be used.

Figure 72-14. Trigger point injection or dry needling technique for the superior division of the lateral pterygoid muscle.

The needle should be replaced immediately if it contacts the bone and feels as if the tip has developed a burr that “catches” or “scratches,” instead of gliding smoothly through the tissue. A 3.8-cm (1½-in) 22- to 27-gauge needle or 0.30 × 50 mm filiform needle is adequate. A thinner needle is more likely to miss blood vessels, but may be deflected by connective tissues and by the contracture knots of TrPs unless the thin needle is inserted rapidly with the “fast in, fast out” technique of Hong.¹¹ When injecting this muscle with a local anesthetic other than 0.5% procaine, it is important not to inject while passing the needle to or from the muscle while the needle is traversing the pterygoid plexus, and in this case, it is important to aspirate for evidence of blood in the syringe before injecting.

The anterior (musculotendinous junction) portion of the inferior division is relatively easily reached *via* the intraoral approach for those familiar with intraoral injection, as described and illustrated by Gelb.⁸⁸ The TrPs of the inferior division would be accessible

only with the insertion of at least 2.5 cm (1 in) of needle into the muscle, and none of the superior division is accessible from inside the mouth. If intraoral tenderness due to enthesopathy persists after inactivating the TrPs in the muscle belly, recovery will be expedited by also injecting this insertional area with local anesthetic. Koole et al⁸⁹ reported successful identification and injection of lateral pterygoid TrPs intraorally. Other authors have recently described a different approach for accessing to the superior muscle belly of the lateral pterygoid muscle.⁹⁰

Digastric and Anterior Neck Muscles (Chapter 12) Figures 72-15, 72-16, and 72-17

If TrP sensitivity persists after the application of manual therapy techniques including TrP pressure release and a home management program, TrPI or DN can be attempted in the anterior neck muscles. With the patient supine, either the posterior or anterior belly of the digastric TrPs may be fixed between the clinician's fingers and needled. When needling the posterior belly of the digastric muscle, it is wise not to penetrate the external jugular vein that is readily identified by blocking the vein lower in the neck (Figure 72-15A). During injection with a 3.8-cm (1½ in) 22-gauge hypodermic needle (Figure 72-10B) or a 0.30 × 30 mm filiform needle, one finger is used to displace the vein; the taut band containing the TrPs is localized between two fingers for tactile guidance of the needle. The internal carotid neurovascular bundle lies deep to the muscle.⁸⁷ It is avoided by determining the size of the muscle by palpation and then by needling within the confines of the muscle; the needle is directed posteriorly, as illustrated (Figure 72-15B). A 27-gauge needle can be used but only with the Hong technique.¹¹

Figure 72-15. Trigger point injection or dry needling of the posterior belly of the digastric muscle. A, Manual occlusion of the external jugular vein to demonstrate its path near the angle of the jaw. B, Injection or DN of the muscle belly using the index finger to displace the external jugular vein to one side. The middle finger presses against the sternocleidomastoid muscle on the posterior aspect of the digastric muscle, and the posterior belly is fixed between the two fingers at the trigger point.

An LTR is an important indicator of a successful injection. When injecting posterior digastric TrPs, no effort is made to distinguish the posterior belly of the digastric muscle from the stylohyoid muscle. Needle penetration of these TrPs may cause a flash of pain over the occipital region, especially if that pain pattern is part of the patient's current pain report.

To needle the digastric anterior belly, the head and neck of the patient are extended, and the TrP spot tenderness in the taut subcutaneous muscle fibers is localized between two fingers of the palpating hand for needling (Figure 72-16).

Figure 72-16. Trigger point injection or dry needling of the anterior belly of the digastric muscle. The patient's head is tilted upward to gain access to the muscle.

If it is necessary to needle the other suprahyoid or infrahyoid muscles, a shorter (1 in, 27-gauge) hypodermic needle or 0.30 × 30 mm filiform needle is recommended with due consideration given to the local anatomy.

Trigger point injection or DN of the longus colli muscle is difficult and requires an advanced level of clinical experience and technique. The guide fingers are placed along a lateral border of the trachea and slowly advanced by separating the musculature from the adjacent trachea by gentle rocking and wiggling motions of the fingers. This palpatory advance stops when the fingertips reach the anterior portion of a vertebra, and the depth beneath the skin is carefully noted. Changes in the direction of pressure help locate the areas of maximum tenderness. The longus colli muscle can be a very thin muscle. The needle is advanced along the path identified by the fingers. It is advanced very slowly and gently as it approaches the depth of the vertebral structures to minimize hard contact with

the bony vertebra. Even gentle contact with the bone can bend the tip of the needle into a “fishhook” that feels “scratchy,” especially whenever the needle is retracted. If this contact occurs, the needle should be immediately withdrawn and replaced. The anterior surface of the longus colli is very gently explored with the needle tip in the regions where palpation against the anterior surface of the vertebral column elicited the greatest tenderness. The clinician’s palpating finger should remain in contact with the TrP during the entire needling technique (Figure 72-17).⁹¹

Figure 72-17. Trigger point injection or dry needling technique for the longus colli muscle. A, Frontal oblique view. B, Sagittal view. Note the middle finger holding the sternocleidomastoid muscle laterally to allow access to the longus colli muscle.

Facial Muscles (Chapter 13) Figures 72-18 and 72-19A

Trigger point injection or DN of TrPs in the facial muscles is usually more effective than treatment by self-stretch alone. Refer to Chapter 13 for the specific anatomic location of each the facial muscles. The facial muscles are very superficial and typically a 0.15 × 15 mm filiform needle can be utilized.

Trigger point injection or DN of the zygomaticus major muscle is performed with the patient in the supine position, and the muscle is held in a pincer grasp between the digits for injection of the taut band at its TrP under tactile guidance. The needle is directed toward the zygomatic bone (Figure 72-18).

Figure 72-18. Trigger point injection or dry needling of the right zygomaticus major muscle, using pincer grasp to localize the trigger points between the digits.

Trigger point injection or DN of the procerus muscle is performed with the patient in the supine position, and the TrP is located and fixed with pincer palpation. The needle is inserted superficially and directed in an inferior direction from the forehead toward the nose (Figure 72-19A).

Figure 72-19. Trigger point injection or dry needling. A, Procerus muscle. B, Frontalis muscle. Note that both muscles can be needled with a pincer grasp.

The other facial muscles may be needled with a similar approach to the ones described above, taking account for the specific anatomy of each.

Occipitofrontalis Muscle (Chapter 14) Figure 72-19B

The frontalis muscle fibers are thin and very superficial, which makes its TrPs difficult to locate with the needle tip. To inject or DN it, a 2.5 cm (1 in), 24- or 25-gauge hypodermic needle or 0.15 × 15 mm filiform needle respectively is directed across the muscle fibers (parallel to the eyebrow), nearly tangential to the skin (Figure 72-19B).

The occipitalis muscle belly is thicker than the frontalis muscle and may require a longer needle. Needling of these posterior TrPs is technically more satisfactory because they seem to lie in a small hollow that holds sufficient muscle mass to receive the needle. However, considerable probing of the area may be necessary to locate them.

Splenius Capitis and Splenius Cervicis Muscles (Chapter 15)

Splenius Capitis (Figure 72-20)

The splenius capitis muscle can be injected safely at the level of C2-C3 with appropriate precautions. The semispinalis capitis muscle lies deep to the splenius capitis muscle (Figure 72-20) and provides a buffer between it and the unprotected portion of the vertebral artery (see Figure 16-3). Also, the exposed artery lies cephalad to the C1 spinous process (see Figure 17-1). Therefore, the splenius capitis muscle can be safely needled by directing the needle inferomedially, below the C2 vertebrae (Figure 72-20), and remaining close to the frontal plane to control the depth of penetration.

The patient is positioned in side-lying with the affected side up, with the head supported on a pillow between the cheek and shoulder without bending or rotating the head and neck. The TrP is located by cross-fiber flat palpation. The clinician's finger identifies the taut band and directs the needle in a superior to inferior direction at a shallow angle toward the palpating finger.

Splenius Cervicis (Figure 72-20)

The patient is positioned the same as described for the splenius capitis muscle. Splenius cervicis TrPs are located mid-muscle belly⁹² and are found by cross-fiber pincer palpation at approximately the level of the C7 spinous process. At this level, the splenius cervicis muscle lies medial and deep to the levator scapulae muscle and continues inferiorly, deep to the rhomboid and serratus posterior superior muscles. This muscle is located between the lower end of the splenius capitis and levator scapulae muscles, and it is best needled with the needle directed from anterior to posterior direction (Figure 72-20). The needle may be directed medially as the muscle is located away from the intervertebral foramen laterally. In this approach, the needle enters the splenius cervicis muscle either anterior to or through the anterior border of the upper fibers of the trapezius muscle. A palpated LTR confirms needle contact with the TrP.

Figure 72-20. Trigger point injection or dry needling of the splenii muscles. A, Mid-portion of the splenius capitis muscle (light red), mid-portion of the splenius cervicis muscle (dark red). The semispinalis capitis muscle is shown without color. Needling of splenius capitis TrPs are safely performed below the thick black line below the level of C2. The exposed part of the vertebral artery lies superior to C1. B, Dry needling of the splenius capitis muscle with the needle directed inferomedially below C2. C, Dry needling of the splenius cervicis muscle with the pincer grasp in the lower cervical spine.

Posterior Cervical Muscles (Chapter 16)

Trigger point injection or DN is simplified by noting which segmental levels the TrPs typically occur for each of the posterior cervical muscles; although clinicians should remember that there is not a specific location of TrPs in any given muscle and the whole muscle must be examined. Injection or DN of TrPs in the upper portion of the

semispinalis capitis muscle above the level of the second spinous process should be avoided because of the proximity of the unprotected vertebral artery; however, this muscle can be needled below that level if appropriate precautions are taken.

Trigger points in the posterior cervical muscles frequently occur bilaterally, so it is often necessary to treat both sides. A common mistake is the failure to needle deeply enough. The vertebral artery is avoided by carefully noting the spinal level and avoiding needling deep into the lateral posterior neck at, or above, the level of the C2 spinous process (Figure 16-3).

Semispinalis Capitis and Cervicis (Figure 72-22)

For TrPI or DN of the semispinalis capitis and cervicis muscles, the patient is positioned side-lying with the affected side up and the taut band and TrPs are fixed by pincer grasp. The middle portion of the semispinalis capitis muscle lies deep to both the upper trapezius and splenius capitis muscles (see Figures 16-3 and 72-21), and therefore it requires relatively deep penetration. The needle is directed anterior to posterior at a shallow angle toward the clinician's finger and the posterior aspect of the cervical vertebrae (Figure 72-22).

Figure 72-21. Cross-section of the neck through the C5 vertebra that corresponds to the mid-muscle belly of the semispinalis capitis muscle. The bony parts of the vertebra are stippled black and are outlined by a dark line surrounding black stipples. The ruler shows that the 5-cm (2-in) needle cannot penetrate the full depth of the posterior cervical muscles without compression of the skin. The vertebral artery is surrounded by the vertebral transverse processes. It travels anterior to, and along, the lateral border of the posterior cervical muscles. Paraspinal muscles and major blood vessels are dark red; other muscles are light red.

Figure 72-22. Trigger point injection or dry needling of the left semispinalis muscles (middle semispinalis capitis, semispinalis cervicis muscles) at approximately C4 level. The red color locates the suboccipital triangle that should not be needled, so as to avoid the unprotected vertebral artery.

During TrPI of splenius cervicis TrPs, Simons et al² noted that a few patients fainted as a result of the strong autonomic stimulus associated with the release of these TrPs. This fainting usually follows multiple large twitch responses with visible deviation of the head in the direction of the twitch. When the head moves, it is likely that the fibers of the splenius capitis and splenius cervicis muscles contract together. If the patient is being treated for a “stiff neck,” any TrP in the levator scapulae muscle should be injected at the same time as those in the splenius cervicis muscle.

Cervical Multifidus (Figure 72-23)

For TrPI or DN of the cervical multifidus muscle, the patient is positioned in prone. These muscles are not readily available for digital palpation; therefore, the needling can be diagnostic as well as therapeutic. The clinical decision to needle these muscles should be based on the deep pain referral and patient symptoms. The needle is inserted approximately 1 cm lateral to the cervical spinal process below C2 and above T1 vertebral levels (Figure 72-23). The needle is directed inferomedially toward the TrP and lamina of the cervical vertebrae. In a cadaveric study using ultrasound, Fernández-de-las-Peñas et al⁹³ have demonstrated that this DN approach is safe and effective to access the cervical multifidus muscle.

Figure 72-23. Trigger point injection or dry needling for the cervical multifidus muscle.

Suboccipital Muscles (Chapter 17) Figure 72-24

If normal joint motion has been restored and other manual therapy techniques have failed to obtain expected results, and if the TrPs are resistant to noninvasive methods, it may be necessary to consider needling of the suboccipital musculature with full precautions. Trigger point injection or DN requires a comprehensive anatomic knowledge, especially in terms of the location and relationship of the vertebral artery to the suboccipital muscles. The obliquus capitis inferior muscle is the suboccipital muscle that can be safely needled because of the vertebral artery's position above the arch of C1.

For TrPI or DN of the obliquus capitis inferior muscle, the patient is positioned in prone. This muscle is needled between the spinous process of C2 and the transverse process of C1. The needle is directed in a cranial and medial (oblique) direction toward the patient's opposite eye (Figure 72-24).

Figure 72-24. Trigger point injection or dry needling of the obliquus capitis inferior muscle. Note that the left index finger is palpating the C2 spinous process and the middle finger is

palpating the transverse process of C1. The needle is directed toward the opposite eye.

2. UPPER BACK, SHOULDER, AND ARM PAIN (SECTION 3)

Levator Scapula Muscle (Chapter 19) Figure 72-25

For TrPI or DN of the levator scapula muscle (Figure 72-25), the patient is positioned in side-lying on the unaffected side with the back toward the clinician, and the patient's body is angled across the treatment table by placing the shoulder close to the edge of the table near the clinician. A pillow should support the head. The patient rests the uppermost arm on the body, with the elbow bent to balance it. If more tension is desired in the levator scapulae muscle, the uppermost arm can be placed in full internal rotation with the hand across the back to produce scapular winging. The clinician presses the free upper border of the trapezius muscle aside and palpates the levator scapulae muscle as it emerges from beneath the trapezius muscle (see Figure 20-7, Regional Anatomy, and Figure 72-21, Cross Section). The muscle is held in a pincer grasp for the needling technique. For the portion of the muscle that attaches to the superior angle of the scapula, the TrP is fixed between the clinician's index and middle fingers. The needle is inserted and directed toward the superior angle and upper border of the scapula at a shallow angle (Figure 72-25A).

Figure 72-25. Trigger point injection or dry needling of the levator scapulae muscle. A, The needle directed toward the superior angle of the scapula. B, Mid-muscle belly between C2 and C4.

For the mid-muscle portion, cross-fiber pincer palpation is used to identify TrPs laterally between the anterior border of the upper trapezius muscle and the transverse process of C1-C4. The TrP is fixed with a pincer grasp and the needle is directed toward the clinician's finger, or the TrP is fixed against a transverse process (Figure 72-25B). This muscle frequently has multiple taut bands and TrPs in its numerous fascicles, thereby making more extensive needling than most muscles necessary. This technique is also well illustrated by Rachlin.⁹²

Scalene Muscles (Chapter 20)

Trigger point injection or DN may be necessary for complete relief of symptoms caused by the scalene muscles, but it must be done with a full understanding of, and respect for, the local anatomy (see Figure 20-7).

Anterior and Medium Scalenes (Figure 72-26)

For TrPI or DN in the anterior and middle scalene muscles, the patient is positioned supine and the head is turned slightly away from the side to be needled (Figure 72-26). In addition, it may help to elevate the head and shoulder slightly with a pillow to place the sternocleidomastoid and trapezius muscles in a slackened position.

The anterior scalene muscle is located in a triangle formed by the base of the clavicle, the external jugular vein, and the lateral edge of the clavicular head of the sternocleidomastoid muscle. The middle scalene muscle is located in a triangle formed by the base of the clavicle, the brachial plexus, and the scalenus posterior muscle. All scalene TrPI or DN is performed at least 3.8 cm (1½-in) above the clavicle.

For the anterior scalene muscle, the needle is directed toward the transverse processes of the cervical vertebrae about 3 cm above the clavicle (Figure 72-26A). A taut band is fixed between the clinician's index and middle fingers to localize it for needling and to provide hemostasis during and after injection. The needle should be inserted well above the apex of the lung, which ordinarily extends about 2.5 cm (1 in) above the clavicle.⁸⁷

Figure 72-26. Trigger point injection or dry needling of the scalene muscles. A, Scalenus anterior muscle. B, Scalenus medius muscle. Fingers straddle the middle scalene muscle with the index finger in the groove between the scalenus anterior and medius muscles to locate the brachial plexus. The needle is directed posteriorly away from the groove to avoid the nerve fibers of the plexus.

When penetrated by the needle, scalene TrPs often refer sharp intense pain, strongly suggestive of neuropathic pain, to the arm and hand. This reproduction of the referred pain pattern is typical of scalene TrPs and does not necessarily indicate needle contact with brachial plexus nerve fibers. Effective penetration of a TrP consistently produces an LTR; penetration of a nerve does not. A 2.5-cm (1-in), 23- or 24-gauge hypodermic needle or a 0.30 × 30 mm filiform needle may be used. After TrPI or DN, pressure is maintained for hemostasis because bleeding within the scalene muscles causes local irritation.

For the middle scalene muscle, the needle should be inserted behind the brachial plexus, directed toward the posterior tubercle of the C2-C7 transverse processes of the cervical vertebra (Figure 72-26B).

Posterior Scalene

For needling of the posterior scalene muscle, the patient is positioned side-lying with the affected side up and the back toward the clinician; the head is tilted slightly toward the involved side to place the upper trapezius muscle on slack. The upper trapezius muscle will need to be pushed posteriorly to gain access to the posterior scalene muscle (see Figure 20-7). The needle is directed toward the posterior tubercle of the C4-C6 transverse processes of the cervical vertebra.

Supraspinatus Muscle (Chapter 21) Figure 72-27

The inclusion of DN of the supraspinatus muscle, combined with an eccentric exercise program, in patients with subacromial pain syndrome has been demonstrated to be effective at long-term follow-up for improving related-disability.⁹⁴

For TrPI or DN of the supraspinatus muscle, the patient is placed side-lying on the uninvolved side or prone, and the affected upper extremity is supported by a pillow. The TrPs are located by cross-fiber flat palpation and fixed between the clinician's index and middle fingers. A 3.2 to 3.8 cm (1.25-1.5 in) hypodermic needle or a 0.30 × 50 mm filiform needle is typically used. The needle is directed inferiorly and posteriorly toward the supraspinous fossa of the scapula just superior to the spine of the scapula (Figure 72-27B). The supraspinatus muscle is accessible only through the upper trapezius muscle, and the penetration of upper trapezius TrPs may produce a visible LTR and elicit referred pain to the neck. Continued movement of the needle deeper to penetrate the supraspinatus TrPs then elicits its referred pain pattern to the upper extremity. The clinician should probe the region with the needle to locate any additional supraspinatus TrPs.

If pressure on a well-localized spot deep in the lateral portion of the supraspinatus muscle refers pain in a pattern characteristic of the supraspinatus muscle, it is likely to be caused by an enthesopathy. The tenderness is elicited by applying pressure deep into the supraspinous fossa in the space between the spine of the scapula and the clavicle, just medial to the acromion. This location is beyond the reach of manual techniques and is marginal for the application of therapeutic pressure. The tenderness is usually best relieved by TrPI or DN of the tender spot using a needle that is long enough to reach it through the overlying upper trapezius muscle (Figure 72-27A). It is important to direct the needle precisely to the spot of deep tenderness. Needle contact with this sensitive region usually causes referred pain to the area of the deltoid muscle and down the arm.

Figure 72-27. Trigger point injection or dry needling of the right supraspinatus muscle and tendon with the patient lying on the left side. A, Needling the lateral region of the musculotendinous junction. B, Mid-muscle belly. For A and B, the index finger of the palpating hand is on the spine of the scapula and the middle finger is on the superior border of the scapula. C, Injecting the region of attachment of the supraspinatus tendon beneath the acromion, viewed from behind.

Tenderness beneath the tip of the acromion that remains following inactivation of supraspinatus TrPs is likely due to enthesopathy of the humeral attachment of the supraspinatus tendon, which is often identified as supraspinatus tendinopathy. This tenderness should respond to injection of a local anesthetic or DN (Figure 72-27C).

Infraspinatus Muscle (Chapter 22) Figure 72-28

DN of the infraspinatus muscle, combined with an eccentric exercise program, has been found to be effective at long-term follow-up for improving related-disability in patients with subacromial pain syndrome.⁹⁴

For TrPI or DN of the infraspinatus muscle, the patient is positioned side-lying on the unaffected side or prone. In the side-lying position, a pillow should be placed under the affected arm. The TrP is identified with cross-fiber flat palpation and fixed between the clinician's index and middle fingers against the scapula bone (Figure 72-28). The TrP is probed with a 3.8 cm (1.5 in) hypodermic needle or a 0.30 × 50 mm filiform needle until the needle elicits an LTR and/or the referred pain pattern of the TrP.

Figure 72-28. Trigger point injection or dry needling for the infraspinatus muscle. A, Superior muscle belly. B, Technique for middle and inferior muscle bellies.

Teres Minor Muscle (Chapter 23) Figure 72-29

A recent case report described the effectiveness of DN of infraspinatus and teres minor muscles for reducing upper extremity symptoms in a patient with an unclear medical diagnosis.⁹⁵ For TrPI or DN of the teres minor muscle, the patient is positioned side-lying on the unaffected side or prone. In the side-lying position, a pillow should be placed under

the affected arm (Figure 72-29A). In prone, the arm is positioned in 90° of glenohumeral abduction (Figure 72-29B). Trigger points are identified with cross-fiber flat palpation and fixed between the clinician's fingers at the lateral border of the scapula. The needle is directed toward the lateral border of the scapula.

Figure 72-29. Trigger point injection or dry needling technique for the teres minor muscle. A, Side-lying with the affected arm positioned to take up slack in the muscle. The index finger of the palpating hand is on the lateral border of the scapula. B, Prone position with the thumb of the palpating hand on the lateral border of the scapula. The needle is angled toward the lateral border of the scapula between the teres major and infraspinatus muscles.

Latissimus Dorsi Muscle (Chapter 24) Figures 72-30 and 72-31

For TrPI or DN of the proximal latissimus dorsi muscle, the patient is positioned in prone or supine with the shoulder abducted to 90°. Proximal TrPs are typically more closely related to shoulder and upper extremity symptoms. The side-lying position may also be used with the affected side up and the arm supported on a pillow. The TrPs are identified with cross-fiber pincer palpation (Figure 72-30). The TrPI or DN techniques are performed by grasping the muscle fibers within the posterior axillary fold in a pincer grasp between the thumb, index, and middle fingers (Figure 72-31A). The needle is directed from anterior to posterior toward the TrPs and the clinician's finger on the undersurface of the muscle. A strong LTR is usually both seen and felt when the needle penetrates a TrP. Both the superficial and deep axillary portions of the muscle should be probed for TrPs.

Figure 72-30. Cross-section view for TrP injection or dry needling technique of the right latissimus dorsi muscle, using pincer grasp.

The muscle must be palpated from origin to insertion to identify TrPs that must be treated to resolve the patient's reported symptoms. Trigger points in the mid-muscle belly are typically associated with thoracic spine pain and lateral trunk pain proximal to the iliac crest. For TrPI or DN, the same technique utilizing a pincer grasp as identified above may be used (Figure 72-31B). Trigger points over the trunk in muscle tissue that can't be pulled away from the trunk may be identified with cross-fiber flat palpation. The intercostal space is blocked above and below the rib where the TrP has been located, the TrP is fixed over a rib, and the needle is directed from a posterior to anterior direction tangentially toward the rib (Figure 72-31C).

Figure 72-31. Trigger point injection or dry needling of the latissimus dorsi muscle. A, Supine position with the arm abducted to 90°. B, Prone position. C, Intercostal space blocking for lower TrPs in the latissimus dorsi muscle.

Teres Major Muscle (Chapter 25) Figure 72-32

For TrPI or DN of the teres major muscle, the patient is positioned prone with the upper extremity in 50° to 60° of glenohumeral abduction. The supine and side-lying positions can also be used to treat this muscle. The TrP is identified within the posterior axillary fold and localized between the thumb and fingers with cross-fiber pincer palpation (Figure 72-32). The TrPI or DN techniques are performed with a pincer grasp and the needle is directed anterolaterally in the prone position (Figure 72-32A) and posterolaterally in the supine position (Figure 72-32B). In side-lying, the needle is directed from a posterior to anterolateral direction, away from the rib cage (Figure 72-32C). LTRs are clearly felt when the needle penetrates the TrP. It is common to have multiple TrPs in the teres major muscle. It is also possible to needle TrPs in the adjacent latissimus dorsi muscle through the

same skin puncture by directing the needle more laterally.

Figure 72-32. Trigger point injection or dry needling of the teres major muscle. A, Prone with pincer grasp. B, Supine with pincer grasp. C, Side-lying using pincer grasp with the upper extremity supported.

Subscapularis Muscle (Chapter 26)

Subscapularis TrPs can be treated from two different approaches: an axillary approach and a medial approach. Each of these techniques will be discussed separately.

Lateral (Axillary) Approach (Figure 72-33 A, B)

For TrPI or DN of the subscapularis muscle, the patient is positioned supine with the arm placed in 90° of glenohumeral abduction and full external rotation. The back of the patient's hand is placed on the forehead and a pillow can be placed under the upper arm if the patient can't tolerate the position (Figure 72-33A). The patient's body weight holds the scapula in position after it is pulled laterally (see Figure 26-4). If sufficient abduction and external rotation is not available to provide room for performing TrPI or DN, manual TrP release techniques should be applied to provide it. The TrPs are identified at the lateral margin of the anterior border of the scapula with cross-fiber flat palpation against the scapula. The TrPs are located and fixed between the fingers. A 6- or 7.5-cm (2½- or 3-in), 22-gauge hypodermic needle or 0.30 × 50 mm filiform needle is inserted between the clinician's fingers into the depth of the axillary fossa (Figure 72-33B). The needle is directed parallel to the rib cage and cephalad, toward the anterior surface of the scapula, directly into the TrP identified by palpation. The needle is inserted through the skin caudal to the TrPs being injected and directed cephalad to avoid encountering the rib cage, which can happen in this location.

Figure 72-33. Trigger point injection or dry needling techniques for the subscapularis muscle. A, Supine position along the axillary border of the scapula. B, Medial approach in prone with the upper extremity of the affected side in the “hammerlock” position.

Medial Approach (Figure 72-33C)

The medial approach requires a special consideration for TrPI or DN. The pain identified with cross-fiber flat palpation in this area could be a result of TrPs in the middle trapezius, lower trapezius, rhomboid, and/or serratus anterior muscles. Therefore, each of these muscles should be examined for TrPs, and if found, they should be inactivated. The subscapularis TrPs are needled with the patient lying prone with the glenohumeral joint in extension, adduction, and internal rotation so the back of the hand on the affected side is placed over the lumbar spine. This position, also known as the “hammerlock” position, will bring the medial border of the scapula away from the thorax. The needle is directed from medial to lateral toward the anterior surface of the scapula (Figure 72-33C).

Rhomboid Muscles (Chapter 27) Figure 72-34

For TrPI or DN of the rhomboid muscles, the patient is positioned prone with a pillow or towel roll placed under the anterior aspect of the shoulder to put the rhomboid muscle in a neutral resting position. Trigger points are identified with cross-fiber flat palpation over the rib cage. The risk of pleural penetration by the needle can be essentially eliminated by placing the index and middle fingers into the intercostal spaces above and below the site to be needled (Figure 72-34). A study looking at the depth of needle insertion for TrP injections for the rhomboid major muscle determined that from 62 patients who visited a clinic with shoulder or upper back pain, subjects who had a body mass index (BMI) <23, the depth from the skin to the rhomboid minor was 1.2 ± 0.2 cm, 1.4 ± 0.2 cm for ≥ 23

BMI ≤ 25 and 1.8 ± 0.3 cm BMI ≥ 25 .⁹⁶ Average thickness of the rhomboid major muscle for the underweight or normal BMI group (BMI < 23) was 0.9 ± 0.3 cm, for the overweight BMI (BMI ≥ 23 , but ≤ 25) was 1.0 ± 0.2 cm, and for the obese group (BMI ≥ 25) muscle thickness was 0.8 ± 0.3 cm.⁹⁶ Therefore, for TrPI or DN of the TrP, a 3.8-cm (1½-in) hypodermic needle or 0.30 × 50 mm filiform needle is directed almost tangential to the surface toward a rib to avoid penetrating an intercostal space, and therefore reaching the lung. Injection of 0.5% procaine or 1% lidocaine reduces postinjection soreness compared with DN.³²

Figure 72-34. Trigger point injection or dry needling technique for the rhomboid muscles. Note the towel roll under the anterior shoulder to place the rhomboid muscle on slack allowing better access to the TrPs. The index and the middle finger of the palpating hand block the intercostal spaces.

Deltoid Muscle (Chapter 28)

Anterior Deltoid (Figure 72-35A)

For TrPI or DN of the anterior deltoid fibers, the patient is positioned supine with the affected shoulder approximately 45° at glenohumeral abduction. Trigger points in the anterior deltoid muscle are identified using cross-fiber flat palpation and are often close to the anterior border of the muscle where the cephalic vein lies subcutaneously between the deltoid and pectoralis major muscles. When needling (Figure 72-35A), the clinician can avoid the vein by placing one finger of the palpating hand on it, penetrating the skin with the needle close to it, and directing the needle away from the vein and into the muscle tissue.

Figure 72-35. Trigger point injection or dry needling in the right deltoid muscle. A, Anterior deltoid muscle, with the patient supine (flat palpation and pincer grasp). B, Middle deltoid muscle, with the patient in side-lying (flat palpation and pincer grasp). C, Posterior deltoid muscle, with the patient lying prone (flat palpation and pincer grasp).

Middle Deltoid (Figure 72-35B)

For TrPI or DN of the middle deltoid fibers, the patient is positioned supine, side-lying, or prone. Because the middle deltoid muscle has multiple interlaced digitations, its taut bands are shorter than in the anterior and posterior fibers, and TrPs are more scattered throughout the muscle. Trigger points are identified with cross-fiber flat or pincer palpation. The TrP is fixed between the clinician's fingers and the needle is directed toward the humerus (Figure 72-35B). The clinician can also use a pincer grasp to fix the TrPs, and the needle can be directed from posterior to anterior or vice versa toward the TrPs and the

clinician's finger.

Posterior Deltoid (Figure 72-35C)

For TrPI or DN of the posterior deltoid fibers, the patient is positioned prone with the affected upper extremity in approximately 45° of glenohumeral abduction. Trigger points in the posterior deltoid are identified using cross-fiber flat palpation and fixed between the clinician's index and middle fingers. The needle is directed toward the humerus (Figure 72-35C).

Coracobrachialis Muscle (Chapter 29) Figure 72-36

For TrPI or DN of the coracobrachialis muscle, the patient is positioned supine with the shoulder at approximately 60° of abduction and external rotation. The coracobrachialis muscle can be needled above or below the pectoralis major muscle because the musculocutaneous nerve is located beneath the pectoralis major muscle and over the coracobrachialis muscle.

The TrPs are identified with cross-fiber flat palpation deep in the axilla by reaching beneath the pectoralis major muscle and pressing against the humerus on the dorsal aspect of the combined bundle of the short head of the biceps brachii and coracobrachialis muscles (Figure 72-36). The brachial artery is identified in the neurovascular bundle that lies posterior and medial to the coracobrachialis muscle, between the coracobrachialis muscle and the attachment of the lateral head of the triceps brachii muscle to the humerus. These structures must be clearly identified prior to TrPI or DN. To needle the proximal portion of the coracobrachialis muscle near the origin at the coracoid process, the needle is inserted above the pectoralis major muscle and through the anterior deltoid muscle, and it is directed shallowly toward the coracoid process that is localized with the clinician's palpating finger (Figure 72-36B).

Figure 72-36. Trigger point injection or dry needling of the coracobrachialis muscle. The neurovascular bundle must be identified before TrPI or DN and avoided. A, Proximal portion. B, Schematic diagram showing injection of the coracobrachialis muscle (dark red) through the deltoid and pectoralis major muscles. C, DN technique just distal to the pectoralis major muscle.

For TrPI or DN of the lower portion of the coracobrachialis muscle, the needle is directed from medial to lateral toward the upper third of the humerus (Figure 72-36C). Infiltration of local anesthetic may cause temporary weakness and anesthesia in the distribution of the musculocutaneous nerve with prompt recovery in 15 or 20 minutes depending on the solution used for injection.

Biceps Brachii Muscle (Chapter 30) Figure 72-37

For TrPI or DN of the biceps brachii muscle, the patient is positioned supine with the arm slightly abducted, the elbow is flexed to about 45°, and the TrPs are identified with cross-fiber pincer palpation and held firmly in a pincer grasp between the clinician's thumb, index, and middle fingers. The TrPs are needled in the region within the pincer grasp and probed to ensure the penetration of all TrPs that can produce LTRs. This technique may be used for both the short head and long head of the biceps brachii muscle. The needle is

directed from medial to lateral or lateral to medial toward the clinician's finger (Figure 72-37A). Needle penetrations may be aimed nearly tangential to the humerus, or may be directed perpendicularly toward it, avoiding the medial and lateral borders of the muscle.

Figure 72-37. Trigger point injection or dry needling of the biceps brachii muscle. A, Short head using the pincer grasp. B, Long head with the TrP fixed between the clinician's fingers.

Additionally, the TrPs may be located for needling by using flat palpation and straddling them with the index and middle fingers of the palpating hand. The TrPs are held against the underlying brachialis muscle, as in Figure 72-32B. During TrPI or DN, the clinician should avoid the median and radial nerves that lie along the medial and lateral borders of the distal portion of the biceps brachii and brachialis muscles, respectively.

Brachialis Muscle (Chapter 31) Figure 72-38

For TrPI or DN of the brachialis muscle, the patient is positioned supine with the arm slightly abducted, the elbow flexed to about 45°, and the palm facing up. The TrPs are identified with cross-fiber flat palpation by pushing the biceps brachii muscle medially. The brachialis muscle is a thick muscle, and its TrPs frequently lie deep, next to the humerus. During TrPI or DN, the clinician should avoid the median and radial nerves that lie along the medial and lateral borders of the brachialis muscle, respectively.⁸⁷ Approaching the muscle from the lateral side of the arm (Figure 72-38), the needle is directed medially and upward, probing widely to explore the lateral and middle portions of the muscle. The needle may lightly contact the humerus, which ensures reaching the full depth of the muscle. If the needle contacts the bone, it should be replaced immediately.

Figure 72-38. Trigger point injection or dry needling of the brachialis muscle, with the biceps brachii muscle pushed aside in a medial direction.

Triceps Brachii and Anconeus Muscle (Chapter 32)

Patient Supine or Side-Lying (Long Head; Figure 72-39)

For TrPI or DN of TrPs in the medial portion of the long head of the triceps brachii muscle, the patient is positioned in supine with the shoulder abducted and externally rotated, so that the antecubital space faces up to place the long head on a slight stretch (Figure 72-39A). The clinician identifies TrPs using cross-fiber pincer palpation and lifts the muscle belly away from the underlying bone, the adjacent major blood vessels and nerve, and away from the lateral head of the triceps brachii muscle (beneath which the radial nerve courses). The TrP is fixed and needled between the tips of the digits. Effective penetration of these TrPs by the needle produces LTRs that are easily seen and can be felt by the palpating fingers and thumb.

Figure 72-39. Trigger point injection or dry needling of the triceps brachii muscle. A, Anterior approach, with the patient supine. B, Posterior approach, with the patient lying on the uninvolved side.

If it is a more convenient position, or if the TrPs are located in the lateral part of the long head, this area can be approached from the lateral aspect of the arm. To do so, the patient is positioned side-lying with the affected side up, facing away from the clinician (Figure 72-39B), permitting the clinician to grasp the muscle and needle the TrPs as previously described.

Patient Side-Lying (Medial Head Lateral Border; Figure 72-40A)

For TrPI or DN of TrPs in the medial head of the triceps brachii muscle, the patient is positioned in side-lying with the affected side up and the arm supported on a pillow (Figure 72-40A). The TrP is identified using cross-fiber flat palpation distally in the lateral border

of the medial head, adjacent to the attachments of the extensor carpi radialis longus and brachioradialis muscles. For TrPI or DN, the TrP is fixed between the fingers by pressing the muscle on both sides of the TrP against the humerus, and the needle is directed toward the humerus (Figure 72-40A).

Figure 72-40. Trigger point injection or dry needling technique of the triceps brachii muscle in side-lying. A, Technique for needling the lateral border of the medial head, distally in the arm. B, Technique for needling the lateral border of the lateral head proximal (top) and distal (bottom) to the radial groove.

Patient Side-Lying (Lateral Head; Figure 72-40B)

For TrPI or DN of TrPs in the lateral head of the triceps brachii muscle, the patient is positioned in side-lying with the affected side up and the arm supported on a pillow. Commonly, TrPs are located along the lateral border of the lateral head, just above the exit of the radial nerve that courses beside the brachialis muscle and then beneath the brachioradialis muscle. Trigger points are identified with cross-fiber flat palpation and fixed between the clinician's index and middle finger. The needle is inserted tangentially into a

thin layer of muscle (Figure 72-40B) and may be directed either distally or proximally.

Patient Supine (Medial Head Medial Border; Figure 72-41)

For TrPI or DN of TrPs in the medial border of the medial head of the triceps brachii muscle, the patient is positioned prone with the arm in 90° of glenohumeral abduction with the arm off the examination table and resting on a pillow in the lap of the clinician (Figure 72-41). The TrPs are identified using cross-fiber flat palpation. The region of the TrPs is fixed between the clinician's index and middle fingers, with the needle directed parallel to the muscle fibers and usually upward toward the shoulder. These TrPs are not especially close to the neurovascular bundle.

Figure 72-41. Trigger point injection or dry needling of the medial border of the medial head of the triceps brachii muscle.

Anconeus (Figure 72-42)

For TrPI or DN of TrPs in the anconeus muscle, the patient is positioned prone, with the

elbow flexed to about 45°. The TrPs are identified with cross-fiber flat palpation and the needle is directed toward the ulna between the olecranon process and the lateral epicondyle of the humerus (Figure 72-42).

Figure 72-42. Trigger point injection or dry needling of the anconeus muscle. The index finger of the palpating hand is on the lateral epicondyle and the middle finger is on the olecranon process. A, Supine with the elbow flexed and arm supported on a pillow. B, Prone.

3. FOREARM, WRIST, AND HAND PAIN (SECTION 4)

Wrist Extensor and Brachioradialis Muscles (Chapter 34)

Wrist Extensors (Figure 72-43)

For TrPI or DN of the wrist extensor muscles, the patient is positioned supine with the forearm in full pronation resting on a pillow or other support. Because all three wrist extensor muscles are relatively superficial, palpation can precisely localize TrPs for needling. The extensor carpi radialis longus (ECRL) TrPs are identified with cross-fiber pincer palpation and then fixed with a pincer grasp between the clinician's thumb, index, and middle fingers. The needle is directed either medial to lateral or vice versa toward or between the clinician's fingers (Figure 72-43A). The ECRL muscle can also be needled with a flat palpation technique with the needle directed toward the radius. The extensor carpi radialis brevis (ECRB) muscle is medial to the ECRL muscle and its TrPs may be 3 or 4 cm (about 1½-in) more distal than ECRL TrPs. These TrPs are identified with cross-fiber flat palpation. The TrPs in the ECRB muscle are fixed between the clinician's index and middle finger and the needle is directed toward the radius (Figure 72-43B).

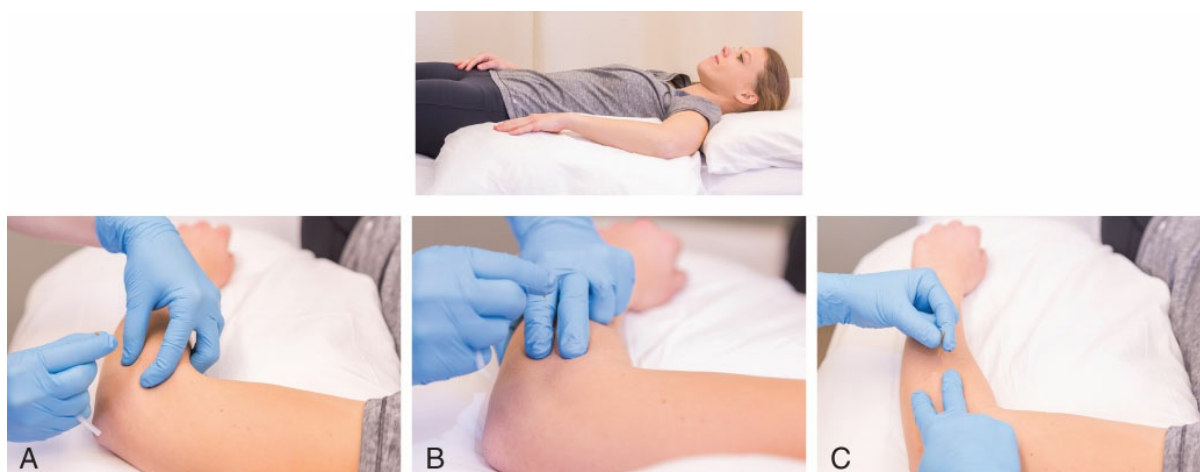

Figure 72-43. Trigger point injection or dry needling technique of the wrist extensor muscles. A, Extensor carpi radialis longus muscle with pincer grasp technique. B, Extensor carpi radialis brevis muscle with flat palpation technique. C, Extensor carpi ulnaris muscle with flat palpation technique.

For TrPI or DN of the extensor carpi ulnaris muscle, TrPs are identified with cross-fiber flat palpation and fixed between the clinician's index and middle finger. The needle is directed toward the ulna (Figure 72-43C).

Brachioradialis (Figure 72-44)

For TrPI or DN of brachioradialis TrPs, the patient is positioned supine with the forearm in pronation resting on a pillow or other support. The brachioradialis TrPs are identified with cross-fiber pincer palpation and fixed with a pincer grasp between the clinician's thumb, index, and middle fingers. The needle is directed from medial to lateral or vice versa toward or between the clinician's fingers (Figure 72-44).

Figure 72-44. Trigger point injection or dry needling of the brachioradialis muscle using the pincer grasp technique. Note that the forearm is in a neutral position.

For the purposes of TrPI or DN, it is useful to distinguish TrPs that lie in the deepest brachioradialis fibers (which usually have no effect on wrist motion) from those in the underlying ECRL fibers that radially deviate and extend the wrist; the superficial (sensory) branch of the radial nerve passes between these two muscles.

When referred pain is evoked in the base of the thumb by a deep TrPI in the proximal forearm, the TrP may lie either in the brachioradialis muscle or in the underlying supinator muscle.

Extensor Digitorum and Extensor Indicis Muscles (Chapter 35)

Extensor Digitorum (Figure 72-45 A, B)

For TrPI or DN of the extensor digitorum muscle, the patient lies supine with the forearm in full pronation resting on a pillow or other support. Because this muscle is relatively superficial, palpation can precisely localize TrPs for TrPI or DN. The TrPs in the extensor digitorum muscle are identified with cross-fiber flat palpation, and the TrPs are fixed

between the clinician's index and middle finger (Figure 72-45A). Because these are very flat muscles, it is best if the needle is inserted approximately 1 cm away and is directed toward the TrPs and the radius. Clinically, the middle finger extensor-muscle belly exhibits strong LTRs and clear pain patterns, as elicited by examination and needle penetration of the TrPs.

Figure 72-45. Trigger point injection or dry needling of the finger extensor muscles. A, Middle finger extensor muscle. B, Ring and little finger extensor muscles. Injection deep into the fourth and fifth finger extensor muscles sometimes also reaches a trigger point in the underlying supinator muscle, which refers pain to the lateral epicondyle. C, Extensor indicis muscle.

The TrPs in the 4th and 5th finger extensor muscles are located between those in the middle finger extensor fibers and the extensor carpi ulnaris muscle. The TrPs are identified with cross-fiber flat palpation and fixed between the clinician's index and middle fingers.

The needle is inserted about 1 cm away from the TrP and directed toward the point of deep tenderness (Figure 72-45B).

Occasionally, a deep radial (dorsal interosseous) nerve block may inadvertently be produced during injection of these TrPs. The patient should be warned beforehand of possible temporary extensor-muscle weakness that resolves in 15 or 20 minutes depending on the solution that has been injected.

Extensor Indicis (Figure 72-45C)

For TrPI or DN of the extensor indicis muscle, the patient is in the same position as for the other wrist and finger extensor muscles. Extensor indicis TrPs are identified with cross-fiber flat palpation at the dorsal aspect of the middle third of the radius. The TrP is fixed between the clinician's index and middle finger and the needle is directed toward the radius (Figure 72-45C).

Supinator Muscle (Chapter 36) Figure 72-46

For TrPI or DN of TrPs in the supinator muscle, the patient is positioned supine with the upper extremity in slight abduction, elbow slightly flexed, and forearm supported and fully supinated. The brachioradialis muscle is pushed laterally so TrPs can be identified with cross-fiber flat palpation against the radius. For TrPI or DN, the needle is directed proximally into the TrP just lateral to the attachment of the biceps brachii tendon, where maximum tenderness was found on palpation (Figure 72-46). It is often difficult to see or feel an LTR in this muscle except through the needle. When the forearm is supinated, the deep radial nerve passes through the muscle lateral to this area (see Figure 36-1B and C) and thus is not usually encountered during TrPI or DN. The dorsal aspect of the muscle may also be treated with TrPI or DN in a similar manner.

Figure 72-46. Trigger point injection or dry needling of the supinator muscle from the ventral aspect, with the brachioradialis muscle pushed laterally.

Palmaris Longus Muscle (Chapter 37) Figure 72-47

For TrPI or DN of the palmaris longus muscle, the patient lies supine with the arm slightly abducted, elbow extended, and the forearm fully supinated. The palmaris longus muscle, if present, is medial to the flexor carpi radialis muscle. Palmaris longus TrPs are identified by cross-fiber flat palpation and then fixed between the clinician's index and middle fingers. The needle is directed toward the TrPs and radius bone (Figure 72-47).

Figure 72-47. Trigger point injection or dry needling technique for the palmaris longus muscle.

Wrist and Finger Flexor Muscles (Chapter 38)

Wrist Flexor Muscles (Figure 72-48A, B)

For TrPI or DN of TrPs in the flexor carpi radialis (FCR) muscle, the patient is positioned supine with the upper extremity in slight abduction, elbow slightly flexed, and forearm supported and fully supinated. Trigger points in the FCR muscle are identified using cross-fiber flat palpation and are then fixed between the clinician's index and middle fingers. The needle is directed toward the TrPs and the radius bone (Figure 72-48A).

Figure 72-48. Trigger point injection or dry needling technique for the wrist and finger flexor muscles. A, Flexor carpi radialis muscle. B, Flexor carpi ulnaris muscle. C, Flexor digitorum superficialis muscle. D, Flexor digitorum profundus muscle.

For TrPI or DN of TrPs in the flexor carpi ulnaris (FCU) muscle, the patient is positioned supine with the glenohumeral joint in external rotation and the elbow in 90° flexion supported on a pillow to accommodate range-of-motion limitations (Figure 72-48B). The TrPs in the FCU muscle are identified by cross-fiber flat palpation and then fixed between the clinician's index and middle fingers. The needle is directed toward the TrP and the ulna bone (Figure 72-48B).

Finger Flexor Muscles (Figure 72-48C, D)

For TrPI or DN of the flexor digitorum superficialis (FDS) and flexor digitorum profundus (FDP) muscles, the patient is positioned supine with the elbow slightly flexed and the forearm in supination. Trigger points in the FDS muscle are identified by cross-fiber flat palpation and then fixed between the clinician's index and middle fingers. The needle is

directed toward the interosseous membrane (Figure 72-48C). The median nerve runs between the FDS and FDP muscles, and the ulnar nerve runs between the FCU and FDP muscles. Both nerves should be avoided by directing the needle from midline toward the radius or ulna bones.

For TrPI or DN of the FDP muscle, TrPs are identified by needle insertion and eliciting an LTR and/or identifiable pain pattern. Trigger points in the FDP muscle are usually located approximately 3 cm (about 1½-in) distal to the medial epicondyle (Figure 72-48D). Trigger points in the FDP muscle are sometimes responsible for entrapment of the ulnar nerve and may also be needled as illustrated for the FCU muscle (Figure 72-48B) except that they lie deeper and require penetration to at least 2 cm (nearly 1 in); this depth reaches beyond the FCU muscle into the FDP muscle.

Pronator Teres and Quadratus Muscles (Figure 72-49)

For TrPI or DN of the pronator teres muscle, the patient is positioned supine with the elbow slightly flexed and the forearm supinated. Trigger points are identified using cross-fiber flat palpation and then fixed between the clinician's index and middle fingers. The median nerve travels between the humeral head and ulnar heads of the pronator teres muscle; therefore, the muscle should be needled 1 to 2 cm below the medial epicondyle to avoid hitting the median nerve. The needle is directed toward the TrP and ulna bone (Figure 72-49A). The pronator teres muscle can also be needled in the distal portion of the muscle toward the radius.

Figure 72-49. Trigger point injection or dry needling technique for the pronator muscles. A, Pronator teres muscle. Note that the needle is directed toward the ulna (top) or distally toward the radius (bottom) to prevent hitting the median nerve. B, Pronator quadratus muscle dorsal approach. Note that the needle is directed from midline either radially (top) or ulnarly (bottom) to avoid hitting the anterior interosseous nerve.

For TrPI or DN of the pronator quadratus muscle, the patient is positioned the same as in the techniques for the pronator teres muscle. Trigger points in this muscle are identified with needle penetration because the muscle is too deep to palpate. The anterior interosseous nerve runs in the center of the forearm between the transverse and oblique heads of the muscle. The needle is directed toward the radius or ulna bones in the distal third of the forearm (Figure 72-49B).

Adductor and Opponens Pollicis Muscle (Chapter 39)

Adductor Pollicis (Figure 72-50A)

For TrPI or DN of the adductor pollicis muscle, the patient is positioned supine with the

forearm pronated or in mid-position. Trigger points are identified by cross-fiber pincer palpation and fixed with a pincer grasp between the clinician's thumb, index, and middle fingers (Figure 72-50A). The needle is directed from dorsal to ventral into the muscle and slightly toward the 2nd metacarpal. As the needle is directed toward this guiding finger, it should pass to the radial side of, or perhaps penetrate, the first dorsal interossei muscle.

Figure 72-50. Trigger point injection or dry needling techniques for thumb muscles. A, Dorsal approach for the adductor pollicis muscle. B, Radial approach for the opponens pollicis muscle.

Opponens Pollicis (Figure 72.50B)

For TrPI or DN of the opponens pollicis muscle, the patient is positioned supine with the forearm supinated. Trigger points are identified with either cross-fiber pincer or flat palpation. The needle is inserted from the radial aspect to avoid going through the palmar aspect of the thenar eminence (Figure 72-50B).

Interosseous, Lumbrical, and Abductor Digiti Minimi Muscles (Chapter 40)

Interossei and Lumbricals (Figures 72-51A and 72-52)

Trigger points in the palmar interosseous and lumbrical muscles are difficult to palpate; therefore, adequate exploration of the area with a needle is important. For TrPI or DN of the first dorsal interossei muscle, the patient is positioned supine with the hand in a mid-pronated or fully pronated position. Trigger points are identified with cross-fiber flat palpation, and the patient's index finger is fixed between the clinician's thumb and index fingers (Figure 72-51A). The needle is directed toward the TrP and the radial aspect of the 2nd metacarpal bone (Figure 72-51A).

Figure 72-51. Trigger point injection or dry needling technique of the intrinsic hand muscles. A, First dorsal interosseous muscle approached from the dorsal aspect. B, The abductor digiti minimi muscle, approached from the ulnar aspect of the hand.

For TrPI or DN of the second dorsal interossei muscle, the needle is aligned with the side of the 3rd metacarpal bone in the second interosseous space and is inserted into the center of the area (Figure 72-52A). If any tenderness remains, the needle is aligned with the 2nd metacarpal bone on the other side of the space, and the other head of the muscle is examined for TrPs.

For TrPI or DN of the first palmar interossei muscle (Figure 72-52A), the needle is directed away from the 3rd metacarpal bone to reach the muscle, which lies beneath the ulnar side of the 2nd metacarpal (Figure 72-52B).

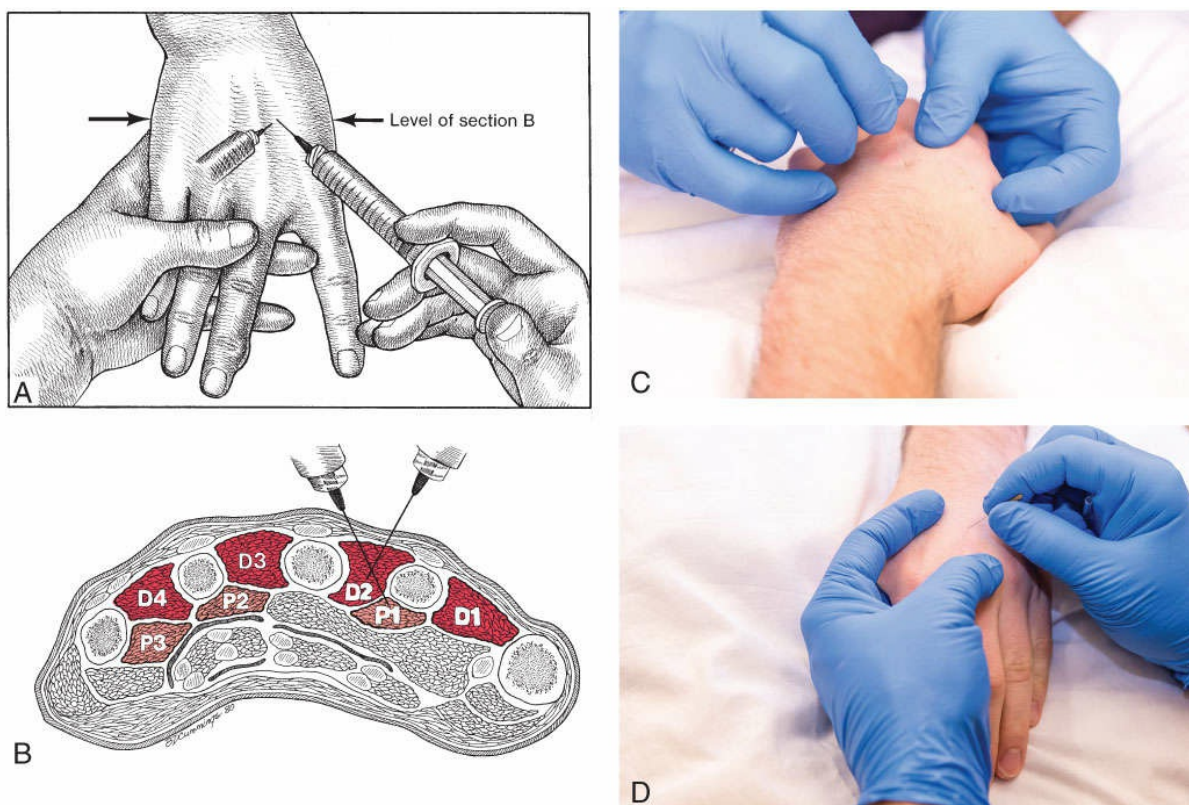

Figure 72-52. Trigger point injection or dry needling technique for the interossei muscles. A, The complete syringe is injecting a trigger point in the more ulnar penna of the second dorsal interosseous muscle; its corresponding Heberden's node is shown. The incomplete syringe is injecting the first palmar interosseous muscle that is reached as the needle penetrates deep to the 2nd metacarpal bone. B, Cross-section of A showing relation of the needles to the muscles being injected—dorsal interosseous muscles (dark red) and palmar interosseous muscles (light red). C, DN of the dorsal interosseous muscle. D, DN of the first palmar interosseous muscle.

For TrPI or DN of the four lumbrical muscles, the needle is inserted between the metacarpal bones like the interosseous technique. The lumbrical muscles lie closer to the palmar aspect of the hand on the radial side of its perspective metacarpal bone.

Abductor Digiti Minimi (Figure 72-51B)

Trigger points in the abductor digiti minimi muscle are identified with either cross-fiber flat or pincer palpation and are fixed with a pincer grasp between the clinician's thumb and index fingers. The needle is directed toward the 5th metacarpal bone (Figure 72-51B).

4. TRUNK AND PELVIS PAIN (SECTION 5)

Pectoralis Major and Subclavius Muscles (Chapter 42)

Trigger point injection or DN requires care when injecting pectoral musculature given its location over the ventral surface of the ribcage. Therefore, the clinician must be mindful of

the lung field and the depth of penetration of the needle to avoid entering the pleural cavity, possibly creating a pneumothorax. In the event that the clinician suspects that the needle violated the pleural cavity of the lung, the patient should be instructed to seek emergency care if he or she develops symptoms such as shortness of breath, persistent cough, or unusual chest or rib cage pain. The patient should inform the emergency room staff that he or she received a TrPI or DN treatment over the chest wall. Radiographs of the chest are used to confirm a pneumothorax. Pleural penetration during a TrPI or DN technique typically causes a more severe pain than that of TrPs. While a pneumothorax is less likely to occur when using a filiform needle than when using a hypodermic needle, it has been reported.⁹⁷

The clinician should be positioned comfortably and right-handed clinicians may have to perform the needling technique of the left pectoralis major muscle from the right side reaching across the patient, whereas the technique for the right pectoralis major muscle would be performed on the right side and vice versa for left-handed clinicians. Female patients should be asked to cover the breast with the hand and possibly move the breast tissue aside so TrPs may be needled effectively. For TrPs in the medial aspect of the sternal head, the patient's large breasts can be positioned on the ipsilateral side to move the breast tissue away from the medial aspect of the muscle.

Pectoralis Major Clavicular Head (Figure 72-53A)

For TrPI or DN of the clavicular head of the pectoralis major muscle, the patient is positioned prone with the upper extremity slightly abducted. Trigger points are identified with cross-fiber pincer palpation and fixed with a pincer grasp between the clinician's thumb, index, and middle fingers (Figure 72-53A). The needle is directed shallowly and tangentially toward the clinician's fingers to avoid penetration of the lung field and directed toward the clavicle or the shoulder (Figure 72-53A). Trigger point injection or DN may also be performed with a flat palpation; however, this technique increases the risk of penetration into the lung field.

Figure 72-53. Trigger point injection or dry needling of the pectoralis major muscle. A, Clavicular head utilizing a pincer grasp. B, Flat palpation technique for upper sternal fibers. Note the index and middle finger over the intercostal space to protect the lung field. C, Mid-sternal and abdominal fibers using a pincer grasp. D, Parasternal fibers with flat palpation with the intercostal spaces blocked.

Pectoralis Major Sternal and Abdominal Heads (Figure 72-53B-D)

About half of this most proximal portion of the pectoralis major's sternal section lies beneath the clavicular section (see Figure 42-2). Trigger points are identified with cross-fiber flat palpation and fixed over a rib between the clinician's index and middle fingers, which are placed in the intercostal spaces to prevent penetration into the lung field (Figure 72-53B). Trigger points in the upper, mid-sternal, and abdominal portion of the muscle are identified with cross-fiber pincer palpation and fixed with a pincer grasp between the clinician's thumb, index, and middle finger as in the technique for the clavicular head. The needle is directed tangentially and shallowly toward the clinician's finger and TrPs (Figure 72-53C).

Sternalis Muscle (Chapter 43) Figure 72-53D

Trigger points in the sternalis muscle are identified using cross-fiber flat palpation, and the TrP is fixed over a rib or the sternum between the clinician's index and middle finger which blocks the intercostal space. For TrPI or DN of the sternalis muscle, the technique described for needling the parasternal fibers of the pectoralis major muscle would be utilized (Figure 72-53D). The needle is directed toward the rib, and when a TrP is penetrated, the patient typically reports a projection of pain under the sternum and sometimes across the upper pectoral region and down the ulnar aspect of the arm as far as the elbow. LTRs are not observed in this muscle.

Pectoralis Minor Muscle (Chapter 44) Figure 72-55

Trigger point injection or DN requires care when injecting deeper pectoral musculature because the muscle is located over the ventral surface of the ribcage. Therefore, the clinician must be mindful of the lung field and the depth of penetration of the needle to avoid entering the pleural cavity, possibly creating a pneumothorax.

Parasternal and costal pectoral TrPs are identified with cross-fiber flat palpation, and the TrPs are fixed over a rib. The clinician identifies and blocks the intercostal spaces over and under the corresponding rib with the index and middle fingers of the palpating hand to avoid entering the lung field (Figure 72-53D). The needle is directed toward the rib tangentially and shallowly. If the rib can't be accurately identified, this technique should not be performed.

Subclavius Muscle (Figure 72-54)

Trigger points in the subclavius muscle can't be precisely identified with manual palpation; however, tenderness in the area of the muscle may be indicative of TrPs. For TrPI or DN, the patient is positioned supine. The needle is directed toward the point of maximum tenderness beneath the clavicle, usually in the middle of the muscle toward the junction of its medial and middle thirds (Figure 72-54).

Figure 72-54. Trigger point injection or dry needling of the subclavius muscle.

The patient is positioned supine with the upper extremity in a neutral position and supported with a pillow. Female patients should be asked to cover the breast with a hand and possibly move the breast tissue aside to allow the TrPs to be needled effectively. Trigger point injection or DN is performed by directing the needle nearly parallel to the chest wall and not toward the ribs, using pincer palpation wherever the patient's anatomy permits.

Trigger point injection or DN of pectoralis minor TrPs should be done after those in the pectoralis major muscle. Trigger points in the pectoralis minor muscle are identified with either cross-fiber pincer or flat palpation through the pectoralis major muscle, and the coracoid process should also be identified. To needle the proximal portion of the pectoralis minor muscle, the needle is directed superiorly and slightly laterally toward the coracoid process. The clinician must be aware that the neurovascular bundle to the arm lies under the pectoralis minor muscle close to the coracoid process. The angle of the needle is shallow, almost tangential to the rib cage (Figure 72-55A).

Figure 72-55. Trigger point injection or dry needling of the pectoralis minor muscle. A, Proximal portion using flat palpation. The needle is directed cranially, laterally, and shallowly toward the coracoid process. B, Mid-muscle belly using a pincer grasp. Finger tips are on the thoracic wall to avoid entering the thorax.

Serratus Anterior Muscle (Chapter 46) Figure 72-56

For TrPI or DN of the serratus anterior muscle, the patient is positioned in side-lying with the affected side up and the upper extremity resting on pillows in front, or the scapula is in adduction with shoulder extension with the elbow in flexion behind the patient to rest the wrist and hand on the trunk. Trigger points in the serratus anterior muscle are identified using cross-fiber flat palpation and fixed over a rib with the clinician's index and middle fingers over the intercostal space above and below the rib. The needle is directed toward the rib, at a shallow angle nearly tangential with the chest wall until the needle encounters the TrPs. These TrPs lie in the thin layer of the muscle between the rib and the skin (Figure 72-56). The pain reaction on needle contact with TrPs in this muscle is often less intense than the response from that of many other muscles.

Figure 72-56. Trigger point injection or dry needling of the serratus anterior muscle with the patient side-lying on the opposite side. A, Arm in front supported on pillows over the sixth rib in the mid-axillary line. B, Adduction of the scapula and extension of the arm afford access to the muscle's upper portion. The needle is directed toward an underlying rib. Note that the clinician's fingers block the intercostal spaces.

Because the long thoracic nerve exclusively supplies the serratus anterior muscle, some degree of anesthesia of this motor nerve is to be expected when injecting an anesthetic. However, the patient is unlikely to notice only temporary weakness of a part of the serratus anterior muscle.

Whenever possible, the clinician locates the pectoralis minor muscle underneath the pectoralis major muscle. The muscle is held between the thumb and the fingers in a pincher grasp with the tips of the fingers and thumb against the ribcage to determine the proper needling angle. The needle is directed toward the fingers to avoid needling into the lung field (Figure 72-55B).

Intercostal and Diaphragm Muscles (Chapter 45)

Trigger point injection or DN of the intercostal muscles should be performed only by highly trained clinicians and only with the use of ultrasonography for exact placement of the needle in the intercostal muscles.⁹⁸ Although beyond the scope of this textbook, a more common intervention for chest wall pain is an ultrasound-guided intercostal nerve block. Both are high-risk procedures for a pneumothorax.

Simons et al² described a technique for diaphragm TrPI, but in light of consultation with international experts, we have determined that TrPI or DN of the intercostal or diaphragm muscles places the patient at a high risk for a pneumothorax, hemothorax, hemothysis, or cardiac tamponade and therefore cannot be recommended here.⁹⁹

Serratus Posterior Superior and Inferior Muscles (Chapter 47)

Serratus Posterior Superior (Figure 72-57A)

For TrPI or DN of the serratus posterior superior muscle, the patient is positioned in prone with the scapula in full abduction and the arm hanging off the table, or the arm can be placed in extension, adduction, and internal rotation with the back of the hand resting on the low back (Hammerlock position). The TrPs are identified with cross-fiber flat palpation and fixed against an underlying rib, and the clinician's index and middle fingers are placed above and below the rib blocking the intercostal space (Figure 72-57A). The needle is directed nearly tangential to the thorax and is pointed toward a rib at all times.

Figure 72-57. Trigger point injection or dry needling technique for serratus posterior superior and inferior muscles. A, Serratus posterior superior muscle in prone with the scapula fully abducted. The black line denotes the vertebral border of the scapula. The needle is directed nearly tangential to the chest wall and toward a rib; the clinician's fingers block the intercostal spaces. B, Serratus posterior inferior muscle in prone. The needle is directed at a shallow angle toward the ninth, tenth, eleventh, or twelfth rib, depending on the location of the TrPs, and the clinician's fingers block the intercostal spaces.

Serratus Posterior Inferior (Figure 72-57B)

For TrPI or DN of the serratus posterior inferior muscle, the patient is positioned in prone or side-lying on the opposite side. Trigger points are identified with cross-fiber flat palpation and fixed against an underlying rib with the clinician's index and middle fingers

placed above and below the rib, blocking the intercostal space. The needle is directed at a shallow angle toward the ninth, tenth, eleventh, or twelfth rib, depending on which digitations are involved (Figure 72-57B).

Thoracolumbar Paraspinal Muscles (Chapter 48)

For TrPI or DN of the thoracolumbar paraspinal muscles, the patient is positioned prone with a pillow under the abdomen to passively position the lumbar spine in a neutral position. If a patient has an increased thoracic kyphosis, additional pillows may be required so the patient is comfortable.

Superficial Paraspinal (Erector Spinae) (Figure 72-58)

For TrPI or DN of the longissimus thoracis muscle, a cross-fiber flat palpation technique is used and the needle is inserted slightly superior to the TrP and is directed tangentially at a shallow angle toward the clinician's fingers and the TrPs (Figure 72-58A). If possible, the TrP can be fixed against and underlying rib, and the clinician may block the intercostal spaces with the index and middle finger.

Figure 72-58. Trigger point injection or dry needling techniques for the superficial thoracolumbar paraspinal muscles. A, Longissimus thoracis muscle using flat palpation and shallow needling technique with intercostal spaces blocked. B, Iliocostalis thoracis muscle using intercostal space blocking, and the needle is directed toward the rib. C, Iliocostalis lumborum muscle, prone with the needle directed inferomedially. D, Iliocostalis lumborum muscle, side-lying using a pincer grasp technique.

For TrPI or DN of the iliocostalis thoracis muscle, a cross-fiber flat palpation is used, and the TrP is fixed against an underlying rib, and the clinician's middle and index finger are placed over the intercostal spaces below and above the rib. The needle is directed tangentially toward the TrP and rib (Figure 72-58B). The iliocostalis lumborum TrPs are identified with a cross-fiber flat palpation, and the TrP is fixed between the clinician's index and middle finger. The needle is inserted just superior to the TrP and is directed inferomedially toward the TrP and between the clinician's fingers (Figure 72-58C). Alternatively, for the iliocostalis lumborum muscle, the patient can be positioned side-lying with the affected side up, and a pincer grasp technique is utilized below the 1st lumbar vertebrae. The needle is directed from a lateral to medial direction toward the lumbar spine across the iliocostalis lumborum muscle (Figure 72-58D).

Deep Paraspinal (Multifidus) (Figure 72-59)

For TrPI or DN of the thoracic and lumbar multifidus muscle, TrPs are identified with cross-fiber flat palpation in the thoracic region, and in the superficial multifidus muscle of the lumbar region just lateral to the spinous processes. The deep paraspinal muscles can be palpated only by utilizing a hypodermic or filiform needle that is at least 5 cm (~2 in) long. The region between the transverse process and the spinous process is considered a safe zone for needling in the absence of scoliosis (Figure 72-59A). Within this zone, the needle is directed somewhat caudally and medially, nearly parallel to the long axis of the spine and toward the base of the spinous process (Figure 72-59B and C).

Figure 72-59. Trigger point injection or dry needling techniques for the deep paraspinal

(multifidus) muscles. A, Safe needling zone in the valley next to the spinous process. B, Thoracic multifidus muscle with the needle directed inferomedially toward the lamina of the thoracic vertebra. C, Lumbar multifidus muscle with the needle directed in a slight medial and caudal direction toward the lamina of the lumbar vertebra. Both techniques are performed in the safe needling zone of the trunk.

Abdominal Muscles (Chapter 49)

Most of the abdominal muscles can be reached with a 3.8-cm (1½-in) hypodermic needle or a 0.30 × 50 mm filiform needle, unless the patient is obese. Better control of the needle is obtained by inserting it at a shallow angle instead of inserting it nearly perpendicular to the skin. The shallower angle makes it easier to align the shaft of the needle with, or perpendicular to, the muscle fibers, and to feel the changes in consistency of fat, fascia, and muscle as the needle penetrates successive layers. Care should be taken to avoid penetrating the peritoneal cavity with the needle. The patient is positioned supine with a pillow or bolster under the knees to relax the abdominal muscles.

External and Internal Oblique Abdominis (Figure 72-60)

Trigger point injection or DN of TrPs in the fibers of the external oblique muscle overlying the ribs employs a technique similar to the injection of the serratus anterior or serratus posterior muscles, with intercostal space blocking provided by the clinician's index and middle fingers with the TrP fixed against the rib below. The needle is directed shallowly toward the rib.

Trigger points in the external and internal oblique muscles are identified at the lateral aspect of the abdominal wall using cross-fiber pincer palpation, and the TrPs are fixed with a pincer grasp away from the abdominal contents with the clinician's thumb, index, and middle fingers. The needle is directed from an anteromedial to a posterolateral direction precisely into the TrPs between the clinician's fingers (Figure 72-60A). Alternatively, the side-lying position can be used for TrPI or DN of the lateral abdominal wall.

Figure 72-60. Trigger point injection or dry needling of the external and internal abdominal oblique muscles. A, Lateral abdominal wall using a pincer grasp pulling the muscles away from the abdominal contents. B, External oblique muscle proximal to the pubic arch.

For TrPI or DN of lower external oblique fibers proximal to the pubic bone, TrPs are identified with cross-fiber flat palpation and fixed between the clinician's index and middle fingers. The needle is directed from above tangentially and shallowly toward the TrPs and the pubic bone (Figure 72-60B).

The transverse abdominis muscle is the deepest of the abdominal muscles, and because of its depth and close proximity to the abdominal contents, it is not usually considered for TrPI or DN interventions unless the clinician can utilize ultrasound guidance.

Rectus Abdominis and Pyramidalis (Figure 72-61)

For TrPI or DN of the rectus abdominis muscle, its TrPs are identified by cross-fiber flat palpation. There are several transcriptions in this muscle; therefore, the entire rectus

abdominis muscle should be palpated for TrPs. The clinician is positioned opposite to the side that is to be needled. Once the TrP has been identified, the clinician depresses the abdominal wall just lateral to the TrP in the muscle and creates a shelf or “wall” by pulling the muscle toward the midline. The needle is directed medially toward the *linea alba*, tangential to the abdominal wall (Figure 72-61A).

Figure 72-61. Trigger point injection or dry needling of the rectus abdominis muscle. A, Mid-muscle, pulling the muscle toward the clinician creating a shelf. B, Upper rectus abdominis muscle in the space between the costal margin and the xiphoid process. The needle is directed parallel to the lower ribs and shallowly. C, Lower rectus abdominis muscle. The needle is directed shallowly toward the pubic bone. D, Pyramidalis muscle. The needle is directing superiorly and shallowly close to the midline, away from the pubic bone.

Trigger point injection or DN of upper rectus abdominis TrPs in the space between the costal margin and the xiphoid process requires careful skill with attention to the depth of needle penetration to avoid entering the abdominal cavity or the lung field. The needle is directed shallowly and parallel to the lowest ribs into the TrPs (Figure 72-61B).

For TrPI or DN of the lower rectus abdominis muscle, the TrPs are identified with

cross-fiber flat palpation and fixed between the clinician's index and middle fingers. The needle is directed toward the pubic bone (Figure 72-61C). Attention to needle depth is key because there is no posterior sheath to the rectus abdominis below the arcuate line, which lies a short distance below the navel. Trigger point injection or DN of the pyramidalis muscle is accomplished by directing the needle superiorly and shallowly close to the midline, away from the pubic bone (Figure 72-61D).

Quadratus Lumborum Muscle (Chapter 50) Figures 72-62 and 72-63

For TrPI or DN of the quadratus lumborum muscle, the patient is positioned in side-lying with the side to be treated facing up. If there is minimal space between the iliac crest and the twelfth rib, the patient can bring the ipsilateral arm overhead, and a bolster placed under the torso may improve access to the muscle. Anatomic landmarks that should be identified include the iliac crest, twelfth rib, and the spinous process of the 4th lumbar vertebrae (see Figure 50-11). The quadratus lumborum muscle is identified by cross-fiber flat palpation in the more anterior fibers of the iliocostal portion of the quadratus lumborum muscle near the crest of the ilium just lateral to the iliocostalis lumborum muscle below the L3 level (Figure 72-62). The latissimus dorsi muscle lies between the quadratus lumborum muscle and the skin. Strong pressure is applied to depress the subcutaneous tissue over the quadratus lumborum muscle. A 62- to 87-mm (2½- to 3½-in) 22-gauge hypodermic needle or 0.30 × 60 to 75 mm filiform needle is adequate. The needle is aimed essentially straight downward toward the tender spot and must be long enough to reach the depth of the transverse processes (Figure 72-63A). Penetration of a TrP in this muscle usually elicits a strong pain response in the patient, though LTRs are difficult to detect in these deep fibers. The muscle is explored with the needle for TrPs by successive partial withdrawals and reinsertions, probing down to the transverse processes. Some of the needle shaft must always be left extending outside the skin for safety. Otherwise, if the needle is inserted fully to its hub and the patient sneezes or lateral pressure is accidentally exerted on the syringe, the needle could snap at the hub and disappear under the skin.

Figure 72-62. Trigger point injection or dry needling technique for the quadratus lumborum muscle (dark red) as seen in cross-section (patient side-lying). The compressed latissimus dorsi muscle, through which the needle usually must pass, is medium red, and the other neighboring muscles are light red. The cross-section passes through the body of the L3 vertebra.

Figure 72-63. Trigger point injection or dry needling of the quadratus lumborum muscle. A, Deep quadratus lumborum muscle at L3. B, Iliotransverse fibers of the quadratus lumborum muscle.

For TrPI or DN of the iliotransverse portion of the quadratus lumborum muscle, TrPs are identified with cross-fiber flat palpation just lateral to the edge of the iliocostalis lumborum muscle at the level of the 4th lumbar vertebrae. The needle is directed inferolaterally toward the anterior surface of the iliac crest (Figure 72-63B).

Iliopsoas Muscle Group (Chapter 51) Figures 72-62 and 72-64

Generally, TrPI or DN of these muscles should be performed following inactivation of associated TrPs in the quadratus lumborum, rectus abdominis, rectus femoris, hamstring, and gluteal muscles. Iliopsoas TrPs can usually be inactivated by using manual therapy techniques, TrP self-pressure release, and self-stretching exercises. Occasionally, TrPs that remain require needling techniques. Iliopsoas muscle group TrPs can be identified with cross-fiber flat palpation in three areas with the patient in the supine position: (1) deep under the rectus abdominis muscle and abdominal contents for the psoas major muscle, (2) inside the brim of the pelvis on the anterior surface of the iliac crest just medial to the anterior superior iliac spine for the iliacus muscle, and (3) lateral to the femoral triangle

above the combined insertion into the lesser trochanter (see Figure 51-4).

For TrPI or DN of the psoas major muscle, the patient is positioned in side-lying with the side to be treated facing up. If there is minimal space between the iliac crest and the twelfth rib, the patient can bring the ipsilateral arm overhead, and a bolster placed under the torso can improve access to the muscle. Anatomic landmarks that should be identified include the iliac crest, twelfth rib, and the spinous process of the 4th lumbar vertebrae (see Figure 50-11). Strong pressure is applied to depress the subcutaneous tissue over the lateral trunk wall. A 62- to 87-mm (2½- to 3½-in) 22-gauge hypodermic needle or 0.30 × 60 to 75 mm filiform needle is adequate. The needle is aimed slightly anteriorly downward toward the TrP and must be long enough to reach the depth of the transverse processes of L4 vertebrae (Figure 72-64A). If the needle touches the transverse process, it must be repositioned more anteriorly to penetrate the posterior fibers of the psoas muscle. The clinician will depend on symptom report from the patient because LTRs are quite difficult to determine because of the depth of the muscle.

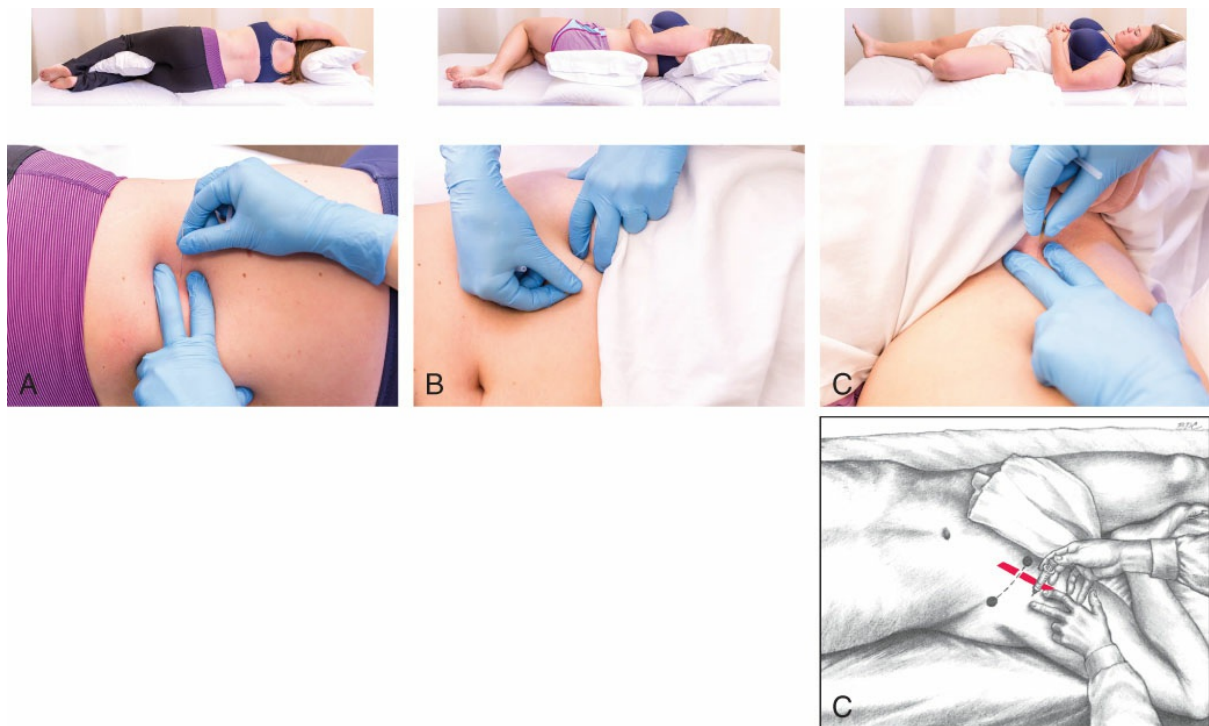

Figure 72-64. Trigger point injection or dry needling of the iliopsoas muscle group. A, Psoas major muscle, side-lying. B, Iliacus muscle, side-lying and ¼ turn backward (semisupine). C, Distal iliopsoas muscle group. The solid circles (lower illustration) cover the anterior superior iliac spine and the pubic tubercle. Between them, the inguinal ligament lies beneath the dashed line. The femoral artery is red. The thigh is abducted and externally rotated to separate the iliopsoas muscle and the femoral artery. The needle is directed toward the trigger point tenderness close to the lesser trochanter, laterally, away from the femoral artery.

For TrPI or DN of the iliacus muscle, the patient is positioned side-lying with the

trunk and pelvis $\frac{1}{4}$ turned backward (semisupine) to allow better access to the muscle. The clinician identifies the tender area inside the brim of the pelvis behind the anterior superior iliac spine and uses the index and middle fingers to fix the TrP against the anterior surface of the iliac crest. The needle is directed inside the crest of the ilium between the clinician's fingers and directed to the TrPs (Figure 72-64B). The needle must travel close to the inner surface of the ilium and may occasionally contact the bone, which ensures that the needle is within the muscle. LTRs are rarely observed, and a pain response by the patient usually indicates that the needle encountered TrPs.

For TrPI or DN of the distal portion of the iliopsoas muscle group, the patient is positioned supine near the edge of the plinth with the thigh slightly extended, abducted, and externally rotated to separate the iliopsoas muscle as far as possible from the femoral nerve and artery (Figure 72-64C). The femoral artery is identified by palpation medial to the iliopsoas muscle; however, the clinician must be aware that the femoral nerve lies between the iliopsoas muscle and the femoral artery. The clinician maintains contact with one finger on the femoral artery, and the needle is directed laterally and away from the femoral artery and nerve toward the lesser trochanter (Figure 72-64C).

Pelvic Floor Muscles (Chapter 52)

Generally, only the perineal and sphincter ani muscles are accessible for TrPI or DN therapy. Needling treatment should be employed only if the TrP and its taut band are unmistakably palpable and precisely located. For TrPI or DN of the ischiocavernosus muscle in either sex, and of the bulbospongiosus muscle in the male patient, the clinician uses cross-fiber flat palpation to localize the TrPs. In a female patient, a TrP in the bulbospongiosus muscle is localized and held between a fingertip in the vagina and the tip of the thumb on the labium majus and then needled through the labium.

Needling of the sphincter ani muscle is performed bimanually. A 10-mL syringe with a 63-mm (2½-in) 21-gauge needle or a 0.30 × 50 mm filiform needle is used. A palpating finger localizes the taut band and its TrPs in the anal sphincter muscle. When the needle approaches the sphincter ani muscle, its tip is felt by the finger in the rectum, and that finger then directs the needle precisely to the TrP. Frequently, there is a cluster of TrPs to be inactivated. The muscle should be thoroughly palpated for any remaining TrPs, and these should be treated before the needle is withdrawn.

Pubococcygeus Muscle of the Pelvic Diaphragm

For TrPI or DN of the pubococcygeus muscle, the patient is positioned in side-lying on the involved side with hips flexed to 90° and a pillow between the knees. The patient is asked to assist by lifting the gluteal muscles away from the anus. To approximate the muscle, the clinician places one finger on the perineal body and the other on the anal sphincter muscle. The other hand is used to palpate the pubococcygeus muscle through rectal palpation. The needle is angled at 45° toward the pubic bone, perpendicular to the muscle surface, and directly into the TrP identified by palpation. When the needle approaches the

pubococcygeus muscle, its tip is felt by the finger in the rectum, and that finger then directs the needle precisely to the TrPs.

Iliococcygeus Muscle of the Pelvic Diaphragm

The patient is positioned in side-lying on the involved side with hips flexed to 90° and a pillow between the knees. The patient is asked to assist by lifting the gluteal muscles away from the anus. The clinician places the fingers slightly inferior and lateral to the anal sphincter muscle to approximate the muscle, lateral to the pubococcygeus muscle. The other hand palpates the iliococcygeus muscle through rectal palpation. The needle is directed at a 45° angle toward the pubic bone, perpendicular to the muscle surface and directly into the TrP identified by palpation. When the needle approaches the iliococcygeus muscle, its tip is felt by the finger in the rectum, and that finger then directs the needle precisely to the TrPs.

Coccygeus Muscle of the Pelvic Diaphragm

The patient is positioned in side-lying on the involved side with hips flexed to 90° and a pillow between the knees. The patient is asked to assist by lifting the gluteal muscles away from the anus. The clinician identifies the coccygeus muscle through rectal palpation. With the other hand, the clinician places one finger on the coccyx and the other on the inferior lateral angle of the sacrum to approximate the location of the muscle. The needle is angled away from the rectum, perpendicular to the muscle surface and directly into the TrP identified by palpation. When the needle approaches the coccygeus muscle, its tip is felt by the finger in the rectum, and that finger then directs the needle precisely to the TrPs.

Ischiocavernosus

The ischiocavernosus muscle runs parallel to the ischiopubic ramus in both women and men, inserting into the ischial tuberosity distally. In the lithotomy position, the length of the ischiopubic ramus is examined to identify TrPs in the muscle belly through cross-fiber flat palpation. The needle is angled perpendicular to the muscle surface, directed toward the ischiopubic ramus and into the TrPs identified by internal or external palpation. In male patients, it is helpful to use a towel around the scrotum and have the patient move the scrotum out of the way. In female patients, the labia should be moved to the opposite side.

Bulbospongiosus (Bulbocavernosus)

In the lithotomy position, the muscle is identified with cross-fiber flat palpation. In the male patient, external palpation is sufficient. It is helpful to use a towel around the scrotum to help the patient move the scrotum out of the way. The clinician places one finger on the perineal body and the other superolaterally onto the muscle to brace the tissue. Muscle contraction can confirm placement. In the female patient, the same external technique may be used. Alternatively, the clinician can palpate the muscle using a cross-fiber pincer

palpation with the index finger inserted into the vagina. The muscle attachments to the perineal body distally and the clitoral aponeurosis proximally should be noted. The needle is directed at an angle, perpendicular to the muscle surface and directly into the TrP identified by palpation.

For male and female patients, the muscle can also be treated by directing the needle at a slightly tangential angle that may be preferred for women in cases of hypersensitivity or when patients do not consent to vaginal insertion. In female patients, the labia should be moved to the opposite side and caution used when needling near the area of the clitoris.

Superficial and Deep Transverse Perinei

In the lithotomy position, the needle is directed perpendicular to the muscle surface and directly into the TrP. The needle may also be directed slightly tangential to the muscle surface to avoid needling through the muscle. Placing one finger on the perineal body and the other on the lateral border of the ischial tuberosity helps brace the tissue. Muscle contraction can confirm placement. In female patients, it may be preferential to utilize vaginal palpation of the transverse perineal muscle and to identify its TrPs by cross-fiber pincer palpation, holding the TrP in a firm pincer grasp prior to needle insertion. In male patients, it is helpful to use a towel around the scrotum and have the patient move the scrotum out of the way. In female patients, the labia should be moved to the opposite side.

5. HIP, THIGH, AND KNEE PAIN (SECTION 6)

Gluteus Maximus Muscle (Chapter 54) Figure 72-65

For TrPI or DN of the upper portion of the gluteus maximus muscle, the patient is positioned prone with a pillow under the abdomen to place the lumbar spine in a neutral position. For TrPI or DN of the lower portion of the gluteus maximus muscle, the patient is positioned in side-lying; however, this position may also be used to needle the entire gluteus maximus muscle. Trigger points in the gluteus maximus muscle are identified using cross-fiber flat palpation for the entire muscle and cross-fiber pincer palpation in the lower portion.

In the prone position, the TrPs are identified and fixed between the clinician's index and middle finger with a strong compression of the subcutaneous tissue by the palpating hand to reduce the distance from the skin to the muscle, especially in those patients with a thick layer of subcutaneous fat. For thin individuals, a 21- or 22-gauge, 37-mm (1½-in) hypodermic needle or a 0.30 × 50 mm filiform needle is sufficient, but for some patients, a 21-gauge, 60-mm (2-in) or longer hypodermic or filiform needle may be necessary to penetrate the subcutaneous fat and the full thickness of the gluteus maximus muscle. The needle is directed between the clinician's fingers toward the TrPs (Figure 72-65A). Localized twitch responses are readily observable for this muscle when the needle penetrates the TrPs. The clinician should be aware of the path of the sciatic nerve when performing deep TrPI or DN of the gluteus maximus muscle.

Figure 72-65. Trigger point injection or dry needling of the gluteus maximus muscle. A, Gluteus maximus muscle in prone using the flat palpation technique. Note the compression of tissue by the palpating hand to reduce the space between the skin and the muscle. B, Lower portion side-lying using a pincer grasp, the needle is directed toward the TrP and lower fingers.

For TrPI or DN of the lower portion of the gluteus maximus muscle, TrPs are identified and fixed with a pincer grasp between the clinician's thumb, index, and middle fingers. The needle is directed toward the clinician's finger in the underside of the muscle (Figure 72-65B).

Gluteus Medius Muscle (Chapter 55) Figure 72-66

For TrPI or DN of the gluteus medius muscle, the patient is positioned either in prone or side-lying. Trigger points are identified using cross-fiber flat palpation and fixed between the clinician's index and middle finger with a strong compression of the subcutaneous tissue by the palpating hand to reduce the distance from the skin to the muscle, especially in patients with a thick layer of subcutaneous fat. Similar needle sizes as described in the gluteus maximus techniques should be utilized. The needle is inserted and directed toward the TrPs and deep needling contact with periosteum of the iliac crest is common (Figure 72-66). It is sometimes possible to detect an LTR through the overlying thick gluteus maximus muscle.

Figure 72-66. Trigger point injection or dry needling of the gluteus medius muscle. A, Posterior fibers. B, Anterior fibers.

Gluteus Minimus and Tensor Fasciae Latae Muscles (Chapter 56)

Gluteus Minimus (Figure 72-67)

Dry needling of lateral hip muscles has been found to be as effective as cortisone injections in patients with greater trochanteric pain syndrome.⁵⁵ For TrPI or DN of the gluteus minimus muscle, the preferred patient position is side-lying; however, the prone position may also be used. Trigger points are identified with cross-fiber flat palpation and fixed between the clinician's index and middle finger with a strong compression of the subcutaneous tissue by the palpating hand to reduce the distance from the skin to the muscle. Similar needle sizes as described in the gluteus maximus muscle techniques should be utilized. The needle is inserted and directed toward the TrP and with deep needling contact with periosteum of the iliac crest is very common (Figure 72-67A).

Figure 72-67. Trigger point injection or dry needling of the gluteus minimus muscle. A, Anterior fibers. B, Posterior fibers above the piriformis muscle to avoid the sciatic nerve.

For TrPI or DN of the posterior fibers, the lower posterior border of the gluteus minimus muscle is located by defining the upper limit of the piriformis muscle. Directing the needle above this line and in an upward direction normally eliminates the risk of accidentally penetrating the sciatic nerve as it exits the pelvis through the sciatic foramen (Figure 72-67B).

Tensor Fasciae Latae (Figure 72-68)

For TrPI or DN of the tensor fasciae latae muscle, the preferred patient position is side-lying (Figure 72-68A); however, the supine position may also be used (Figure 72-68B). In either position, TrPs are identified using cross-fiber flat palpation and fixed between the clinician's index and middle finger. The needle is directed posteriorly and toward the TrP (Figure 72-68). If the tensor fasciae latae muscle has been accurately identified, no major nerves or vessels lie in the path of the needle.

Figure 72-68. Trigger point injection or dry needling of the tensor fasciae latae muscle. A, Side-lying with flat palpation. B, Supine with flat palpation. The solid circle locates the anterior superior iliac spine. The dotted line identifies the inguinal ligament. The open circle marks the greater trochanter.

Piriformis and External Rotator Muscles (Chapter 57)

Piriformis (Figure 72-69)

For TrPI or DN of the piriformis muscle, the patient is positioned in side-lying or prone. The piriformis muscle can be needled either laterally, near the greater trochanter, or medially, immediately lateral to the sacrum. The clinician should identify the piriformis muscle attachments at the medial border of the sacrum (S2-S4) and the greater trochanter of the femur.

To needle the lateral part of the piriformis muscle, the patient lies on the uninvolved side with the uppermost hip flexed to approximately 90°. The superior border of the piriformis muscle is located by visualizing a line that runs from just above the greater trochanter to the point where the palpable border of the sacrum encounters the ilium at the inferior border of the sacroiliac joint. This piriformis line, shown in Figure 72-69A, is divided into thirds, and the piriformis muscle is palpated using cross-fiber flat palpation just inferior to it. The TrP is localized and fixed between the clinician's index and middle fingers.

Figure 72-69. Trigger point injection or dry needling of the piriformis muscle. The open circle locates the greater trochanter; the dotted line, the palpable margin along the edge of the sacrum; and the solid line, marked in thirds, overlies the upper margin of the piriformis muscle. A, Technique for the lateral portion of the piriformis muscle. B, Bimanual technique for the medial piriformis muscle. The left hand locates the TrP tenderness via intrapelvic palpation, and the right hand directs the needle toward that fingertip. C, Medial piriformis muscle.

Usually a 22-gauge, 50-mm (2-in) hypodermic needle is used on a 10-mL syringe, or a 0.30 × 50 mm filiform needle for lateral piriformis TrP location. The needle must be of sufficient length to reach through the skin, the gluteus maximus muscle, and the piriformis muscle to the hip joint capsule. This depth of penetration is necessary to ensure penetrating all of the TrPs in this portion of the piriformis muscle. Needle penetration of a TrP is recognized by the pain response of the patient, and particularly if it reproduces the patient's referred pain.

For TrPI or DN of the medial portion of the piriformis muscle, Simons and Travell¹⁰⁰ recommend that needling of TrPs in the medial region be accomplished bimanually. One finger palpates the inner surface of the medial third of the piriformis muscle using the rectal

or vaginal route; the other hand inserts the needle externally, directing the needle toward the intrapelvic palpating fingertip (Figure 72-69B). With sufficient finger-reach, it is possible to palpate both the pelvic inner surface of the piriformis muscle and the pelvic sciatic nerve against the sacrum, as well as the area of the greater sciatic foramen.

The medial portion of the piriformis muscle can also be needled without internal palpation. The needle is inserted just lateral to the sacrum and below the piriformis line and directed medially and inferiorly toward the TrPs and sacrum (Figure 72-69C).

Quadriceps Femoris and Sartorius Muscles (Chapter 58)

Rectus Femoris (Figure 72-72A)

For TrPI or DN of the rectus femoris muscle, the patient is positioned supine with a small towel roll placed under the knee to keep the knee in slight flexion. Trigger points are identified with cross-fiber flat palpation and then fixed between the clinician's index and middle fingers (Figure 72-72A). If the involved muscle has been confirmed to be the rectus femoris muscle and not the sartorius muscle, there should be little likelihood of penetrating the femoral artery or nerve with the needle.

Vastus Intermedius (Figures 72-72B and 72-73)

For TrPI or DN of the vastus intermedius muscle, the patient is positioned in the same way as the one for the rectus femoris muscle. Trigger points are identified with cross-fiber flat palpation; however, direct palpation of this muscle is quite difficult because it lies deep to the rectus femoris muscle, and TrPs in this muscle are often located just above the femur. The approximate location of the suspected TrP is fixed between the clinician's index and middle finger and the needle is directed from anterior to posterior toward the TrPs in the muscle (Figure 72-72B). Inactivating TrPs in this muscle requires much persistence and can be frustrating because the true severity is easily underestimated. Needling of TrPs in the vastus intermedius muscle usually causes intense referred pain.

As shown in the cross-section in Figure 72-73, there is no clear anatomic delineation between the deep lateral fibers of the vastus intermedius muscle and the deep medial fibers of the vastus lateralis muscle. They are commonly involved together. Many of the difficulties experienced when injecting TrPs or DN in one muscle apply to the other. When one finds TrPs in either the vastus intermedius or vastus lateralis muscles that need TrPI or DN, it is prudent to explore for TrPs in the other muscle.

Obturator Internus (Figure 72-70)

For TrPI or DN of the obturator internus muscle, the patient is positioned side-lying with the affected side down with the top hip and knee flexed (see Figure 57-8). Trigger points are identified at the insertion of the obturator internus muscle on the medial aspect of the ischial tuberosity. The needle is directed slightly anterior and toward the medial aspect of

the ischial tuberosity into the TrP (Figure 72-70).

Figure 72-70. Trigger point injection or dry needling of the obturator internus muscle at the medial border of the ischial tuberosity. Affected side down.

Alternatively, the obturator internus muscle can be needled with the patient in the lithotomy position. Trigger points are identified by cross-fiber flat palpation toward the obturator foramen, which is just lateral to the inferior border of the pubic ramus and the insertion of the adductor longus muscle tendon. The needle is directed laterally into the TrPs identified with either internal or external palpation.¹

Obturator Externus, Gemelli, and Quadratus Femoris (Figure 72-71)

No literature describes the identification and injection of TrPs in the remaining four short external rotators. For practical purposes, localization to a specific muscle is not necessary and one need only distinguish two groups of muscles: the two gemelli muscles and lateral part of the obturator internus muscle constitute one group; the quadratus femoris and underlying obturator externus muscles constitute the other. The patient is positioned prone, and TrPs in these muscles are identified with cross-fiber flat palpation on the

posterior aspect of the greater trochanter. Pain upon palpation at the upper $\frac{1}{3}$ of the greater trochanter may be attributed to TrPs in the gemelli and obturator internus muscles. Pain upon palpation at the lower $\frac{2}{3}$ of the greater trochanter may be attributed to TrPs in the obturator externus and quadratus femoris muscles (see Figure 57-7).

When a TrP is identified in one of these groups and TrPI or DN is deemed necessary, the path of the sciatic nerve as it crosses over these muscles, usually midway between the ischial tuberosity and the greater trochanter, must be considered. The needle is directed toward the medial, posterior surface of the greater trochanter. The location at the posterior greater trochanter along with the patient's pain report can lead the clinician to determine which muscles are affected (Figure 72-71).

Figure 72-71. Trigger point injection or dry needling of the hip external rotator muscles. The black line depicts the greater trochanter of the femur. A, Gemelli and obturator internus muscles at the upper $\frac{1}{3}$ of the posterior greater trochanter. B, Obturator externus and quadratus femoris muscles at the lower $\frac{2}{3}$ of the posterior greater trochanter.

Vastus Medialis (Figure 72-72 C, D)

A recent study has demonstrated that DN of the vastus medialis muscle was effective for improving range of motion and related-disability in individuals who have undergone surgical reconstruction after complete anterior cruciate ligament rupture.¹⁰¹

For TrPI or DN of the vastus medialis muscle, the patient is positioned with the hip flexed and abducted and the knee flexed to approximately 90°, as illustrated in Figure 72-72C and D, to make the entire muscle accessible. Trigger points in the vastus medialis muscle are identified with cross-fiber flat palpation and fixed between the clinician's index and middle finger. For TrPI or DN in the proximal portion of the muscle, the femoral artery, which courses along that border, should be identified and the needle should be angled laterally away from the sartorius muscle and the artery (Figure 72-72C). For TrPI or

DN of the distal portion of the muscle, the needle is directed toward the TrPs and femur, and it is very common to make contact with the femur with the needle (Figure 72-72D).

Figure 72-72. Trigger point injection or dry needling techniques for the quadriceps femoris muscle group. A, Rectus femoris muscle. B, Vastus intermedius muscle. C, Vastus medialis proximal muscle. Note that the needle is directed slightly anteriorly and laterally. D, Vastus medialis muscle distal location.

Figure 72-73. Cross-sectional anatomy of the right thigh at mid-thigh level (see Figure 58-1), looking down from above. The blood vessels are dark red and the quadriceps muscles are medium red. All other muscles, including the adductor group and hamstring muscles, are light red.

Vastus Lateralis (Figure 72-74)

For TrPI or DN of the large vastus lateralis muscle, the patient is positioned supine for the anterior portion and side-lying for the posterior portion. To access the posterior portion, it is often necessary to push the biceps femoris muscle aside to reach the posterior vastus lateralis muscle, which is located posteriorly against the posterior aspect of the femur. Trigger points in the vastus lateralis muscle are identified with cross-fiber flat palpation, and because of the size of this muscle, multiple TrPs are usually identified. The TrP is fixed between the clinician's index and middle finger, and the needle is directed in an anterior to posterior direction into the muscle belly and under the iliotibial band in the supine position (Figure 72-74A and B).

Figure 72-74. Trigger point injection or dry needling of the vastus lateralis muscle. A, Proximal anterior portion. B, Proximal distal portion. C, Posterior portion with a pincer grasp. D, Distal portion with patella glided medially.

For TrPI or DN of the posterior portion of the vastus lateralis muscle in the average-sized individual, 63-mm (2½-in) hypodermic or 0.30 × 50 mm filiform needle may be required to reach the deepest part of the muscle posteriorly. The patient is positioned side-lying, and the TrPs are identified with cross-fiber pincer palpation and then fixed with a pincer grasp in between the clinician's thumb, index, and middle fingers. The needle is directed slightly anteriorly to stay in the vastus lateralis muscle and not enter the adjacent hamstring muscle (Figure 72-74C). When penetrated, these TrPs are likely to refer pain to the back of the knee. This is a region where the needle may have to substitute for the palpating finger to find the TrPs. Locating all of the vastus lateralis TrPs and needling them specifically can be tedious, but it becomes necessary when other methods of therapy fail to inactivate them fully.

Genu Articularis and Tensor of the Vastus Intermedius (Figure 72-75A, B)

For TrPI or DN of the genu articularis muscle, the needle is directed through or

underneath the tendon of the distal rectus femoris muscle toward the femur. The tensor of the vastus intermedius muscle is needled by angling the needle slightly laterally toward the vastus lateralis and vastus intermedius muscles (Figure 72-75A and B).

Figure 72-75. Trigger point injection or dry needling of the (A) genu articularis muscle. B, Tensor of the vastus intermedius muscle. C, Sartorius muscle.

Sartorius (Figure 72-75C)

For TrPI or DN of the sartorius muscle, TrPs are identified with cross-fiber flat palpation and fixed in between the clinician's index and middle fingers, whereas the needle is directed tangentially, nearly parallel to the surface of the skin (Figure 72-75C). It is common that a sartorius TrP can be discovered serendipitously during TrPI or DN of a vastus medialis TrP deep to the sartorius muscle. When the needle encounters this superficial sartorius TrP, the patient reports a sharp or tingling pain felt diffusely over the adjacent thigh.

Adductor Muscles (Chapter 59)

Adductor Longus and Adductor Brevis(Figure 72-76A, B)

The femoral artery lies deep to the sartorius muscle and lateral to the long and short adductor muscles. For this reason, the femoral artery should first be located by palpating for a pulse and the anterolateral border of the adductor longus muscle, and then the needle should be directed posteromedially from there. In this way, one injects away from, not toward, the femoral artery.

For TrPI or DN of the adductor longus and brevis muscles, the patient is positioned supine with the hip and knee flexed and the hip externally rotated and abducted. Trigger points in both muscles are identified by cross-fiber pincer palpation and then fixed with a pincer grasp between the clinician's thumb, index, and middle fingers. For the adductor longus muscle, the needle is directed from an anterior to posterior direction into the TrPs of the muscle (Figure 72-76A).

Figure 72-76. Trigger point injection or dry needling of the adductor longus, adductor brevis, and adductor magnus muscles. A, Adductor longus muscle using the pincer grasp technique. B, Adductor brevis muscle using the pincer grasp. C, Adductor magnus muscle, mid-portion (through the gracilis muscle) with the flat palpation technique. D, Adductor magnus muscle, ischiocondylar portion with a pincer grasp.

For TrPI or DN of the distal vastus lateralis muscle, the patient is positioned side-lying, the patella is glided medially, and the TrPs are identified with cross-fiber flat palpation and fixed between the clinician's index and middle fingers. The needle is directed toward the TrP and femur (Figure 72-74D).

For TrPI or DN of the adductor brevis muscle, TrPs are fixed with a pincer grasp and the needle is inserted between the pectineus and adductor longus muscle, perpendicular to the adductor brevis muscle, and directed posteriorly toward the clinician's fingers and into the TrPs of the muscle (Figure 72-76B). Oftentimes, the adductor longus and brevis muscles may be needled together with the same pincer grasp technique.

Adductor Magnus (Figures 72-76C, D and 72-77)

A review of cross-sectional anatomy (Figure 72-77) is recommended before injecting the deeper portions of the adductor magnus muscle. For TrPI or DN of the adductor magnus muscle, the patient is positioned supine, hip and knee flexed, and the hip in external rotation and abduction. Trigger points in the proximal ischiocondylar portion are identified with cross-fiber pincer palpation and fixed with a pincer grasp in between the

clinician's thumb, index, and middle fingers. The needle is directed from an anterior to posterior direction (Figure 72-76C).

Figure 72-77. Cross-section of the thigh at the junction of its upper and middle thirds. See Figure 60-1 for the level of cross-section. Hamstring muscles, arteries, and veins are dark red. At this level, the adductor magnus muscle (intermediate red) is considerably larger than the hamstring muscle group. Other muscles of the thigh are light red. In this section, the semitendinosus and biceps femoris muscles appear to be fused. Redrawn with permission from Anderson JE. *Grant's Atlas of Anatomy*. 8th ed. Baltimore, MD: Williams and Wilkins; 1983.

For TrPI or DN in the mid-portion or proximal adductor magnus region, the femoral artery is unlikely to be encountered because the adductor longus muscle lies between the femoral artery and the anterior surface of the adductor magnus muscle. However, when needling from the medial aspect of the thigh (Figure 72-76D), the sciatic nerve, which passes against the adductor magnus muscle, between it and the hamstring musculature, should be avoided. The nerve passes deep to the ischiocondylar and middle parts of the adductor magnus muscle.

Gracilis (Figure 72-76C)

For TrPI or DN of the gracilis muscle, the patient is positioned as in the technique for the adductor magnus muscle. If more tension is needed on the muscle, the knee is extended.

Trigger points are identified by either cross-fiber flat or pincer palpation of this superficial muscle, and they may be needled using either the pincer or flat palpation technique, depending on the flexibility of the subcutaneous tissue. The needle is directed perpendicular into the TrP which is fixed between the clinician's index and middle finger (Figure 72-76C).

Pectineus (Figure 72-78)

Simons et al¹⁰⁰ recommended release of the adductor magnus, longus, and brevis TrPs prior to performing TrPI or DN to the pectineus muscle. For TrPI or DN of the pectineus muscle, the patient is positioned supine with the hip and knee flexed, and the hip in external rotation and abduction to gain maximal access to the pectineus muscle. This position also shifts the femoral artery toward the lateral margin of the muscle, because the vessel is fixed distally at the adductor hiatus. Trigger points are identified with cross-fiber flat palpation and fixed in between the clinician's index and middle fingers. The femoral pulse is detected and the needle is directed medially and posterior into the muscle and TrPs (Figure 72-78).

Figure 72-78. Trigger point injection or dry needling of the pectineus muscle (light red). The thigh of the patient is placed in abduction, external rotation, and slight flexion. A, The solid circle locates the anterior superior iliac spine; the dashed line, the inguinal ligament; and the open circle, the pubic tubercle. The femoral artery (dark red) is avoided by palpating its pulsations and directing the needle medially away from it. B, Dry needling with middle finger of the palpating hand on the femoral artery.

Hamstring Muscles (Chapter 60) Figure 72-79

Prior to TrPI or DN of the hamstring muscles, one should review the course of the sciatic

nerve. It passes down the posterior thigh underneath the long head of the biceps femoris muscle, which crosses over it about mid-thigh. Proximally, the nerve reaches the lateral border of the long head while still deep to the gluteus maximus muscle. Distally, at the popliteal space, the nerve's tibial portion emerges from under the medial border of the long head of the biceps femoris muscle about where the semimembranosus muscle and the long head part company. The femoral blood vessels join the sciatic nerve at about this same level by emerging posteriorly through the adductor canal from beneath the middle portion of the adductor magnus muscle. The tibial neurovascular bundle then lies deep to the semitendinosus muscle fibers and passes down the limb near the midline behind the knee. The fibular branch of the sciatic nerve follows beside or deep to the medial border of the short head of the biceps femoris muscle to the knee. When needling hamstring TrPs, it is wise to limit treatment to only one side of the body during every visit.

For TrPI or DN for both medial and lateral hamstring muscles, the patient is positioned prone with a pillow or bolster under the ankles to place the knee in slight flexion. Trigger points in the semimembranosus and semitendinosus muscles are identified with either cross-fiber flat or pincer palpation. For the flat palpation technique, the TrP is fixed between the clinician's index and middle fingers, and the needle is directed toward the ischial tuberosity (Figure 72-79A). Alternatively, the patient can be positioned supine with the hip in abduction and external rotation with the knee flexed. A pincer grasp is used to fix the TrPs and the needle is directed laterally through the muscle mass toward the clinician's fingers (Figure 72-79B).

Figure 72-79. Trigger point injection and dry needling of the hamstring muscles. A, Proximal attachment of semitendinosus and semimembranosus muscles with the flat palpation technique. B, Semitendinosus and semimembranosus muscles, supine with hip in external rotation and abduction with a pincer grasp. C, Biceps femoris muscle long head. D, Biceps femoris muscle short head.

For TrPI or DN of the long and short heads of the biceps femoris muscle, the patient is positioned prone with a pillow under the ankle. Trigger points in the long head of the biceps femoris muscle are identified with cross-fiber flat palpation and fixed between the clinician's index and middle finger. The needle is inserted close to the midline of the thigh and is directed laterally, away from the sciatic nerve and other major neurovascular structures (Figure 72-79C).

For TrPI or DN of the short head of the biceps femoris muscle, the TrPs are identified with cross-fiber flat palpation and fixed between the clinician's index and middle finger. The needle is directed from a lateral to medial direction and angled toward the femur. The fibular branch of the sciatic nerve travels along the medial aspect of the muscle and should be avoided (Figure 72-79D).

Popliteus Muscle (Chapter 61) Figure 72.80

For TrPI or DN of the popliteus muscle, the clinician visualizes the course of the popliteal artery and vein and the tibial and fibular nerves in the posterior leg and popliteal fossa to avoid them. The muscle belly can be approached from either its lower medial part or its upper lateral part, depending on where the TrPs are located. For the medial portion, the patient is positioned in side-lying on the affected side with the hip and knee flexed to 90°. The palpating hand displaces the medial head of the gastrocnemius muscle laterally toward the middle of the leg, and popliteus TrPs are identified with cross-fiber flat palpation on the posterior surface of the proximal third of the tibia. A 38-mm (1½-in) 22-gauge hypodermic or 0.30 × 50 mm filiform needle is directed from a medial to lateral direction and angled slightly anteriorly toward the TrP and posterior aspect of the tibia (Figure 72-80A). It is very common for the needle to touch the posterior part of the tibia when needling the medial aspect of the popliteus muscle.

Figure 72-80. Trigger point injection or dry needling of the popliteus muscle. A, The solid circle locates the medial condyle of the tibia. The medial head of the gastrocnemius muscle is pressed aside posterolaterally to allow access to the popliteus muscle. B, The gastrocnemius muscle is partially slackened by plantar-flexing the foot at the ankle, whereas the knee is slightly flexed to permit slackening of popliteus muscle tension. A pillow is placed under the lateral aspect of the knee moving the gastrocnemius muscle laterally allowing better access to the popliteus muscle. C, Upper lateral portion, prone, medial to the biceps femoris muscle insertion. Note that the clinician's middle finger of the palpating hand is on the biceps femoris tendon.

For TrPI or DN of the upper lateral end of the muscle, the patient is positioned prone with a bolster under the ankle. Trigger points are identified with cross-fiber flat palpation and fixed between the clinician's index and middle fingers. Caution is necessary when inserting the needle to keep the point of penetration medial to the biceps femoris muscle and tendon to avoid the fibular nerve that courses medial or deep to them (Figure 72-80B).

6. LEG, ANKLE, AND FOOT PAIN (SECTION 7)

Tibialis Anterior Muscle (Chapter 63) Figure 72-81

For TrPI or DN of the tibialis anterior muscle, the patient is positioned supine with a pillow under the knee. The TrPs are identified with cross-fiber flat palpation and fixed between the clinician's index and middle fingers. A 21-gauge, 38-mm (1½-in) hypodermic or a 0.30 × 50 mm filiform needle is directed at about a 45° angle toward the tibia to avoid the underlying anterior tibial artery and vein and the deep fibular nerve (Figure 72-81).

Figure 72-81. Trigger point injection or dry needling of the tibialis anterior muscle. Note that the needle is angled medially toward the tibia to avoid the deep fibular nerve.

Fibularis Muscles (Chapter 64)

Fibularis Longus (Figure 72-82A)

For TrPI or DN of the fibularis longus muscle, the patient is positioned side-lying with the affected side up and a pillow placed under the leg and foot, and the hips and knees are flexed to 90°. Before needling the fibularis longus muscle, the clinician should first locate the common fibular nerve by palpation behind the fibular head. The nerve travels obliquely and deep to the fibularis longus muscle in the proximal third of the lateral leg. Trigger points are identified with a cross-fiber flat palpation and fixed between the clinician's index and middle finger below the proximal third. A 22-gauge, 37-mm (1½-in) hypodermic needle or a 0.30 × 50 mm filiform needle is directed from lateral to medial toward the TrPs and the fibula (Figure 72-82A). Ordinarily, TrPI does not cause a nerve block, but the TrP may be so close that sometimes the local anesthetic solution spreads as far as the nerve. It is wise to warn patients prior to injection that the foot may “go to sleep” briefly if there is any

“spillover” of the anesthetic solution and to reassure them that the foot will “wake up” within 15 or 20 minutes as the anesthetic effect fades.

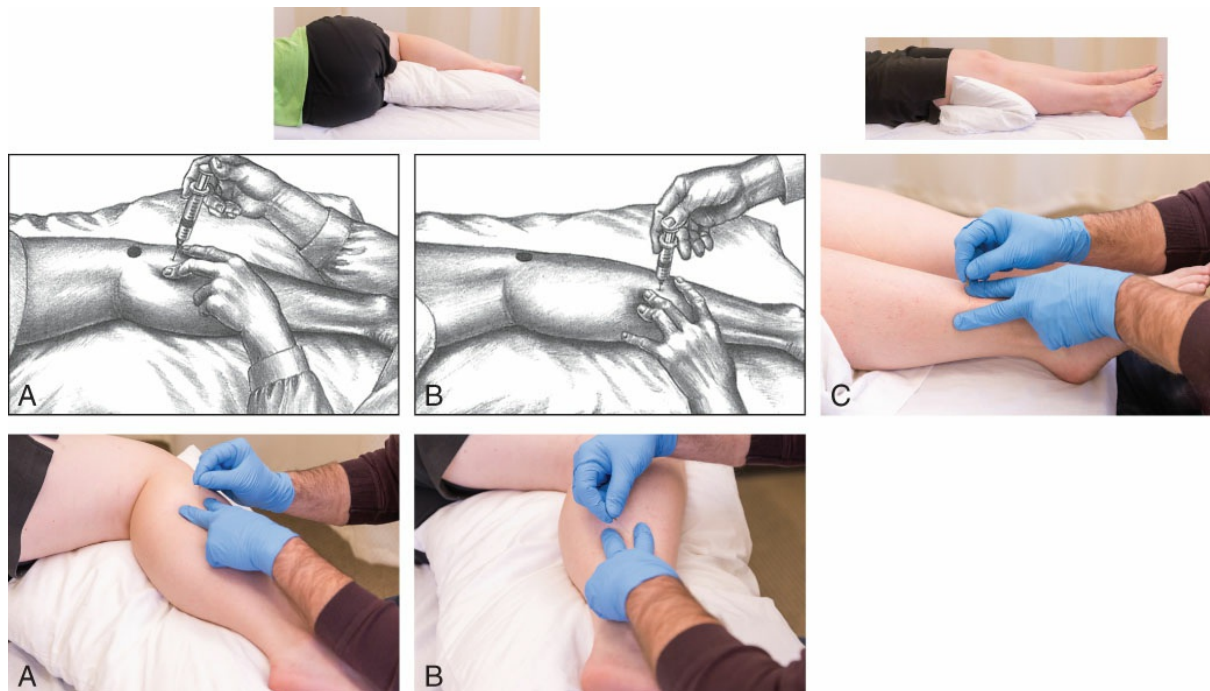

Figure 72-82. Trigger point injection or dry needling of TrPs in the fibularis muscles. The circle marks the head of the fibula. Note the pillow between the knees that extends to the ankles so that it supports the leg being injected. A, Fibularis longus muscle needling near, but distal, to the course of the common fibular nerve that crosses the fibula just below the fibular head. The needle is directed toward the underlying bone. B, Fibularis brevis muscle, posterolateral approach, near the junction of the middle and lower thirds of the leg on either side of, and deep to, the tendon of the fibularis longus muscle. C, Fibularis tertius TrP needling, anterior to posterior toward the fibula.

Fibularis Brevis (Figure 72-82B)

The procedure for TrPI or DN of the fibularis brevis muscle is similar to that described for the fibularis longus muscle, except that the TrPs are more distal, usually near the junction of the middle and distal thirds of the leg. The superficial fibular nerve runs between the fibularis brevis and tertius muscles. Trigger points are identified with cross-fiber flat palpation and fixed between the clinician’s index and middle fingers. The needle is directed into the muscle from the posterolateral direction down toward the fibula, passing deep to the fibularis longus tendon to avoid needling the nerve (Figure 72-82B).

Fibularis Tertius (Figure 72-82C)

For TrPI or DN of the fibularis tertius muscle, the patient is positioned supine with a pillow placed under the knee. Trigger points are identified with a cross-fiber flat palpation and fixed between the clinician’s index and middle fingers. The needle is directed from an

anterior to posterior direction toward the TrP and the fibula (Figure 72-82C). This angle avoids the superficial fibular nerve overlying the fibularis brevis muscle and stays well clear of the deep fibular nerve and anterior tibial vessels on the interosseous membrane.

Gastrocnemius Muscle (Chapter 65) Figures 72-83 and 72-84

For TrPI or DN of the gastrocnemius muscle, the clinician must be aware of the neurovascular structures, especially when considering needling the proximal medial or lateral heads of the gastrocnemius muscle. The proximal part of the medial head of the gastrocnemius muscle lies between the tibial nerve and the tendons of the semitendinosus and semimembranosus muscles, and the proximal portion of the lateral head of gastrocnemius muscle lies between the fibular nerve and the tibial nerve. The popliteal fossa must be thoroughly palpated to locate the nerves and tendons if needling of the proximal gastrocnemius muscle is indicated. Clinicians should identify the available safe needling zone between the semitendinosus muscle tendon and the tibial nerve, and the space between the fibular and tibial nerves and the relationship with the biceps femoris muscle tendon. Anatomic variations regarding a premature split of the two divisions of the common fibular nerve may be identified in the popliteal space and needling the proximal part of the lateral head of the gastrocnemius or plantaris muscles would not be indicated. The medial sural cutaneous nerve descends between the medial and lateral heads of the gastrocnemius muscle. When needling the central bellies of either head, the midline is avoided by angling the needle medially when needling the medial head and laterally when needling the lateral head.¹

The patient is positioned prone for needling both the medial and lateral heads, and a pillow placed under the ankle and foot to position the knee in slight flexion. Trigger points in the medial head of the gastrocnemius muscle are identified with cross-fiber pincer palpation, and the TrPs are fixed with a pincer grasp between the clinician's thumb, index, and middle fingers. A 37-mm (1½-in), 22-gauge hypodermic needle or a 0.30 × 50 mm filiform needle is directed medially toward the TrPs and the clinician's fingers on the anterior aspect of the muscle (Figure 72-83A). The gastrocnemius muscle is very prone to postneedling soreness. The medial head is more vulnerable to this than the lateral head, perhaps because the TrPs in the medial head tend to be more tender and are usually more numerous. The muscle may remain sore for as long as 5 or 6 days following TrPI or DN and, for the first day or two, the patient may experience marked discomfort while walking or standing. For this reason, one should avoid needling both the right and left gastrocnemius muscles at the same visit because doing so might temporarily immobilize the patient.

Figure 72-83. Trigger point injection or dry needling of the gastrocnemius muscle in prone. A, Medial head mid-muscle belly using a pincer grasp technique. B, Lateral head near the midline with the flat palpation technique. C, Proximal medial head with the flat palpation technique. D, Proximal lateral head with the flat palpation technique.

For TrPI or DN in the lateral head of the gastrocnemius muscle toward the midline of the muscle, the TrPs are identified with cross-fiber flat palpation and fixed between the clinicians' index and middle fingers. The needle is directed in a posteroanterior direction with a slight lateral angulation into the muscle and TrPs (Figure 72-83B). A pincer grasp technique can also be used to needle TrPs in the lateral head mid-belly with the needle directed laterally toward the clinician's fingers on the opposite side of the muscle as described for the medial head.

For TrPI or DN of the proximal medial and lateral heads of the gastrocnemius muscle, the TrPs are identified with cross-fiber-flat palpation and fixed between the clinician's index and middle fingers. The needle should be directed away from the midline to avoid the neurovascular bundle that passes through the popliteal space (Figure 72-83C). When needling the proximal portion of the medial head, the possibility of a displaced popliteal artery must be considered. The popliteal artery should be located by palpation before needling so that it can be avoided. When needling the proximal portion of the lateral head, the needle is directed laterally away from midline (Figure 72-83D).

Alternatively, the medial head may be needled with the patient side-lying on the affected side (Figure 72-84A) and the lateral head side-lying with the affected side up

(Figure 72-84B).

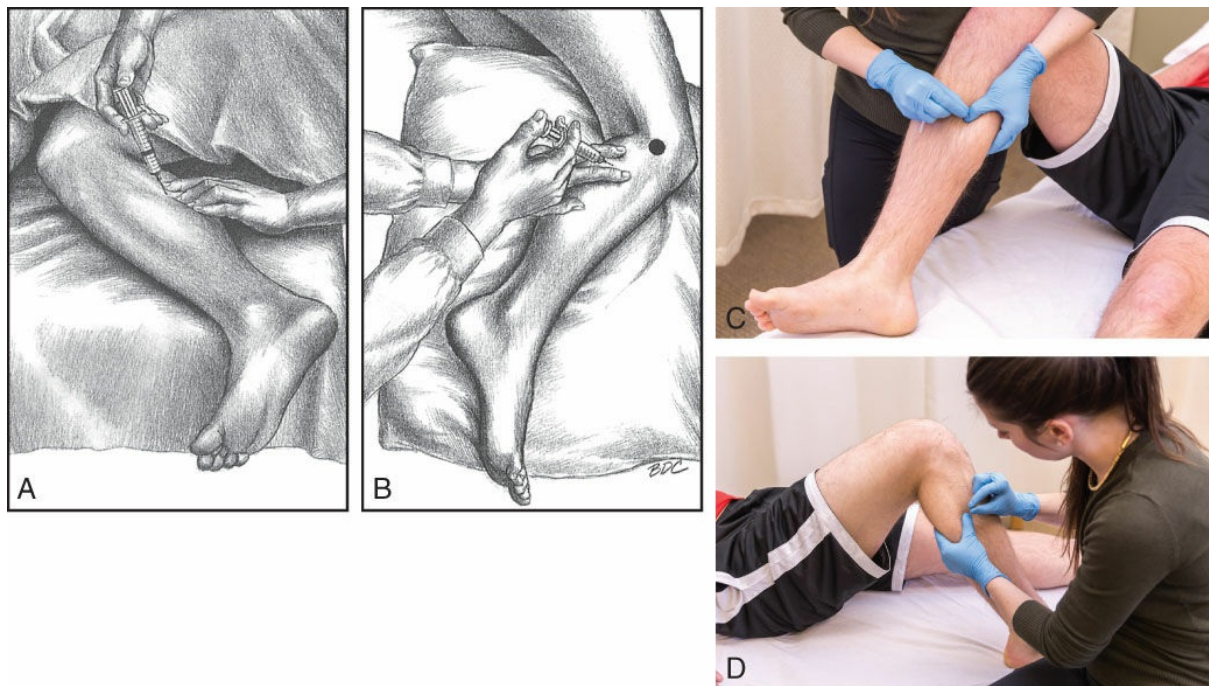

Figure 72-84. Trigger point injection or dry needling of gastrocnemius muscle alternate position. A, Medial head with the patient lying with the affected side down. B, Lateral head with the patient side-lying with the affected side up. C, Hook-lying medial head. D, Hook-lying lateral head.

Soleus and Plantaris Muscles (Chapter 66)

Soleus Muscle (Figure 72-85)

Care is exercised to avoid the tibial nerve, posterior tibial artery, and posterior tibial veins on those unusual occasions when TrPs need to be needled deep in the midline of the muscle. Postneedling soreness of the soleus muscle is often severe and can be reduced by having the patient avoid strenuous activity for a few days.

For TrPI or DN of the soleus muscle, the patient is positioned in prone or side-lying depending on which aspect of the muscle needs to be treated. In many patients, a 37-mm (1½-in) 22-gauge hypodermic needle or a 0.30 × 50 mm filiform needle is sufficient depending on the size of the muscle. Trigger points in the muscle are identified by cross-fiber pincer palpation, and the TrPs are fixed with a pincer grasp between the clinician's thumb, index, and middle fingers. The needle is directed toward the clinician's finger on the opposite side (Figure 72-85A). In side-lying, the soleus muscle is easily approached from the medial side distal to the bulge that marks the lower end of the gastrocnemius muscle fibers. The patient lies on the right side for needling treatment of the right soleus muscle, with the uppermost (left) leg in front of the involved one (Figure 72-85B). The clinician applies counter pressure to the TrP with one finger pressing directly on the TrP

from the lateral side of the muscle, while the needle is inserted on the medial side and aimed directly at the center of that finger.

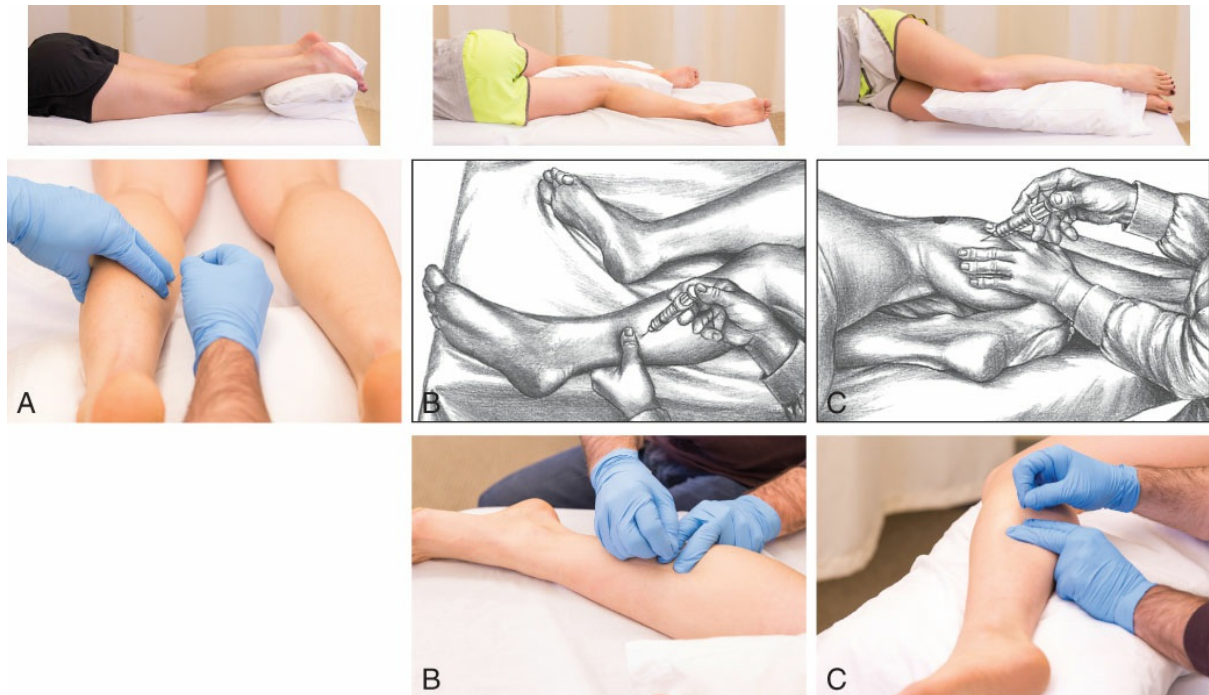

Figure 72-85. Trigger point injection or dry needling of the soleus muscle. A, Medial approach in prone position. B, Medial approach with the patient lying on the same (right) side. C, Lateral approach with the patient lying on the opposite side.

For TrPI or DN of the lateral aspect of the soleus muscle, the patient lies on the opposite side so that this muscle can be approached laterally. The needle is directed toward the fibula at the spot of maximum tenderness, which is encountered deep, close to the bone (Figure 72-85C).

Plantaris Muscle (Figure 72-86)

For TrPI or DN of the plantaris muscle, TrPs are identified by cross-fiber flat palpation and fixed between the clinician's index and middle fingers. The needle is directed through the lateral head of the gastrocnemius muscle at the level of the tibial plateau to avoid the popliteal neurovascular bundle in the midline (Figure 72-86). The technique is similar to the TrPI or DN of the proximal lateral head of the gastrocnemius muscle.

Figure 72-86. Trigger point injection or dry needling of the plantaris muscle through the lateral head of the gastrocnemius muscle.

Tibialis Posterior Muscle (Chapter 67) Figure 72-87

Travell and Simons¹⁰⁰ did not recommend injection of the tibialis posterior muscle, especially from behind. The concern was “that there is no access to the muscle without passing close to nerves, arteries, and veins”. Because the muscle lies so deep, localization of the TrPs will be imprecise. The poor localization of the TrPs in this muscle would require considerable probing for the TrPs with the needle, which would increase the danger of its encountering a nerve or an artery. If arterial bleeding resulted, it might be difficult to know promptly that it was occurring, and even more difficult to apply counter pressure effectively to stop the bleeding.¹⁰⁰ Review of the cross-sectional anatomy (see Figure 67-1) gives insight to the concern regarding the depth of the muscle and the proximity to the tibial nerve, artery, and veins.

Manual palpation for TrPs in the tibialis posterior muscle is not possible; however, tenderness to deep palpation may be indicative of TrPs in this muscle. For identification of TrPs in the tibialis posterior muscle, the needle is utilized both diagnostically and for

treatment. The patient is positioned side-lying on the affected side with the hip and knee flexed to 90°. The needle is directed deeply in a lateral direction with slight anterior angulation. The needle is kept close to the posterior aspect of the tibia or even touching the bone with the tip of the needle as a reference of location (Figure 72-87).

Figure 72-87. Trigger point injection or dry needling of the tibialis posterior muscle.

Long Toe Extensor Muscles (Chapter 68)

Extensor Digitorum Longus (Figures 72-88 and 72-89A)

If it is necessary to inject TrPs in the long extensor muscles of the toes, the clinician should take care to avoid the deep fibular nerve and anterior tibial vessels. This evasion is less difficult for TrPI or DN in the extensor digitorum longus muscle than in the extensor hallucis longus muscle. The deep fibular nerve passes across the fibula deep to the extensor digitorum longus muscle (Figure 72-88). The nerve then accompanies the anterior tibial vessels that together lie on the interosseous membrane deep to the extensor hallucis longus

muscle.

For TrPI or DN of the extensor digitorum longus muscle, the patient is positioned supine. Trigger points are identified with cross-fiber flat palpation and fixed between the clinician's index and middle fingers. The needle is inserted close to the lateral border of the tibialis anterior muscle and directed from anterior to posterior toward the fibula (Figure 72-89A). The patient should be warned in advance about the possibility of some numbness and that the muscle may become "lazy" following the injection. Depending on the solution injected, the nerve conduction will recover in 15 or 20 minutes. It is common for this transient nerve block to occur.

Figure 72-88. Cross-section through the lower part of the middle third of the right leg, viewed from above. Major blood vessels and the tibialis anterior muscle are dark red; other muscles are light red. Level of the cross-section, below the gastrocnemius muscle belly, is shown in Figure 63-1. From Anderson JE. *Grant's Atlas of Anatomy*. Baltimore, MD: Williams & Wilkins; 1983 (after Figure 4-73).

Extensor Hallucis Longus (Figure 72-89B)

For TrPI or DN of the extensor hallucis longus muscle, the patient is positioned supine, and the TrPs are identified with cross-fiber flat palpation and fixed between the clinician's index and middle fingers. The needle is inserted close to the lateral border of the tibialis anterior muscle in an anterior to posterior direction with a lateral angulation toward the fibula (Figure 72-89B). The clinician must be especially careful of the depth of needle

penetration. One may have to pass the needle through the lateral portion of the tibialis anterior muscle to direct the needle toward the fibula at an angle deep enough to reach the TrPs in the extensor hallucis longus muscle, but one must be sufficiently superficial to avoid the underlying deep fibular nerve and anterior tibial vessels (Figure 72-88). The deep fibular nerve and the anterior tibial vessels are covered by the medial part of the extensor hallucis longus muscle and the tibialis anterior muscle. Angling the needle laterally toward the fibula helps avoid contact with the neurovascular bundle.

Figure 72-89. Trigger point injection or dry needling of the long toe extensor muscles. A, Extensor digitorum longus muscle. B, Extensor hallucis longus muscle.

Long Toe Flexor Muscles (Chapter 69)

Flexor Digitorum Longus (Figure 72-90A)

For TrPI or DN of the flexor digitorum longus muscle, the patient is positioned side-lying on the affected side with the hip and knee flexed to about 90°. Trigger points are identified with cross-fiber flat palpation and fixed between the clinician's index and middle finger against the posterior surface of the tibia. The needle is deeply directed in a lateral direction with slight anterior angulation. By angling the needle toward the posterior surface of the tibia through the medial edge of the soleus muscle, the clinician minimizes the danger of penetrating the tibial nerve and posterior tibial vessels. The needle is kept close to the posterior aspect of the tibia or even touching the bone with the tip of the needle as a reference of location (Figure 72-90A).

Figure 72-90. Trigger point injection or dry needling of the long toe flexor muscles. A, Flexor digitorum longus muscle, side-lying. B, Flexor hallucis longus muscle, prone.

Flexor Hallucis Longus (Figure 72-90B)

The TrPs in the flexor hallucis longus muscle are even more difficult to needle precisely than those in the flexor digitorum longus muscle. Figure 72-88 illustrates the intimate association between the fibular blood vessels and the medial portion of this muscle. For TrPI or DN of the flexor hallucis longus muscle, the patient is positioned prone and the TrPs are identified using deep cross-fiber flat palpation through the gastrocnemius and soleus muscles. The needle is directed laterally away from the fibular vessels toward the posterior surface of the fibula. The posterior aspect of the fibula is used as an anatomic landmark to assure the proper position of the needle and to ensure sufficient depth of penetration to reach the TrPs in this muscle (Figure 72-90B).

Foot Intrinsic Muscles (Chapter 70)

Plantar Muscles—First Layer (Figure 72-91)

Abductor Hallucis Muscle. For TrPI or DN of the abductor hallucis muscle, the patient is positioned side-lying on the affected side with the knee flexed and the leg and foot supported on the table. The clinician stabilizes the leg to prevent any sudden or reflexive movements of the leg and foot (Figure 72-91A). Trigger points are identified with cross-fiber flat palpation and are fixed between the clinician's index and middle finger. The needle is directed laterally toward the underlying bone (Figure 72-91B). The neurovascular bundle passes deep to the muscle in the proximal third near its attachment. Although one might expect the TrPs in the abductor hallucis muscle to be close to the surface, they may

be deep in this surprisingly thick muscle. The main TrPs often lie close to the bone, so it is usually necessary to advance the needle to the periosteal level and then to explore the muscle for TrPs just short of that depth. These deep TrPs in the muscle are easily overlooked.

Figure 72-91. Trigger point injection or dry needling of the plantar foot muscles' first layer. A, Position for the clinician to stabilize the leg against reflexive movements. B, Abductor hallucis muscle. C, Flexor digitorum brevis muscle, medial approach. D, Flexor digitorum brevis muscle, plantar approach. E, Abductor digiti minimi muscle.

Flexor Digitorum Brevis Muscle. For TrPI or DN of the flexor digitorum brevis muscle, the patient is positioned side-lying on the affected side, and the TrPs are identified by deep palpation through the plantar aponeurosis and from the medial border of the foot (Figure 72-91C). The needle enters at the medial border of the sole angled laterally to reach the flexor digitorum brevis muscle, between the medial and lateral plantar nerves. This technique is better tolerated by some patients and may be safer considering the neurovascular bundle.

Trigger point injection or DN of the flexor digitorum brevis muscle may also be performed with the patient in the prone position with the foot off the end of the table. The clinician positions himself or herself so that the leg can be stabilized against any reflexive movements during the technique. Trigger points are identified with cross-fiber flat palpation at an area of focal tenderness and fixed between the clinician's index and middle

fingers. The focal area of tenderness could be caused by the plantar fascia, the flexor digitorum brevis, or the flexor accessorius (quadratus plantae) muscles or any combination thereof. The needle is guided from a plantar to dorsal direction toward the tender area down to bone (Figure 72-91D). The depth of penetration, tissue quality, and any referred pain will assist the clinician in identifying which structure is being needed.

Abductor Digiti Mini Muscle. For TrPI or DN of the abductor digiti minimi muscle, the patient is positioned in side-lying on the unaffected side. The clinician positions himself or herself so that the leg can be stabilized against any reflexive movements during the technique. Trigger points are identified using cross-fiber flat or pincer palpation and then fixed between the clinician's fingers. This muscle is not very thick, unlike the abductor hallucis muscle, and its taut bands and TrPs are generally easily localized. The needle is directed in a dorsomedial direction toward the underlying bone (Figure 72-91E).

Plantar Muscles—Second Layer (Figure 72-92)

Flexor Accessorius (Quadratus Plantae) Muscle. For TrPI or DN of the flexor accessorius (quadratus plantae) muscle, the technique and position as described for the flexor digitorum brevis muscle may be used or, the plantar approach can also be used (Figure 72-92A). Alternatively, the patient is positioned side-lying on the affected side, and the TrPs are identified by deep palpation through the plantar aponeurosis and from the medial border of the foot (Figure 72-92B). The needle enters at the medial border of the sole angled laterally to reach the flexor accessorius (quadratus plantae) muscle between the medial and lateral plantar nerves. This technique is better tolerated by some patients and may be safer considering the neurovascular bundle.

Figure 72-92. Trigger point injection or dry needling of plantar foot muscles' second layer.

Flexor accessorius muscle (quadratus plantae) A, Plantar approach. B, Medial approach.

Lumbrical Muscles. The lumbricals are small muscles and are indistinguishable by palpation from the plantar interosseous muscles. The TrPs would probably be included when needling the plantar interosseous muscles, as described later in this section (fourth layer).

Plantar Muscles—Third Layer (Figure 72-93)

Flexor Hallucis Brevis. For TrPI or DN of the flexor hallucis brevis muscle, the patient is positioned in side-lying with the affected side down. The clinician positions himself or herself so that the leg can be stabilized against any reflexive movements during the technique. Trigger points are identified with cross-fiber flat palpation and fixed between the clinician's index and middle fingers. Because the proper digital nerve lies superficial to this muscle, the needle enters the medial side of the foot to pass deep to the nerve and superficial to the 1st metatarsal bone into flexor hallucis brevis TrPs (Figure 72-93A). When the needle penetrates the TrP, an LTR may produce abrupt flexion movements of the first phalanx of the great toe.

Figure 72-93. Trigger point injection or dry needling of the plantar foot muscles' third layer. A, Flexor hallucis brevis muscle. B, Adductor hallucis muscle, oblique head. C, Adductor hallucis muscle, transverse head, dorsal approach (top) and plantar approach (bottom).

Adductor Hallucis Muscle. For TrPI or DN of the adductor hallucis muscle, the patient is positioned in side-lying on the affected side. The clinician positions himself or herself so that the leg can be stabilized against any reflexive movements during the technique. A focal area of tenderness is noted with deep cross-fiber flat palpation on the distal plantar aspect of the foot immediately behind the 2nd metatarsal head. The needle enters the medial side of the foot to pass deep to the digital nerve and superficial to the 1st metatarsal bone through the flexor hallucis brevis muscle into the oblique head of the adductor hallucis muscle (Figure 72-93B). LTRs may cause the great toe to move toward the second toe, confirming that the targeted TrP was needled.

For TrPI or DN of the transverse head of the adductor hallucis muscle, the patient is positioned supine. Trigger points are identified with deep cross-fiber flat palpation in the plantar aspect of the foot just proximal to the metatarsal heads and are fixed by the clinician

with a modified pincer grasp with the thumb on the dorsal aspect of the foot and the index and middle fingers on the plantar aspect of the foot. The needle is inserted in the dorsum of the foot between the metatarsal bones and directed toward the clinician's fingers on the plantar aspect of the foot (Figure 72-93C). Needling of the transverse head of the adductor hallucis muscle is the same as the technique for the dorsal interossei muscle between the 1st and 2nd metatarsal bones.

Fourth Layer (Dorsal and Plantar Interossei Muscles) (Figures 72-94 and 72-95)

For TrPI or DN of the dorsal and plantar interosseous muscles, they are approached from the dorsal surface of the foot. Figure 72-94 is an anatomic cross-section through the foot just proximal to the metatarsal heads showing the relationship of the dorsal and plantar interosseous muscles. The patient is positioned supine with a pillow under the knee. After localizing a TrP in the dorsal interosseous muscles by palpation, the clinician needles the muscle between the metatarsal bones. A modified pincer grasp is used, as described for the transverse head of the adductor hallucis muscle. The fingers of one hand press upward from the plantar surface of the foot into the interosseous space, whereas the needle is directed toward the clinician's finger (Figure 72-95A). Care should be taken to explore both bellies of a dorsal interossei muscle in order to locate all of the TrPs on each side of the interosseous space, and therefore, the needle must probe in both a medial and lateral direction as depicted in Figure 72-94.

Figure 72-94. Cross-section through the foot just proximal to the metatarsal heads, viewed from the front. The dorsal interosseous muscles (D) are dark red; the plantar interossei muscles (P) are light red; other muscles, uncolored. Adapted from Ferner H, Staubesand J. *Sobotta Atlas of Human Anatomy*. 10th ed. Vol 2. Baltimore, MD: Urban and Schwarzenberg; 1983.

Figure 72-95. Trigger point injection or dry needling of the plantar foot muscles' fourth layer. A, Dorsal interosseous muscles. B, Plantar interosseous muscles.

For TrPI or DN of a plantar interossei muscle that is localized by tenderness to deep pincer palpation from the plantar side of the foot, the TrP is fixed by a modified pincer grasp as previously described (Figure 72-95B). Figure 72-94 shows why, in order to reach the first plantar interosseus muscle through a dorsal approach, the needle must angle laterally between the 2nd and 3rd metatarsal bones to probe the muscle that lies on the medioplantar aspect of the 3rd metatarsal.

Dorsal Intrinsic Foot Muscles (Figure 72-96)

Extensor Digitorum Brevis and Extensor Hallucis Brevis Muscles. For TrPI or DN of the extensor digitorum brevis and extensor hallucis brevis muscles, the patient is positioned supine. Trigger points are identified by cross-fiber flat palpation and fixed between the clinician's index and middle fingers (Figure 72-96). The needle is directed from medial to lateral into the muscle toward the underlying bone, which the needle typically contacts. The deep fibular nerve and vessels run medial to the extensor hallucis brevis muscle, and therefore, the needle should be directed laterally.

Figure 72-96. Trigger point injection or dry needling of the dorsal intrinsic foot muscles. A, Extensor digitorum brevis muscle. B, Extensor hallucis brevis muscle.

Manual Therapy Considerations

Timothy J. McMahon, Derek Clewley, César Fernández De Las Peñas, Timothy Flynn, Visnja King, and John Sharkey

1. INTRODUCTION

This chapter presents manual therapy techniques that can augment or complement the assessment and treatment of neuromusculoskeletal conditions, myofascial dysfunction, and, specifically, trigger points (TrPs). In no way exhaustive or comprehensive of the breadth of possible manual therapy techniques, this chapter provides an overview regarding the theoretical constructs of each technique and how these techniques may affect TrPs and myofascial dysfunction in regard to patient selection and application. Readers who are interested in an in-depth study of each technique are encouraged to explore more detailed description and application of techniques in other clinical textbooks and continuing education course work.

Manual therapy is defined as “a clinical approach utilizing skilled, specific hands-on techniques, including but not limited to soft-tissue mobilization, manipulation/mobilization, used by appropriate healthcare providers to diagnose and treat soft-tissue and joint structures for the purpose of modulating pain, increasing range of motion, reducing or eliminating soft-tissue inflammation, inducing relaxation, improving contractile and non-contractile tissue repair, extensibility and or stability, facilitating movement, and improving function”.¹ Manual therapy is one of the oldest and most influential interventions in medicine dating back to ancient Thai cultures and described on Egyptian papyrus. The manual therapy techniques discussed in this chapter will include mobilization/manipulation, TrP pressure release, postisometric relaxation, strain counterstrain (SCS), neuromuscular therapy, and massage.

2. JOINT MOBILIZATION AND MANIPULATION

2.1. Overview

Joint mobilization is defined by the International Federation of Orthopaedic Manipulative

Physical Therapists as “a manual therapy technique comprising a continuum of skilled passive movements to a joint complex that are applied at varying speeds and amplitudes, that may also include a small-amplitude/high-velocity therapeutic movement (manipulation) with the intent to restore optimal motion, function, and/or to reduce pain”.^{1,2} Manipulation is usually defined as a passive, high-velocity, low-amplitude thrust applied to a joint complex within its anatomic limit with the intent to restore optimal motion, function, and/or reduce pain (Figure 73-1), whereas mobilization is typically utilized to describe nonthrust techniques (Figure 73-2). Readers are referred to Mintken et al³ for terminology.

Figure 73-1. Thrust mobilization/manipulation of the cervicothoracic junction.

Figure 73-2. Nonthrust mobilization/manipulation of the cervical spine. Posterior-to-anterior-directed force in the mid-cervical spine.

Joint mobilization/manipulation has been, historically, an approach intended to resolve painful conditions thought to be related to the targeted joint. This direct pathoanatomic model influenced most of the clinical research, and thus, there is very little evidence for the direct effects of manual therapy on TrPs or myofascial dysfunction. Clinicians usually use joint-biased manual therapy interventions to treat conditions that are thought to be related to a myofascial dysfunction, such as fibromyalgia and other persistent (chronic) pain conditions. Mechanically, it is theorized that treating a joint can reduce the associated myofascial pain in the muscles around the joint, thereby, offering an explanation for the reduction in pain that may be experienced by the patient.⁴ There is preliminary evidence supporting that a spinal manipulation can reduce TrP sensitivity in related innervated muscles⁵; however, this study included only latent TrPs.

2.2. Mechanisms of Joint-Biased Manual Therapy Interventions

The mechanisms of manual therapy have been a consistent topic researched over the last several years. In relation to high-velocity, low-amplitude manipulation techniques, two basic paradigms explaining their underlying effects have been suggested: biomechanical and neurophysiological.

Traditionally, biomechanical effects of manual therapies, based on palpation or manual identification for positional/movement faults and the choice of technique, were thought to be major determinants to effectiveness and positive therapeutic outcomes. However, because of poor reliability for assessment of the dysfunctional segment(s), demonstration of reduced specificity of the segment treated (including multiple popping sounds outside of the targeted area), and the ability to treat a distal area with positive effects, all help build the

case for alternate underlying mechanisms aside from biomechanics.⁶ Additionally, the fact that the ability to accurately locate the exact area of treatment is not directly associated to clinical outcomes^{7,8} and that the vertebral motions and resulting neuromuscular reflex responses appear to be temporally related to the applied force during a manipulation⁹ also reduce the relevance of biomechanical mechanisms as a sole explanation.

In the last decade, more authors have proposed that manual therapies are effective because of multiple interactions of biomechanical and/or neurophysiological responses.^{7,10} Bialosky et al⁸ described a comprehensive model proposing the potential interaction of both biomechanical and neurophysiological effects. The model begins with a mechanical stimulus, such as joint mobilization or manipulation, to the mechanoreceptors that increase discharge, starting a cascade of neurophysiologic effects including afferent discharge mediated by the spinal cord to reduce pain, alter range of motion, and improve muscular function. This model includes peripheral, spinal, and supraspinal mechanisms. The neurophysiologic mechanisms incorporate the patient's pain experience and beliefs with the complex interaction between the central and peripheral nervous systems.¹⁰ Several studies support these potential neurophysiologic mechanisms of manual therapy. For instance, hypoalgesia and sympathetic activity responses succeeding after the application of different manual therapies are controlled by the periaqueductal gray substance.¹¹ Additionally, a lessening of temporal summation, which is mediated by the dorsal horn of the spinal cord, has been found when assessing immediate effects on thermal pain sensitivity following spinal manipulation in both healthy people and subjects with low back pain.^{11,12}

Peripheral mechanisms may potentially be affected by manual therapy techniques because of the direct influence that occurs following a musculoskeletal injury. When an injury resulting in tissue damage occurs, an inflammatory response ensues that stimulates nociception and a pain response along with the healing process. Studies have demonstrated a potential impact on the inflammatory mediators and peripheral nociceptors with changes in blood and serum levels of cytokines, blood levels of beta-endorphin, anandamide, *N*-palmitoylethanolamide, serotonin, and endogenous cannabinoids following manual therapy.¹³

Pickar¹⁴ also theorized that manual therapy may act as a counter irritant for pain modulation by "bombarding the central nervous system with sensory input from the muscle proprioceptors" which in turn demonstrates the need to consider spinal cord-mediated mechanism in manual therapy. Other indirect findings of spinal-mediated mechanisms include bilateral hypoalgesic effects, decreased afferent discharge in related segments, motor neuron pool activity, and changes in muscle activation.¹⁰

In addition to spinal-mediated mechanisms, supraspinal mechanisms have been also demonstrated to impact the pain experience.¹⁵ The structures involved in the pain experience include the anterior cingulate cortex, amygdala, periaqueductal gray, and rostral ventromedial medulla. Current evidence supports that manual therapy is able to activate supraspinal mechanisms.¹¹ For instance, a significant decrease in the amplitude of somatosensory-evoked potentials following cervical spine manipulation has been

reported.¹⁶

Other variables that may impact the supraspinal mechanisms may include patient expectation, placebo, and psychosocial factors (see Chapter 5). Patient expectation has been shown to influence spinal manipulation–induced hypoalgesia with similar responses to those presented to patients in either a positive, neutral, or negative expectation.⁶

2.3. Patient and Intervention Selection

Typically, manual therapy interventions, including joint mobilization/manipulation, have been applied for the correction of hypomobility or malalignment with the basis of biomechanical effects; however, current evidence provides information that manual therapy may in fact provide an effect on the nervous system and in the spinal cord directly for mediation of pain. Because the choice of technique does not correlate to clinical outcomes,⁷ there may be a freedom to utilize manual therapy from a neurophysiological point of view rather than from a biomechanical point of view to provide a change in a patient's pain processing and in turn improve clinical outcomes and function. Nevertheless, the application of manual therapy interventions, such as spinal manipulation, should be integrated into a comprehensive clinical reasoning process on the basis of the neuroscience paradigm.

Impairments can take several forms, including, but not limited to, range of motion, strength, pain, and function. Any assessment should include palpation for TrPs along with the assessment of joint dysfunction.⁴ These findings must be correlated to the patient's symptoms. By establishing baseline impairment values, a clinician can assess intervention effectiveness, both within session and between sessions. This assessment allows the clinician to better determine the effectiveness of an intervention, even if the theoretical construct does not explain the potential benefit. Additionally, pain associated with a musculoskeletal dysfunction may be caused by both muscle and joint tissue dysfunctions.⁴ Managing a potential joint-related problem (ie, loss of range of motion due to a joint issue) with myofascial approaches may provide benefit. Likewise, muscular disturbances (ie, myofascial dysfunction) may respond to thrust manipulation.⁵ Therefore, it is important to determine clinical features and physical musculoskeletal impairments in a patient before selecting a manual therapy approach. There is increasing evidence supporting that multimodal approaches including both joint-biased and muscle-biased interventions are more effective than either intervention alone.

A ritualistic aspect of manual therapy interventions exists that involves patient–therapist communication and the “laying on of hands.” Furthermore, manual therapy is rarely provided in a vacuum, rather it is a component of a comprehensive treatment program that at a minimum includes patient education and exercise. Therefore, separating out the individual contributions of all of the factors in a patient encounter and finding out how each relates to patient outcomes is often a difficult task. Patients frequently have a positive view of manual therapy. Specifically, it has been shown that there is a significant relationship between patient expectations and outcomes, with more than 80% of patients

with neck complaints expecting that manual therapy will provide relief from symptoms, prevent disability, and improve activity level and sleep.¹⁷ Further, positive patient expectations toward manipulation demonstrated prognostic factors to predict patient outcomes.¹⁸

Ultimately, because of the paucity of research performed on joint-biased interventions for myofascial dysfunction, the decision to use joint mobilizations, including both thrust and nonthrust approaches, is mainly based on a clinical reasoning. Nonetheless, there is sufficient evidence for the selection of joint mobilization techniques for what is presumed to be a myofascial dysfunction including the identification of impairments that might be a factor in influencing the condition. These impairments have been identified in a thorough clinical examination that includes joint range of motion and the assessment of joint mobility. Furthermore, after performing a joint-directed intervention for a myofascial dysfunction, it is in the best interest of the patient for the clinician to reassess both the joint impairment and the presumed myofascial dysfunction.

2.4. Joint-Biased Interventions and Management of Myofascial Dysfunction

Scientific literature investigating joint-biased interventions for TrP dysfunction is limited, although the joint has been implicated in myofascial dysfunction.⁴ The following section describes some of the research integrating joint-biased and muscle-biased interventions taking the head and the neck as an example.

Neck pain, a condition that is heterogeneous in nature, is often treated by clinicians utilizing a manual therapy approach. Recent clinical practice guidelines support the use of TrP or muscle-biased approaches for the management of neck pain.¹⁹ Furthermore, there exists a large amount of literature advocating the use of joint-biased manual therapy approaches for a number of different types of neck disorders.²⁰ For instance, the upper cervical spine (ie, C0/C1, C1/C2, and C2/C3 joints) has been considered responsible for the development of significant impairment including neck pain, headaches, and orofacial pain. These joints have also been identified as possible causes of TrPs in the craniocervical region leading to some of the aforementioned regions that can be painful. In this scenario, the upper portion of the trapezius is a muscle that can easily develop active TrPs. Thrust manipulation of the upper and middle cervical spine has been shown to reduce pain pressure sensitivity in the upper fibers of the trapezius muscle and may be considered when targeting treatment of this muscle for neck pain and upper extremity dysfunction.⁵ The use of thrust manipulation to the cervical spine has been shown to reduce pain pressure thresholds for individuals experiencing neck pain, further justifying the consideration of using thrust techniques for neck pain.²¹ Therefore, a combined approach including both myofascial-directed approaches with joint mobilization may be effective, especially if the patient exhibits TrPs in some of the surrounding musculature of the neck.

Orofacial pain is also thought, to some extent, to be associated with both myofascial and joint dysfunctions. Joint range of motion associated with jaw pain may be improved with a myofascial treatment approach. A systematic review concluded that a onetime

myofascial technique was shown to improve range of motion of the mandible; however, the quality of evidence was low with a high risk of bias.²² Nevertheless, a onetime treatment of a myofascial technique is not a pragmatic approach for improving range of motion or any symptom, and typical clinical practice will incorporate a variety of treatments on the basis of the patient's impairments. A multimodal approach is, in fact, supported by different systematic reviews regarding this topic.^{23,24} Therefore, it is worth considering both approaches, particularly because of the dual nature of temporomandibular pain disorders (eg, joint and myofascial). Additionally, clinicians are advised to treat patients using a regional interdependent approach, especially for both orofacial and neck pain. By treating the cervical spine with joint mobilizations (ie, nonthrust techniques), one may expect to have improved orofacial pain symptoms.²⁵ The evidence is supportive for incorporating both thrust and nonthrust techniques for the cervical and upper cervical spine for patients with orofacial pain to improve objective measures typically associated with jaw region myofascial dysfunction, eg, pain pressure threshold and the assessment of TrPs.²⁶

It is important to consider that only a small number of musculoskeletal conditions have been presented here because of limited evidence related to the effectiveness of joint-biased interventions for myofascial dysfunction. Joint mobilization or manipulation is not a panacea treatment, and explanations for benefit are primarily theoretical. Even so, the evidence for joint-biased interventions can be conflicting for a number of conditions. Most studies investigating joint-biased approaches have used this intervention as part of a comprehensive treatment plan, similar to studies that investigate myofascial treatment approaches. In a clinical context, these interventions, ie, joint mobilizations and myofascial treatments, are often part of a multimodal treatment approach. However, a patient in the early phase of treatment may be best managed using one category of manual therapy interventions to enable the clinician to ascertain which approach was most effective.

3. TRIGGER POINT PRESSURE RELEASE

3.1. Overview

Several muscle-biased manual therapies are advocated for the management of TrPs. The term "TrP pressure release" has replaced the concept of ischemic compression used in the first edition of this book.²⁷ The first systematic review analyzing the available evidence was published in 2005 and found a few trials investigating muscle-biased manual therapy for the management of TrPs.²⁸ A more recent meta-analysis published concluded that muscle-biased manual therapies, mostly those focusing on TrPs, are effective for decreased pain sensitivity where there is a rationale for its use.^{29,30} Clinical evidence and the nature of TrPs indicate that, when applying digital pressure to a TrP to inactivate it, there is no need to exert sufficient pressure to produce ischemia, as previously suggested.³¹ Because the core of the TrP is already hypoxic surrounded by increased tissue oxygen tension, there is no reason to expect that additional ischemia as such would be helpful. Treatment needs to be directed at the release of the contracted sarcomeres of the TrPs. It is clinically important to consider that the term "ischemic" is associated with the presence of self-reported pain by

the patient during the compression intervention.

Simons³¹ proposed that compressing the sarcomeres by direct pressure in a vertical or perpendicular manner may equalize the length of the sarcomeres in the TrP and consequently decrease the pain; however, this notion has not been scientifically investigated. Other hypotheses suggest that pain relief from direct pressure may result from reactive hyperemia within the TrP or a spinal reflex mechanism for the relief of muscle tension.³² It is almost sure that different mechanisms are involved concurrently in this process.

3.2. Patient and Intervention Selection

Different compression techniques have been described depending on the amount of pressure, the duration of application, the position of the muscle (shortened/lengthened), or the presence/absence of pain during the intervention. Trigger point pressure release techniques employ the barrier release concept in which tissue resistance is noted and released before more intense pressure is applied.³³ The pressure release approach seems to be equally effective clinically and is not likely to produce appreciable additional ischemia. In fact, Hou et al³² found that low pressure below pain threshold for a prolonged period (90 seconds) or high pressure over pain threshold (pain tolerance) for a shorter period (30 seconds) was equally effective for decreasing pressure pain sensitivity over TrPs. Therefore, TrP pressure release is tailored to the needs of the individual's muscles, is less uncomfortable, and, therefore, is more likely to be preferred by the patient. The patient learns what optimal pressure feels like for subsequent self-pressure release treatment for home management. The barrier release approach, however, does require a higher-order skill of manual therapy.

Therefore, in clinical practice, the pressure level, duration of application, and position of the muscle are determined on the basis of the sensitizing mechanisms of the patient and the degree of irritability of the tissue. In a patient with a low degree of sensitization, more intense and/or painful techniques can be applied. Nevertheless, Gay et al²⁹ found that the intensity of pressure applied during muscle-biased techniques may be an important parameter for producing a positive effect in some patients. Therefore, a thorough clinical reasoning approach should be applied when deciding the amount and duration of the muscle-biased intervention on the basis of the findings of the physical examination.

Clinicians should also consider applying intentional consecutive sessions to the same patient instead of a single hard session. This hypothesis has been supported by a recent study suggesting that TrP manual therapy does not exhibit decreased tolerance to repetitive applications because both single and multiple applications decreased the sensitivity to pressure at the TrP.³⁴

3.3. Clinical Application

To apply TrP pressure release, the clinician lengthens the muscle to the point of increasing resistance within the comfort zone of the patient and then applies gentle, gradually

increasing pressure on the TrP until the finger encounters a definite increase in tissue resistance (engages the barrier) (Figure 73-3). At that point, the patient may feel a degree of discomfort but should not experience pain. This pressure is maintained (but not increased) until the clinician senses relief of tension under the palpating finger. The palpating finger increases pressure enough to take up the tissue slack and to engage a new barrier (the finger “follows” the releasing tissue). The clinician again maintains only light pressure until more of the muscle tension releases under the finger. During this period, the clinician may change the direction of pressure to achieve better results. This process of TrP pressure release can be repeated for each band of taut muscle fibers in that muscle. The virtue of this technique is that it is painless and imposes no additional strain on the TrP, and thereby avoids aggravating the symptoms.

Figure 73-3. Gluteus maximus TrPs pressure release. The clinician applies gentle pressure to the TrPs in the gluteus maximus muscle. The patient is asked to gently lift the knee into the clinician’s hand to activate the fibers in the gluteus maximus muscle below the clinician’s knuckle.

In addition to simply taking up the slack in the muscle before beginning the procedure, the entire muscle can be maintained at a slack-free length throughout the process. Release of the TrP may be further enhanced by occasionally performing a contract-relax maneuver alternated with reciprocal inhibition. The goal is to release the contracture knots in the TrP and release the tension they cause in the muscle fibers comprising the taut band.

The barrier release approach may fail to afford relief because of several factors such as the following: (1) the TrP is too irritable to tolerate any additional mechanical stimulation; (2) the clinician misjudged the pressure required to reach the barrier; (3) the clinician pressed too hard, causing pain and autonomic responses with involuntary tensing by the

patient; and (4) the patient has perpetuating factors that make the TrPs hyperirritable and resistant to manual treatment.

Obviously, the effectiveness of this passive approach can often be enhanced by including supplemental techniques. These additional techniques should not cause the patient any further discomfort. For instance, a recent meta-analysis has reported that exercise has small-to-moderate effects on pain intensity at short term in people with myofascial pain and that a combination of different types of exercises seems to achieve greater benefits.³⁵

4. MUSCLE ENERGY TECHNIQUES AND STRETCHING INTERVENTIONS

4.1. Overview

There are many methods of applying a stretching procedure: passive stretching (where the clinician passively stretches the muscle without the patient participating), active stretching (where the patient actively stretches the muscle without participation of the clinician), spray and stretch, or postisometric relaxation.^{27,33} The main differences between these procedures are the intensity of the stretching, the involvement or noninvolvement of the patient, and the inclusion or noninclusion of the muscle contraction. The muscle energy technique (MET) most commonly used in clinical practice is the postisometric relaxation.³³

4.2. Patient and Intervention Selection

A stretching intervention can be applied to almost any muscle. Postisometric relaxation can be used for any muscle that can be lengthened and resisted isometrically, without pain if possible. Postisometric relaxation should be a gentle technique of lengthening of the muscle tissue and not an aggressive stretching. As it has been previously commented, the clinician should choose the application of a muscle energy intervention in any patient with a soft-tissue restriction in any part of the body.

4.3. Clinical Application

For a postisometric relaxation intervention, the muscle is brought to a position of submaximal length without stretch. The subject performs an isometric contraction with a force between 10% and 25% maximum voluntary contraction, with the clinician providing resistance for 6 to 10 seconds (Figure 73-4). It is hypothesized that if contractions performed with a strength greater than 30% of force is achieved, a recruitment of phasic muscle fibers (fast-twitch muscle fibers) occurs.

Figure 73-4. Postisometric relaxation for the infraspinatus muscle. A, Starting position. The clinician resists a gentle contraction by the patient in external rotation motion and holds for 6 seconds. B, Following the contraction, the patients slowly relaxes, letting the arm fall slowly into internal rotation until the barrier is reached. The process is repeated three to five times.

Once the muscle has relaxed, the clinician takes up slack in the muscle again to further lengthen the muscle without pain. The time for relaxation may vary from a few seconds to half a minute. Sensing the relaxation of muscle is essential for the clinician to maximize lengthening without causing reflex tightening of the muscle. Postisometric relaxation can be applied after other TrP interventions, such as dry needling or direct pressure release techniques, for augmenting the effects on the taut band and the TrP area.

Relaxation of the muscle can be enhanced with a variety of techniques. If relaxation of a muscle is unsatisfactory, the isometric contraction portion of the postisometric relaxation technique can be lengthened to 30 seconds.³⁶ Diaphragmatic breathing, coupled with postisometric relaxation, can also be helpful. Combining postisometric relaxation with effective and relaxed breathing can enhance its effectiveness because inhalation facilitates contraction, whereas exhalation facilitates relaxation.³³ Lewit³³ referred to the phenomena as respiratory synkinesis: movement in one direction is coupled with inhalation and movement in opposite direction coupled with relaxation in exhalation. Refer to Chapter 45 for details regarding diaphragmatic breathing.

Eye movements can also be combined with postisometric relaxation because focusing vision in a specific direction can facilitate cervical movement in the same direction. Obviously, this will be most helpful on interventions applied to the cervical spine. Box 73-1 summarizes some key features for providing METs.

Box 73-1 Standards and guidelines for muscle energy technique (MET)

- Assess range of motion before initiating the technique.
- Reiterate the importance of producing a mild contraction to the patient.
- No pain should be felt during or after an MET.
- Inform the patient of possible posttreatment symptoms—occasional soreness.

- Recommend the use of cryotherapy posttreatment, ie, coolant gels, cold sprays, cold water, etc.
- METs can be applied on pregnant women, but care should be taken, and muscles should be brought only through their functional range of motion.
- It is the therapist's responsibility to be aware of the contraindications and appropriate use of METs.

5. STRAIN COUNTERSTRAIN

5.1. Overview

Strain counterstrain (SCS) is a positional release technique that can be characterized as an indirect manual technique. Indirect techniques are manual therapy techniques that move the patient to a position of ease usually away from protective barriers. Jones et al³⁷ defined SCS as “a passive positional procedure that places the body in a position of greatest comfort, thereby relieving pain by reduction and arrest of inappropriate proprioceptive activity that maintains somatic dysfunction.”

Proposed physiologic mechanisms for SCS have focused primarily on aberrant proprioceptive input from agonist and antagonistic muscle spindles and other sensory input as well as proposed changes in local circulation and inflammatory processes. The original theoretical construct of the neurophysiologic mechanism is referred to as proprioceptive theory, an osteopath paradigm.³⁸

The proprioceptive theory postulates that strain activities around a joint or muscle cause agonist muscle spindles to fire rapidly, whereas antagonistic muscle spindles have a reduced output because of rapid shortening. The reduced output of antagonistic muscle spindles stimulates the nervous system through efferent output to cause the intrafusal fibers of muscle spindles to increase tension, thereby causing a resulting gain in gamma motor neuron output on return to a new resting position of the joint and muscle. The resulting effect is increased facilitative tension of agonist and antagonist muscles around a joint. The altered tension and sensitivity of muscle spindles can theoretically cause potential alterations in strength and motor control. Nevertheless, evidence of the proprioceptive theory is sometimes conflicting. Howell et al³⁹ investigated the effects of SCS on patients presenting with Achilles tendonitis compared with a control group who received sham SCS on stretch reflex and H-reflex (Hoffman reflex). This study identified a statistically significant reduction in the stretch reflex in the intervention group compared with matched controls, but the H-reflex did not demonstrate significant between-group changes. Additionally, those patients in the intervention group reported reduced soreness in the Achilles tendon, leaving open the possibility of reduction of pain response having a potential effect on the stretch reflex responses. In another study of foot and ankle application of SCS, Wynn et al⁴⁰ investigated the stretch and Hoffman reflexes and clinical outcomes of subjects with plantar fasciitis. The results of this study did not demonstrate differences in stretch or H-reflex responses, but did improve plantar flexion torque and

reduced pain.

An important and common question from clinicians is what is the difference between a tender point, as described by Jones et al³⁷ in SCS, and myofascial TrPs. Jones et al³⁷ defined tender points as the area of hypersensitivity four times greater than normal. The tender point is approximately 1 cm in diameter and may be located on muscle, ligament, fascia, bone, or tendon. As it can be observed, there is no mention to one of the cardinal signs of TrPs, the referred pain sensation. Myofascial TrPs, which are defined previously in this text, are located within the taut band of muscle belly and may be considered active or latent depending on the ability of the TrP to reproduce the symptoms of the patient or not.

Lewis et al⁴¹ examined the short-term effects of SCS on quantitative sensory measures at tender points of the lumbar region in subjects with low back pain. The results demonstrated immediate increase in pain pressure threshold (PPT) following SCS treatment, but the effect was not evident at 24, 48, and 96 hours. Klein et al⁴² examined the effect of SCS on cervical mobility in patients with neck pain versus a sham control group. The intervention group received only one intervention of SCS and the control group received matched sham treatment. This study found no statistically significant differences in cervical spine mobility between groups because both groups exhibited similar increased range of motion. Similarly, the few studies that have investigated the reliability and validity of SCS tender points assessment have also shown conflicting results. Wong et al⁴³ examined the presence of tender points on the hip area in a sample of healthy subjects and found low levels of reliability and validity. The treatment group did demonstrate a reduced pain of tender points compared with a control group. McPartland and Goodridge⁴⁴ compared the reliability of both SCS tender points and traditional osteopathic examination procedures of the mid-to-upper cervical spine in patients with neck pain. The results demonstrated 72% agreement between examiners ($K = 0.45$) supporting moderate strength of agreement. The study included only posterior and anterior cervical tender points from C3 and above.

Additionally, some studies have also investigated the potential effects of SCS on identified myofascial TrPs despite separate theoretical constructs for SCS (mainly focused on tender points). Ibanez-Garcia et al⁴⁵ compared the effects of SCS versus a control group on latent TrPs in the masseter muscle in asymptomatic subjects. The intervention group experienced improved range of motion and increases in pain pressure thresholds compared with the control group. In a separate study by Rodríguez-Blanco et al⁴⁶ the SCS efficacy was compared with postisometric relaxation versus a control group in treating latent TrPs in the masseter muscle in asymptomatic subjects. The results of this study demonstrated that the postisometric relaxation technique showed significant improvement in active mouth opening, whereas the SCS group did not.

5.2. Patient and Intervention Selection

The advantage for SCS against other compression manual therapies is that it is pain-free and the technique does not involve lengthening of the affected muscle. In fact, patients in

both acute and chronic dysfunction may benefit. Because of low forces and comfortable positioning, SCS affords treatment of patients with osteoporosis, pregnancy, postoperative conditions, hypermobility syndrome, and pediatrics. For instance, in a patient with fibromyalgia syndrome with high excitability of the central nervous system and the presence of allodynia, SCS may be a good first-line manual intervention for avoiding temporal summation of pain. Once the treatment sessions progress, more direct compression techniques, eg, TrP pressure release, could also be used.

5.3. Clinical Application

With SCS, the patient is placed in a position of ease and reduced tenderness of identifiable tender points. The position frequently requires a shortening of muscle or folding of tissues over tender points. This position is maintained for a minimum of 90 seconds (Figure 73-5). During the 90-second hold, the clinician monitors the tender points with gentle palpation. Small adjustments can be made to maximize the reduction in tenderness and tone of the tender points. The patient is returned to neutral positioning slowly so as not to stimulate protective muscle guarding.

Figure 73-5. Strain counterstrain positional release technique for the right Anterior Cervical (AC7) (sternocleidomastoid muscle). A, Starting position with the clinicians thumb between the sternocleidomastoid clavicular and sternal heads at the clavicle. B, The head is moved into flexion, side bending toward and rotation away from the side to be treated.

In regard to the duration of SCS treatment, Dr Jones experimented with varying duration of the technique and was able to reduce the position of release to 90 seconds.³⁷ Less than 90 seconds resulted in some return to the prior level of hypersensitivity. When the position was held for at least 90 seconds, the hypersensitivity of the original point was significantly diminished. He defined a successful treatment as a reduction in tender point pain by 70% compared with initial palpation. Theoretically, the duration of sustained positioning may have significance with the latency involved to reduce aberrant input from proprioceptors, but this has not been scientifically confirmed.

6. NEUROMUSCULAR THERAPY

6.1. Overview

Neuromuscular techniques (NMTs) refer to the manual application of digital pressure or strokes, most commonly applied through finger, thumb, or elbow contact targeting soft tissues (Figure 73-6). These digital contacts can have either a diagnostic (assessment) or therapeutic objective, and the degree of pressure employed varies considerably between the therapist and the modes of application. The clinical reasoning for the application of NMT is based on a potential role of the fascia tissue in the development or perpetuation of TrPs. It seems that the complex nature of the fascia serves to provide a helical medium for forces generated within muscle fibers. Such forces spread to neighboring muscles and are propagated to various fasciae more globally including the skin surface via specialized fascial thickenings called skin ligaments. Fascia is replete with a wide range of specialized mechanoreceptors, including spindle cells, which are activated by movement, no matter the intensity. The viscosity of the deep fascia can alter and influence the gliding potential and function of the associated muscles because of increased viscosity of the hyaluronic acid, creating friction and resistance to normal motion. This in turn inhibits proprioception and muscle function.⁴⁷ Therefore, in such a scenario, fascial restrictions can be perpetuating factors in the etiology and pathophysiology of TrPs. This hypothesis is consistent with a previous theory suggesting that muscle fibers should evolve from the term “protein of contraction” to a more complex and integrated biotensegrity model.⁴⁸

Figure 73-6. Neuromuscular therapy technique for the vastus lateralis muscle.

The application of NMT over a TrP can provide a mechanical load leading to both a lowering of the viscosity of the hyaluronic acid and myofascial tension by returning normal gliding to thickened tissues overlying muscles.⁴⁷ These changes are relevant because it has been proposed that targeting the viscoelasticity of the connective tissues is important to

modify specialized nociceptors within the fascia. As a result of increased thixotropic densification in myofascial tissues, mechanoreceptors change shape and consequentially lead to poorly coordinated muscle contractions, heightened spindle activation, reduced motor control, and myofascial pain.⁴⁷ Therefore, NMT can provide an indirect management technique to the surrounding structure of the TrP leading to successful outcomes without overtaxing the patient. In fact, preliminary evidence suggests that NMT applied to latent TrPs can be effective for increasing range of motion and decreasing pain sensitivity.⁴⁵

6.2. Patient and Intervention Selection

Neuromuscular therapy (NMT) can be applied to any patient with either acute or chronic pain. Nevertheless, it is commonly accepted that NMT interventions should not be applied directly to the injured tissues within the first 72 hours following the injury, as this would tend to encourage increased blood flow to the already congested tissues, reducing the natural splinting that is required in this phase of recovery.⁴⁹ After 72 hours, NMT may be carefully applied to the injured tissues and applications to the supporting structures and muscles involved in possible compensating patterns. The same clinical reasoning approach should be applied when an active TrP is responsible or associated with the symptoms of the patient.

There is no specific rationale for applying an NMT before or after any other muscle-biased or joint-biased intervention. For instance, NMT could be applied before a pressure release or dry needling technique applied specifically for inactivating TrPs. It can also be applied after these interventions for reducing postneedling soreness. Similarly, in a patient with stiff cervical muscles, a spinal mobilization may be painful, and NMT could be applied first to reduce muscle tension, thus facilitating the application of a joint-biased intervention. The clinician should be able to determine the most proper application of the different manual therapy approaches for each particular patient on the basis of a sound clinical reasoning approach.

6.3. Clinical Application

The most important aspects to consider during an NMT technique are the pressure and the speed of the strokes. Clinically, it is proposed that the pressure should be adapted to the texture, stiffness, and character of the underlying tissue. Therefore, the pressure applied during an NMT is not consistent because the character and texture of tissue is always variable. The second aspect is the speed of the stroke. Speed should be adapted, similarly as with pressure, to the texture of the tissue and the presence or absence of pain. Unless the tissue being treated is excessively tender, the gliding stroke usually recommended covers 3 to 4 in (8-10 cm) per second. However, if the tissue is sensitive, a slower pace and reduced pressure is suggested. It is important to develop a moderate gliding speed in order to feel texture and resistance in the tissues. Movement that is too rapid may cause excessive pain or discomfort for the patient. A moderate speed will allow for numerous repetitions that will

significantly increase blood flow and soften the fascia for further manipulation. Nevertheless, the speed should be adapted to each patient during each treatment session. Box 73-2 summarizes some practical aspects to consider during the application of NMT.

Box 73-2 General standards and guidelines during neuromuscular treatment

- Avoid treating too many muscles in a single treatment; limit treatment to between three and five muscles in one clinical session.
- Drag palpation: Fingers or a combination of fingers and thumb are used to locate the TrP and to identify key anatomic landmarks. Making light contact to the skin, without deformation, drag the digit over a 4-in area taking no more than 1 second per sweep. Drag the digit in all directions seeking out areas that feel tense or where sliding is restricted. Other tools, such as knuckles or elbow, can also be used if the sensitivity of the patient permits.
- Regular communication with the patient is advised during the treatment, ensuring that feedback and information is received from the patient.
- Look for nonverbal signs, such as facial expression, breath holding, and/or clenching.
- The most superficial tissues are usually treated before the deeper layers.
- The proximal portions of an extremity should be treated before the distal portions.
- When multiple areas of dysfunction and pain are present, treat the most proximal, most medial, and most painful tissue first avoiding overtreating the patient as a whole as well as the individual tissues.

Some authors have proposed the application of NMT into a specific sequenced series of manual interventions.⁴⁹ In fact, these authors described the Integrated Neuromuscular Inhibition Technique consisting of a “logical” sequence, which incorporates SCS, together with pressure release, MET, and subsequent toning of inhibited myofascial structures. The application of all these techniques is specific to the myofascial structures targeted and involves finely tuned movement within motions of ease. Additional applications such as spray and stretch or the use of topical creams can be included if appropriate. This protocol has been found to be effective for decreasing pain in individuals with upper trapezius TrPs.⁵⁰ An example of the application of the Integrated Neuromuscular Inhibition Technique over the sternocleidomastoid muscle is described in Box 73-3 and Figure 73-7A to D.

Figure 73-7. Integrated Neuromuscular Inhibition Technique application to the sternocleidomastoid (SCM) muscle. A, Cross-fiber pincer palpation to find TrPs. B, Distraction of SCM with respiratory technique. C, Postisometric relaxation. The clinician resists (arrow) gentle left rotation followed by relaxation. D, Reciprocal inhibition. The clinician resists (arrow) right rotation to achieve relaxation of the right sternocleidomastoid muscle.

Box 73-3 Integrated Neuromuscular Inhibition Technique application to the sternocleidomastoid muscle

- Step 1: Identify TrPs in the sternocleidomastoid muscle utilizing cross-fiber pincer palpation (Figure 73-7A).
- Step 2: Identify the current pain level caused by digital palpation of the TrP.
- Step 3: Apply repeated cyclical pressure release for 5 seconds on and 2 seconds off until the patient reports a noticeable reduction in the pain. This can typically take five or more cycles.
- Step 4: Apply sufficient digital pressure to warrant a score of 8 up to 10 on the pain scale used earlier.
- Step 5: Position the targeted myofascial structure in a manner that significantly reduces the perceived pain reported by the patient between 0 and 3/10. This may involve fine-tuning the movements in the sagittal plane stacked on movement in the frontal plane stacked on movement in the transverse plane (in any order).

Distraction or compression can be employed in addition to respiratory techniques (Figure 73-7B).

Step 6: Hold this position for up to one and half minutes, remembering to release the digital compression of the TrPs after 6 seconds. The fingers and thumb can remain in place to confirm a reduction in the tissue stiffness.

Step 7: Postisometric relaxation: The patient is asked to provide a mild contraction of the targeted tissues (Figure 73-7C). This is a crucial phase of the procedure. It is imperative to maintain the structures in place. Hold this contraction for approximately 10 to 12 seconds. The patient should avoid holding the breath. Stretching is not the objective but rather to reestablish normal physiologic pain-free range of motion.

Step 8: Repeat the procedure if required.

Step 9: Alternative to Step 7. If the patient reports that contraction of the targeted myofascial structures is too painful, the opposite structures can be used by having the patient “push” the head into the hands of the therapist (reciprocal inhibition) for 10 to 12 seconds (Figure 73-7D).

Step 10: Reassess to ensure all TrPs have been eradicated.

7. DEEP-STROKING AND OTHER MASSAGE TECHNIQUES

7.1. Overview

The technique of deep-stroking massage (which is also called stripping massage) was historically the first widely accepted technique for treating fibrositis (many original descriptions of which fit myofascial TrPs)²⁷ and was widely practiced at the beginning of the 20th century. Danneskiold-Samsøe et al⁵¹ found that application of deep massage to the “tender nodules” of “fibrositis” or of “myofascial pain” (which were consistent with the clinical characteristics of TrPs) relieved the signs and symptoms of most patients after 10 massage sessions. In this study, those patients experiencing pain relief had a transient elevation of serum myoglobin levels following the initial therapy sessions, but not after the final sessions when symptoms had been relieved and the tenderness and tension of the nodule being massaged had subsided. This finding suggests that the muscle fibers of TrPs and their contracture knots are more susceptible to mechanical trauma than uninvolved fibers and that local tissue manipulation can inactivate the symptoms produced by the TrPs.

This technique is not the same as deep friction massage as described by Cyriax, in which the clinician applies a deep massage across the long axis of the muscle fibers.⁵² The Cyriax technique is more closely related to the strumming massage technique. Strumming is similar to deep-stroking massage except that the strumming finger runs across the taut bands at the level of the TrPs from one side of the muscle to the other. The clinician’s finger pulls perpendicularly across the muscle fibers rather than along the length of the fibers. Fernández de las Peñas et al⁵³ found that the application of transverse friction

massage (strumming massage) was similarly effective for reducing pain sensitivity over latent and active TrPs as pressure release.

7.2. Patient and Intervention Selection

Massage techniques like NMT can be applied to any patient with either acute or chronic pain. Nevertheless, it is commonly accepted that massage interventions should not be applied directly to the injured tissues within the first 72 hours following the injury, because this would tend to encourage increased blood flow to the already congested tissues and reduce the natural splinting that is required in this phase of recovery.⁴⁹ After 72 hours, massage techniques may be carefully applied to the injured tissues, supporting structures, and muscles involved. It may be necessary to perform quantitative sensory tests such as light touch, pain pressure threshold, or heat and cold sensitivity to determine the patient's tolerance to mechanical or thermal stimulation. Clinically, some patients with peripheral and/or centrally evoked pain states may have a delayed response of hyperalgesia if the technique is performed too vigorously.

7.3. Clinical Application

During any massage intervention, the therapist should pay close attention to restrictive barriers and their release. The patient must be positioned comfortably, so that the muscle to be treated is completely relaxed and lengthened without pain to the point that there is no residual slack in the muscle as a whole. The skin should be lubricated if the subcutaneous tissues are tense and immobile. For the deep-stroking massage, the thumbs or a finger of both hands are placed so they trap a taut band between them just beyond the band's TrPs. As the digits encounter the nodularity of the TrP caused by its contracture knots, pressure is exerted to engage the restrictive barrier (Figure 73-8). The digits progress no faster than tissue release occurs as the barrier "gives" to some extent. The purpose of the pressure directed along the length of the taut band is to maximally elongate the shortened sarcomeres to release their tension. The stroking massage should be continued along the length of the remaining taut band beyond the TrP toward the attachment of the muscle, helping restore the sarcomeres to normal length by continuing to exert traction on the contracture knots. The next massage stroke should go in the reverse direction starting on the same taut band but on the other side of the TrP to further release the contracted sarcomeres. This stroke now helps release the abnormal tension on the other half of the taut band and at the other muscle attachment.

Figure 73-8. Deep-stroking massage technique for the vastus lateralis muscle and iliotibial band. Deep strokes from proximal to distal.

Strumming consists of pulling the finger across the middle of the muscle fibers slowly until the TrP is encountered. Light contact is maintained at that point until the operator senses tissue release under the finger. The finger continues pulling across the TrPs in steps as tension releases, usually in a transverse direction of the taut band (Figure 73-9).

Figure 73-9. Strumming massage technique for a thoracic paraspinal muscle TrP. A, Starting position just lateral to the thoracic paraspinal musculature moving fingers medially (arrow). B, Ending position and reversing direction from medial to lateral (arrow).

Therapeutic Exercise Considerations

Blake A. Hampton, Joseph M. Donnelly, and CéSAR Fernández De Las Peñas

1. INTRODUCTION

The physiologic basis of exercise is constructed from a cellular level to guide healthcare professionals in the design of exercise programs for individuals with myofascial pain syndrome or muscle dysfunction. When prescribing therapeutic exercise, enhancing muscular performance via nervous system efficiency, muscular strength, power, endurance, and flexibility are all essential considerations. Clinicians must also consider the effect trigger points (TrPs) have on the variables of therapeutic exercise. If these elements are all adequately addressed, a clinician can create an effective exercise prescription that will address activity limitations and participation restrictions and achieve functional goals.

2. MUSCLE FIBER TYPE

Muscle function is largely dependent on muscle fiber type ratio, which is generally related to an individual's genetic makeup. Fiber type must be considered to optimize results.

A motor unit comprises an individual motor neuron and all of the muscle fibers that it innervates.¹ The number of muscle fibers that a motor neuron innervates is dictated by the primary function of that muscle group. If a muscle group is primarily responsible for fine motor movements, the neuron to muscle fiber ratio may be low (ie, 1:10 for ocular muscles). If a muscle group is primarily responsible for gross motor movements, the neuron to muscle fiber ratio may be high (ie, 1:1000 for the gastrocnemius muscle). The primary reason for this variation in the neuron to muscle fiber ratio is that motor units operate in an “all or none” manner, and partial firing of a motor unit is not possible.

The recruitment of motor units or the muscle activation pattern is also specialized and task- or activity dependent. Smaller, type I motor units are recruited first because of their low threshold of excitation. They contain only a few terminal branches that innervate the muscle cells, and their activity can be maintained for prolonged periods of time on account of slow contraction velocity, high mitochondrial content, and oxidative capacity.¹ When greater force is required, type II motor units are subsequently recruited. With a greater

number of neuronal terminal branches and larger muscle fibers, type II motor units increase the overall force production capacity.¹ Type II motor units have an increased demand for Myosin ATPase because of increased contraction velocity and greater expense of energy. They also fatigue much quicker than type I motor units. The de-recruitment of type II fibers must be considered as type I fibers are also the last to be “turned off” during the contraction cycle. This pattern is significant in that for higher-intensity activities requiring greater velocity and force, greater rest time is needed for adequate recovery. This principle has significant implications when designing aerobic and strengthening exercise prescriptions and for the progression of a therapeutic program.

A phenomenon referred to as “motor unit rotation” has been demonstrated in which newly recruited motor units replace previously active motor units. This substitution allows for improved motor control and sustainability with prolonged low-level contractions.² The phenomenon plays a key role in motor unit recruitment patterns in postural muscles that primarily function in maintaining prolonged low-level muscle contractions. One study suggests that muscle contraction failure may be related to changes in the motor unit recruitment pattern that more commonly occurs in muscles composed of a higher proportion of type II fibers.³ This correlation may explain why speed and agility athletes tend to be more prone to muscle injuries than other athletes.

Although genetic makeup generally determines the ratio of type I to type II muscle fibers in an individual, muscle fiber plasticity allows for the conversion of one fiber type to another.⁴ With training specificity, muscle fibers can adapt somewhat to meet demands. This adaptation progress is highly relevant for muscles, such as the lumbar multifidus, where structural changes (ie, fatty infiltration, atrophy, and muscle fiber distribution) in muscle fibers are often noted in patients with chronic pain.⁵ Nevertheless, this training effect has limitations, and overall genetic makeup is the largest determinant of fiber type ratio in an individual.

3. EFFECTS OF TRIGGER POINTS IN MUSCLE FUNCTION

Evidence suggests that TrPs can have a negative impact on the aspects of muscular function, including fatigue, altered coordination, and altered intramuscular activity patterns.⁶ The presence of pain has been shown to affect motor function of the affected, synergistic, and antagonist muscles by complex central and peripheral mechanisms.⁷ Therefore, it would be expected that patients experiencing pain because of active TrPs would also exhibit altered motor control patterns. Yu and Kim⁸ reported that muscles with active TrPs showed significantly higher median frequency and muscle fatigue than muscles with latent TrPs or no TrPs, suggesting an increased recruitment of motor unit action potential of type II fibers. Yassin et al⁹ observed that patients with active TrPs in the neck-shoulder muscles need more time to react to stimulus (ie, delay in muscle activation) for moving the upper extremity when compared with those with latent or no TrPs in the same muscle. More recently, Florencio et al¹⁰ found that the presence of active TrPs in the cervical muscles determined an altered activation of superficial neck flexor and extensor

muscles during a low-load isometric task of the cervical spine in women with migraine headache.

It should be recognized that the literature related to TrPs and muscle function has been predominantly focused on the presence of latent TrPs. The effect of latent TrPs on muscle function, performance, and efficiency is profound. Supporting evidence has shown that latent TrPs affect pain, muscle activation patterns, rehabilitation, performance training, and the general function of the human body. Ge and Arendt-Nielsen⁶ proposed that latent TrPs contribute to central sensitization mechanisms because of continuous low-level nociceptive inputs. These inputs lead to long-term potentiation causing a facilitated segment of the central nervous system and increasing the perception of pain as well as motor dysfunction. In another study, the same authors showed increased intramuscular electromyography (EMG) amplitude of the upper trapezius muscle when latent TrPs were present during isometric shoulder abduction.¹¹ These authors surmised that synergistic musculature with latent TrPs creates abnormal muscle activation patterns and may lead to synergistic muscle overload and pain propagation.¹¹ Studies by Lucas et al^{12,13} showed variability in muscle activation times in the upward rotators of the shoulder when latent TrPs were present in the muscles of the shoulder girdle complex. Similarly, Bohlooli et al¹⁴ found delayed activation and alteration in recruitment patterns of the upper trapezius muscle during rapid arm elevation in the presence of latent upper trapezius TrPs. Additionally, the synergistic shoulder muscles showed altered recruitment patterns, although these muscles did not exhibit TrPs.¹⁴ The poor efficiency of the shoulder girdle musculature from TrPs leading to variance in muscle activation patterns will ultimately sacrifice performance. These results may have implications related to temporal summation for patients with musculoskeletal pain conditions secondary to the concept that TrPs are considered a neurophysiologic dysfunction that affects and is affected by the central nervous system.^{12,13} Lucas et al¹² suggested that when there is dysfunction in a proximal body segment, distal segments must change workloads and muscle activation patterns to preserve the desired movement outcomes. This concept is important when treating patients with distal extremity dysfunctions when a TrP in a more proximal muscle may be a major contributing factor to pain and/or movement impairment.

Restricted joint range of motion, muscle inhibition, and accelerated muscle fatigue are commonly observed in patients with myofascial pain syndrome, and evidence supports that latent TrPs are contributing factors to these impairments.⁶ In fact, the presence of latent TrPs is associated with overloading active motor units close to the TrP in addition to accelerated muscle fatigue.¹⁵ Motor dysfunction can occur because of long-term potentiation of a nociceptive stimulus and the body's natural defense mechanism to reduce activation of the muscles where pain is perceived. This mechanical hyperalgesia may stem from ischemia associated with TrPs and a release of adenosine triphosphate that may facilitate acid-sensing ion channel number 3 by binding to P2X receptors.⁶ This process may allow for reduced thresholds for nociception that would lead to increased action potentials causing the development of mechanical sensitivity. Substance P, calcitonin gene-

related peptide, bradykinin, serotonin, norepinephrine, glutamate, nerve growth factor, and cytokines are also present in areas surrounding TrPs that lead to chemosensitivity related to inflammation. These inflammatory mediators can then be released by the dorsal root ganglion into the dorsal horn of the spinal cord, leading to spinal cord (central) sensitization. The facilitated segment then creates a feedback loop that can reduce efferent neuron excitability and ultimately cause the inhibition of all muscles associated with that segment, and with time, other agonistic and antagonistic muscles.⁷

All these motor disturbances can be particularly problematic when managing patients with pain and dysfunction related to a movement impairment (ie, subacromial pain syndrome). Failure to address TrPs, either latent or active, in synergistic and antagonist muscles surrounding the shoulder may result in poor outcomes. Therefore, increased intramuscular EMG activity is an important consideration for exercise prescription from both a performance and rehabilitation perspective. Importantly, and from a clinical point of view, latent TrPs can induce motor control disturbances that can have a significant impact on motor function; however, these latent TrPs are not always responsible for or associated with pain symptoms.

4. NEUROMUSCULAR REEDUCATION

The principles of neuromuscular reeducation are inextricable with muscle function and performance. It would be difficult to prescribe therapeutic exercise as it pertains to TrPs without discussing the principles of neuromuscular reeducation. It has been shown that for voluntary movement to occur, functionally active reflex arcs must be intact.¹⁶ If these reflex arcs are impaired, muscle performance as it pertains to strength, power, and endurance will not be properly optimized. Dr Leonard Huddleston, one of the initial practitioners to pioneer neuromuscular reeducation, states that the strength of contraction of a given muscle is determined by the following factors presented in Box 74-1.¹⁶

Box 74-1 Factors that affect the strength of contraction of a muscle

1. Anatomic and physiologic status of the muscle fibers at the time of contraction
2. Number and synchrony of the contracting fibers
3. Number and frequency of nerve impulses reaching the muscle fibers
4. Functional status of the neuromuscular junctions
5. Structural and functional condition of the tissues surrounding the muscle fibers

There is an abundant arrangement of connections from the primary motor cortex, including the primary and secondary somatosensory cortices, the prefrontal cortex, and subcortical regions such as the thalamus, to cortical regions. These connections play a critical role in the recovery of normal effective motor function because of the system's dependence on sensory input.¹⁷ Appropriate motor function is integrated with auditory,

visual, and vestibular input along with proprioceptive input. Impaired sensory function results in poor and ineffectual motor control. The implication is that sensory stimulation plays an essential role in recovery from motor deficits that influence continued propagation of nociceptive input that causes weakness, among other impairments. Exercise prescription that focuses exclusively on motor function is not as effective as an exercise prescription that incorporates both sensory and motor function.¹⁸ The goal of neuromuscular reeducation is to improve the efficiency and synergy in activation of the motor units, thus achieving greater muscle performance by improving organized synaptic facilitation of the motor neurons. Eccentric exercise may also be used to enhance neuromuscular control by addressing alterations in muscle morphology and affecting change in both the peripheral and central nervous systems.¹⁹ Comprehensive exercise programs should include both concentric and eccentric training. Clinicians should be aware when designing exercises to include a greater eccentric emphasis and should consider where eccentric exercises fit in a systematic approach to postinjury retraining. Simons et al²⁰ says that lengthening contractions are safer for the patient to start with as the muscle is able to exert more force with less energy expenditure. These concepts are important in the facilitation of function in muscles with inhibition weakness due to TrPs. Following treatment of TrPs, especially needling therapies to regain optimal muscle performance and motor function, eccentric exercise may enhance neuromuscular control. In fact, it has been previously reported that low-load eccentric exercise provided protection against damage.²¹

5. MOTOR CONTROL TRAINING

Motor control training is a component of neuromuscular reeducation. The foundation for motor control training is motor learning which consists of three phases as described by Fitts and Posner.²² These phases are (1) cognitive phase, (2) associative phase, and (3) autonomous phase.²² In the cognitive phase, the individual cognitively plans each action and is incapable of dual-tasking. In the associative phase, the individual is working to find a solution for the problem in their movement patterns. During the associative phase, it is important to allow the individual to make small errors while performing movement in an effective manner. In the autonomous phase, the individual is no longer having to cognitively work through movements or problem-solve, and he or she is able to automatically perform the movement or task and dual-task.²³

Motor learning also pertains to declarative and procedural learning.²³ In declarative learning, every action and movement is analyzed, and repetitions are vital to this mode of learning. An individual requires approximately 3000 repetitions or more to master a skill.²³ In procedural learning, activities or tasks no longer require conscious thought, and skills are perfected through random practice in changing environments.²³

Motor control can be defined as the ability to control and adjust postures and movements with central commands, spinal reflexes, and the organization of motor programs from activities and movements that the individual has already learned.²³ This process can be facilitated by a variety of activities such as developmental sequences and

functional movement patterns that are similar to the desired movement pattern. There are four progressive phases of motor control, each with specific characteristics that should be manipulated within an exercise program. These characteristics are mobility, stability, controlled mobility/stability, and skill.²³

Mobility is the ability to assume and maintain a posture or position while starting a movement.²³ As often observed clinically, the cause of reduced joint motion can be multifactorial. Joint restriction may be related to intrinsic articular hypomobility, a reflection of muscle imbalance, or a lack of muscle extensibility. In designing a therapeutic exercise program, clinical reasoning must be used to determine when it would be most appropriate to add mobility exercises including TrP management. In some cases, focusing on the impairments of muscle performance and motor control would be a priority, and this may actually reduce the dominance of some of the tight muscle groups.

Stability is the ability to stabilize a new position and control the forces of gravity acting on the body. Controlled mobility and stability occur when the movement can be controlled at any point from a stable foundation. Skill is when all movements are able to be performed, and all parts of the body can move in a controlled fashion in all directions.²³ The motor control phases are applied to specific exercises and positions that the individual cannot yet perform to assist in retraining. Tactile and verbal cueing may be necessary to further facilitate the desired movement patterns. External focus activities can be used to create an environment where functional retraining is goal specific, and the patient must progress through the phases of motor learning in order to achieve mastery of the desired movement pattern. This type of treatment requires a significant amount of time and can be tedious, but it is an extremely important aspect in the treatment of myofascial pain syndrome to avoid muscle overload.

6. PROPRIOCEPTIVE NEUROMUSCULAR FACILITATION

Proprioceptive Neuromuscular Facilitation (PNF) is a treatment concept for motor control and motor learning. It is utilized in many settings to address poor motor programming, deficient muscle activation patterns, and motor output dysfunctions that are commonly seen in individuals with myofascial pain syndrome. The tactile cues required during PNF integrate the sensory and motor systems to improve movement efficiency. The basic neurophysiologic principles of PNF are after discharge, temporal summation, spatial summation, irradiation, successive induction, and reciprocal (innervation) inhibition.²³

After discharge is the effect a stimulus continues to have on the system after that stimulus is removed.²³ This concept is similar to the synaptic facilitation that occurs during neuromuscular reeducation as previously discussed. Temporal summation is the summation of several weaker stimuli in the same location that results in an increase in excitability of the motor neurons. The repetition of movement at lower amplitudes increases the excitability and effectiveness of the motor neurons. Spatial summation refers to weaker stimuli in multiple regions converging to effect greater activity.²³ Applying the concept of spatial summation allows for smaller, multijoint movements that may be less painful and may have

a greater effect on the central nervous system than larger, single-joint movements. Irradiation is an increased response of the muscle that is related to the increase in number and/or strength of the stimuli provided, which may be either inhibitory or facilitatory depending on the desired outcome.²³ Successive induction is another neurophysiologic principle where there is an increase in excitation of the agonist muscle following a contraction of the antagonist muscle. This can be a powerful tool for retraining muscle activation patterns and for strength training. The neurophysiologic increase in the contraction force of the agonist muscle group affords the clinician the opportunity to apply the principle of overload more efficiently.

Reciprocal inhibition or innervation occurs when the contraction of an agonist muscle group results in a simultaneous inhibition of the antagonist muscle group.²³ Reciprocal inhibition is not only an involuntary spinal-level reflex but is effective when a contraction is initiated at the cortical level. When one muscle is activated, its antagonist is reflexively inhibited. The use of reciprocal inhibition is valuable for augmenting relaxation and release of muscle tension when stretching a muscle to inactivate TrPs. This concept is important because the presence of TrPs is associated with a reduced efficiency of reciprocal inhibition that can lead to an increased coactivation of the antagonist muscles following exercise, disordered fine movement control, and unbalanced muscle activation.²⁴ To invoke reciprocal inhibition, the muscles opposing the muscle being stretched are voluntarily contracted to actively assist the stretching movement. Thus, the muscle to be stretched is reciprocally inhibited. This method can be used alone to augment a simple stretch or it can be combined with other techniques such as spray and stretch or manual therapy.

The use of reciprocal inhibition as a neuromuscular mechanism for releasing tension involves more than inhibition of alpha motor neuron activity. The tension-release mechanisms may also be dependent on autonomic effects that are related to the inhibition of spontaneous electrical activity and spike activity of TrPs during exhalation and their augmentation by inhalation and mental stress. One clinical example is seen in an attempt to increase the stretch of the hamstring muscles. The patient or client activates the quadriceps muscle group at the point where the maximum hamstring muscle length is achieved, and upon relaxing the quadriceps muscle, the hamstring muscles are inhibited, thus allowing further stretch of these muscles. This is a technique that is commonly used across practice settings to improve flexibility.

The principle of contract-relax appears in various forms by differing names throughout the musculoskeletal treatment literature. The term contract-relax, as originally taught by Knott and Voss²⁵ and Voss et al,²⁶ was recommended for treatment of marked limitation of the range of passive motion with no active motion available in the muscle opposing the tight muscle. As they described this intervention, contract-relax employed maximum contraction in a pattern movement followed by relaxation of the tight muscle to permit active shortening of the opposing weak muscle. Release of tightness permitted improvement in the range of motion. Through the years, the exact meaning of the term has become somewhat diffuse. There are now numerous variations (and applications) of the basic principle that muscle tension is reduced immediately following voluntary contraction.

The contract-relax used for treating TrPs is a gentle, voluntary, minimally resisted contraction of the muscle. The intent is to activate the fibers of the TrP or surrounding muscle fibers. The contraction is followed by volitional relaxation to permit passive elongation of the muscle to a new stretch length. Contract-relax is the basic procedure in the postisometric relaxation method described by Lewit.²⁷

Hold-relax is a variant of the contract-relax technique that is not commonly used for treating TrPs but may be employed when there is no joint movement desired during or after the procedure. It consists of isometric contraction of the tight muscle followed by relaxation but not via elongation of the tight muscle. When used in the treatment of muscles with TrPs, hold-relax is commonly combined with manual techniques applied directly to the targeted muscle, such as deep stroking massage and TrP pressure release.

7. STRENGTH TRAINING

An exercise prescription should be designed primarily for lengthening, strengthening, and/or conditioning specific muscles at the beginning of the program and for functional integration at the end of the program. Exercise to lengthen the involved muscles is key to sustained relief of myofascial pain. Improved conditioning (exercise tolerance or stamina) and increased strength of a group of muscles, achieved through exercise, reduces the likelihood of their developing TrPs. However, in most patients with active TrPs, conditioning and strengthening exercises can further activate these TrPs, encourage substitution by other muscles, and aggravate symptoms. On the contrary, the same exercises render latent TrPs less prone to reactivation if properly paced at a gradual rate of progression.

The kind of exercise prescribed depends largely on the irritability of the TrPs responsible for the pain. When the patient is experiencing pain at rest for a considerable part of the time, the TrPs should be inactivated with manual or, in some cases, needling therapies before beginning the exercise program. The object is to unload and restore normal range of motion to the overworked sore muscles; at that stage, active exercise that loads a contracting muscle is not indicated.

Strength training is often the main intention of therapeutic exercise programs and is an important intervention to assist the patient in achieving therapeutic and performance goals. There are seven variables that must be considered when developing a strengthening exercise prescription: needs analysis, exercise selection, training load, training frequency, exercise order, volume, and rest periods.²⁸

The needs analysis is the most important design variable and is often times overlooked by practitioners. Prior to designing a strength program, a needs analysis is necessary to appropriately prescribe exercises that are tailored to the particular demands of the individual. A needs analysis includes the analysis of movement patterns, identification of key muscles required to perform the movement, and the examination of muscle imbalances between agonistic, synergistic, and antagonist muscle groups. In the muscle chapters, this group is referred to as the functional unit. This is highly important, because each particular

individual will have specific demands for the muscles based on daily-life activities or sport practice. The exercise program should be adapted to these demands by using the same muscle groups and functional units.

Proper assessment of an individual's training experience requires evaluation of the current program, training age, frequency, and technique. These parameters are used to classify the individual as beginner, intermediate, or advanced in terms of initiating a strengthening program. A beginner classification includes an individual who is not currently training or just began a training program. This group consists of individuals with a training time of less than 2 months, frequency of training that is less than or equal to two to three times/week, and minimal to no training technique experience. Clinically, this is where a large population of patients with myofascial pain syndrome and TrPs can be classified, and these individuals are often times progressed too quickly. An intermediate classification includes those individuals who are currently training, have a training time period of 2 to 6 months, are training at a frequency of two to three times/week, and have basic technique experience. An advanced classification includes individuals who are currently training, have a training time period of at least 1 year, a training frequency of three to four times/week, and a high level of technique experience. Prior to placing an individual on a strength training program, these variables need to be identified to facilitate success.

Physiologic analysis is another aspect of the needs analysis that will help in the specificity of the exercise prescription, and it requires an assessment of the primary energy systems that are utilized during the daily activity or sport. Finally, an injury analysis must also be performed to evaluate common injuries associated with the specific activity or sport and to identify any contributing factors that may be involved with those particular injuries.

Exercise selection is the second design variable that needs to be incorporated into the exercise prescription, and it is determined by needs analysis. The specific adaptations to imposed demands principle is the key to expert selection of any particular exercise.²⁸ Specificity of exercise selection is important to ensure that the individual is trained in a specific manner to produce a particular adaptation or outcome. These adaptations are specific to the mode of training, the muscle group, and the movement pattern needed to perform a specific activity, joint range of motion, velocity of desired movement, type of muscle action, and activation of specific types of muscle fibers that are requirements of the sport or activity.²⁸ An example of specificity can be applied to the rotator cuff muscles. The rotator cuff muscles have a 1:1 ratio of type I and type II muscle fibers.²⁹ Therefore, it is necessary to establish an exercise prescription that includes both strength and endurance for the rotator cuff muscles.

Load is the third design variable, and often, where injuries in strength training occur, it is not managed properly. A study showed that to ensure safe loading, progressive overload should occur at a rate of 2.5% to 5% per week.³⁰ The same study showed that when the training load was increased by 5% to 10% from the previous week, there was less than 10% risk of injury. But when the training load was increased by greater than 15% from the previous week, there was a 21% to 64% risk of injury.³⁰ To apply overload, the program

designer can increase the resistance, increase the training volume, alter rest periods, increase repetition velocity, or alter the sets and repetitions performed. It is important to note that when training with lighter loads, motor learning and coordination are improved.²⁸ Blanch and Gabbett³¹ introduced the concept of acute to chronic workload ratio which has proven to be important when returning the patient or athlete back to function or sport. Acute workload is defined as the training that is performed in the current week.³¹ Chronic workload is defined as the average training that is performed in the previous 4 weeks. An acute to chronic workload ratio of 0.5 would suggest that an individual trained half of the workload he or she prepared for in the previous 4 weeks. An acute to chronic workload ratio of 2.0 suggests that the individual performed twice the amount of work as he or she prepared for in the last 4 weeks. Blanch and Gabbett³¹ concluded that the ideal acute to chronic ratio is less than 1.5 to keep injury risk below 5%.³¹

Frequency of training is the next variable of the exercise prescription that should be considered. Training load is directly related to frequency in that higher training loads require more recovery time. Therefore, the frequency should be reduced to allow for recovery. Lower-extremity exercises require greater recovery times than upper-extremity exercises, and frequency should reflect the regions of training. Multijoint exercises require greater recovery than single-joint exercises, and this should be reflected when prescribing frequency. Training status established from the needs analysis plays a key role in frequency prescription. For individuals with beginner training status, frequency guidelines recommend two to three sessions/week.²⁸ For individuals with intermediate training status, the guidelines recommend three to four training sessions/week.²⁸ And lastly, for individuals with advanced training status, training frequency guidelines recommend four to seven sessions/week.²⁸ A recent meta-analysis showed that major muscle groups should be trained two times/week to maximize hypertrophy and that there was no statistical difference between training two and three times/week.³²

Volume is defined as the total amount lifted in a training session and is an important variable of the exercise prescription. Volume can be based on repetitions or load, known as repetition volume and load volume, respectively. Repetition volume is the total number of repetitions performed for a single exercise.²⁸ For example, a repetition volume for 3 sets of 10 repetitions is 30. Load volume is the amount of weight lifted multiplied by the repetition volume. For the above example, if the individual was lifting 10 lb for each repetition, the load volume would be 300. A basic principle presented by the National Strength and Conditioning Association (NSCA) for load progression is the 2 for 2 rule that states a load should be increased when the individual being trained is able to perform two extra repetitions on the third set for two consecutive sessions.²⁸ Volume assignments for training goals are important for the specificity of training for different aspects such as strength, power, hypertrophy, or endurance.

When designing a strength program, it is vital to incorporate all seven design variables identified in Box 74-2 to ensure the safety of the individual while achieving optimal results. If any of these variables are excluded, the chance of injury increases at the expense of

reduced performance required for specific activities. These exercise prescription design principles are essential when retraining muscles following treatment for TrPs and myofascial pain to enhance performance, return to function, and prevent recurrence of TrPs. For more detailed information regarding programming for strength training, refer to the NSCA's *Essentials of Strength Training and Conditioning* textbook.

Box 74-2 Seven design variables for developing a strengthening exercise prescription

1. Needs assessment
2. Exercise selection
3. Training load
4. Frequency of training
5. Exercise order
6. Volume of load and repetition
7. Rest periods

8. FLEXIBILITY TRAINING

Flexibility training is an important aspect of muscle performance including strength, power, and endurance. In this manual, flexibility training (self-stretch exercises) is contained within the Corrective Actions section of each applicable muscle chapter.

Almost any method that gently stretches (lengthens) a muscle with TrPs and increases its pain-free range of motion is beneficial. However, a rapid, forceful stretch by itself causes pain, protective contraction, and reflex spasm of the muscles. All of these responses hurt the patient and obstruct further elongation of the muscle. Some method of suppressing these reactions must be added in order to release TrP tension. Rapid or “bouncing” stretches are to be avoided; they tend to irritate muscle tissue and TrPs, not release them. It is often possible, with a newly activated or a moderately irritable TrP, to inactivate it immediately by simply passively, slowly stretching the muscle. However, the release can be expedited and made less uncomfortable when stretch is combined with simple augmentation maneuvers such as coordinated exhalation, postisometric relaxation, contract-relax, and reciprocal inhibition.

Two approaches to stretching the muscle are available: elongating the muscle by moving the joint(s) it crosses or elongating it by direct manual traction applied to the muscle. Passive movement of the joint(s) crossed by the muscle is emphasized as a component that can be used for patient self-treatment and detailed on each of the muscle chapters in the Corrective Actions section. There are also numerous methods for augmenting stretch (usually called muscle energy techniques), including postisometric relaxation, reciprocal inhibition, exhalation, directed eye movement, and contract-relax. These various techniques can be used in many different combinations and integrated with

augmentation techniques.

The contracture of the sarcomeres of a TrP must be released. Therefore, lengthening the contracted sarcomere by gentle sustained stretch with augmentation techniques induces gradual reduction in the overlap between actin and myosin molecules and reduces the energy being consumed. When the sarcomeres reach full stretch length, there is minimal overlap and greatly reduced energy consumption. This reduction breaks an essential link in the energy crisis vicious cycle related to TrPs. The sustained increased tension on contracted sarcomeres may cause tearing of the actin attachments to the Z lines as observed by Fassbender.³³

Although there are several factors that affect flexibility and muscle lengthening, the main purpose of this section is to relate flexibility to connective tissue restrictions of the tendons and fascia as well as contractile restrictions in muscle. Fascial restrictions can occur in a response to trauma, inactivity/immobility, inflammation, or disease that results in increased viscosity of the extracellular matrix that causes a reduction in fascial mobility. Once mobility of the fascia has reduced, it can begin to bind to the surrounding soft tissue, impairing normal muscle mechanics and ultimately causing a reduction in soft-tissue extensibility.³⁴ Therefore, the fascia and contractile component of muscle and soft tissue share a close relationship when relating to flexibility. The best treatment for fascial restrictions is a controversial topic. In recent years, self-myofascial release techniques have become popular in rehabilitation settings and gyms alike. Fascia has a thixotropic property, and the extracellular matrix becomes viscous with immobility. Macdonald et al³⁴ suggest that friction generated by self-myofascial release techniques results in warming of the fascia that promotes a more fluid environment of the extracellular matrix, restoring soft-tissue extensibility. They showed, following a bout of foam rolling of 2 minutes, that there was a significant increase in joint range of motion for up to 10 minutes without significant differences in neuromuscular variables including force of contraction and fatigue.³⁴ Healey et al³⁵ found no significant differences in performance between planking and foam rolling for the same amount of time; however, fatigue relating to the activity was significantly less following a bout of foam rolling when compared with planking.

Stretching and flexibility training has long been considered to be the gold standard for improving range of motion and sport performance despite evidence that has suggested otherwise, specifically with preparticipation stretching activities. There is little evidence to support the notion that preparticipation stretching activities will result in a reduced risk of injury, and more studies suggest that static stretching has been shown to affect muscle performance.^{28,36} Avela et al³⁶ showed that there is an immediate reduction in reflex sensitivity of the stretch reflex as well as a significant reduction in stretch-resisting force following a static stretching routine. Stretching should be done immediately following an activity within 5 to 10 minutes when the musculature temperatures are increased or as a separate session.²⁸

9. AEROBIC TRAINING

Aerobic training can be a vital part of therapeutic exercise prescription depending on the patient's goals and medical needs. Aerobic training (conditioning exercise) is important for performance training, functional rehabilitation, and for the management of chronic pain syndromes. To condition both the cardiovascular system and a particular set of muscles, the exercise program should be continued at submaximal level to the point of fatigue. Walking, swimming, bicycling, tennis, treadmill, jogging, and jumping rope are examples of aerobic training exercises. Although not essential for recovery from TrPs, a regular conditioning exercise program is strongly recommended for optimal health and to minimize the chance of reactivating TrPs.

There are five design variables that are associated with aerobic training programs: exercise mode, training frequency, training intensity, exercise duration, and exercise prescription.²⁸

Exercise mode is the specific activity performed by an individual. These activities should be specific to the subject to mimic the movement pattern that will be employed in the patient's desired activity or competition. The different modes of aerobic training are long- or slow-distance training, pace/tempo training, interval training, repetition training, and Fartlek training and can be seen in more detail in Table 74-1.

<div>Table 74-1</div> Types of Aerobic Training and Required Frequency, Duration and Intensity					
	Long, Slow Distance (LSD)	Pace/Tempo	Interval	Repetition	Fartlek
Frequency (sessions/week)	1-2	1-2	1-2	1	1
Duration	Race distance or longer (30-120 min)	20-30 min	3-5 min work followed by 3-5 min rest	30-90 s work followed by 2.5-7.5 min rest (1:5)	20-60 min
Intensity	70% VO ₂ max	At or slightly faster than race pace	Near VO ₂ max	Greater than VO ₂ max	Varies between LSD and pace/tempo training intensities

Adapted from Baechle TR, Earle RW. *Essentials of Strength Training and Conditioning*. 3rd ed. Champaign, IL: Human Kinetics; 2008.

Optimizing training frequency influences positive adaptations in specific physiologic systems.²⁸ Training frequency is the number of training sessions conducted per day or per week and is dependent upon the interaction of exercise intensity and duration. For

example, higher exercise intensities and longer durations may necessitate less frequency in training to allow sufficient recovery from sessions. Recovery is an important aspect of training frequency and is essential to an individual to obtain maximum benefits from the subsequent training session. Sufficient rest times between sessions, along with adequate rehydration, and a high-quality diet are required to ensure that metabolic resources are replenished.

Training intensity is the relative physical effort that is expended during a training session. High-intensity aerobic exercise increases cardiovascular and respiratory function that allows for improved oxygen delivery to working muscles.²⁸ Training intensity also lends itself to skeletal muscle adaptations; as intensity increases, greater recruitment of type II muscle fibers occurs to meet the increased power demand which helps increase aerobic capacity.²⁸ Intensity is specific to the individual's level of training. Slow walking may be considered high intensity for some. Others may need a greater level of challenge to reach an adequate level of intensity. Heart rate is the most frequently used method for prescribing exercise intensity because there is a close relationship between heart rate and oxygen consumption. Two equations are used to calculate target heart rate. The first option is to take the age-predicted maximum heart rate and multiply by the desired exercise intensity. The second method, which is more accurate but more difficult to derive, is the Karvonen formula. This method accounts for resting heart rate and heart rate reserve, giving a more accurate representation of the target heart rate than the maximal heart rate percentage formula. Rate of perceived exertion can also be used to regulate exercise intensity during aerobic training. For example, the 15-point Borg scale can be used to estimate intensity where light intensity would be equal to 9, moderate intensity is equal to 12 to 14, and high intensity can equate to 18 to 20 on the scale.

Exercise duration is the length of time for a given training session and is often influenced by the intensity of exercise. Exercise conducted at an intensity above the maximal lactate steady state, which is about 85% of VO_2max , will require a relatively short duration of about 20 to 30 minutes. Lower-intensity exercises performed at 70% VO_2max or less may be performed for several hours.²⁸

Exercise prescription is the final variable that ties all the other aspects of aerobic program design together for the most important aspect: progression. It is important to note that research indicates that aerobic fitness does not decrease for up to 5 weeks when intensity is maintained and frequency decreases to as few as two times a week.²⁸ This is key when managing rehabilitation time frames for injuries to avoid a reduction in aerobic capacity for patients. When considering a progression in training, exercise frequency, intensity, or duration should not increase more than 10% to 15% each week.²⁸

These program design variables should also be used in the management of patients with myofascial pain syndrome to begin a patient on a graded exercise program. A successful program accounts for the patient's subjective reports and allow him or her to select a starting point. The patient's goals should also be considered in choosing the best mode of exercise. For example, a patient's main goal may be to be able to walk 1 mile in order to

navigate a large campus to see his or her daughter graduate from high school, but the patient is currently unable to walk to the mailbox and back without experiencing increased pain. The first short-term goal would be to walk to the mailbox and back without an increase in the pain report. To do so, the patient would be asked “how far do you think you can walk without absolute certainty that you will not experience or increase your pain?” The patient may say “half way to the mailbox and back.” Then half the distance to the mailbox is the starting point for the graded exercise prescription. The clinician then increases the distance 10% to 15% per week until the patient has achieved his or her goal. If the patient experiences pain at any time in the continuum, then the clinician would revert to the previous distance that the patient was walking until he or she was able to have success. It can be a tedious process and may take a time to achieve goals, but it is highly effective for patients with chronic pain syndromes. This principle can be applied to reach any activity goal by adapting the method to the specific mode of exercise, which can require a little creativity.

Follow these guidelines, and always considering foundations of cardiopulmonary physiology when prescribing aerobic exercises is paramount. By doing so, the patient remains safe throughout the training program and obtains the physiologic adaptations required to achieve his or her goals. For more information on program design, refer to the NSCA’s *Essentials of Strength Training and Conditioning* textbook.

10. FUNCTIONAL EXERCISES

Functional exercise utilizes all of the principles mentioned in the aforementioned sections to formulate an exercise prescription to achieve the patient’s highest level of function. Functional exercises are designed to prepare muscles that work synergistically to achieve movements that are specific to an activity or sport. This preparation is accomplished through simulation of movements required for the specific activity or sport. Functional exercises should be incorporated following neuromuscular reeducation to reinforce proper movement and muscle activation patterns. They should also be performed following strength or aerobic training to enhance and improve performance in the desired activity. Combined movements that incorporate both upper- and lower-extremity motions and simulate the functional task result in greater carryover to a functional activity. Squats, power cleans, and dead-lifts may also be considered functional exercises because they serve to prepare muscles to work together for common daily functional tasks. Yoga, Pilates, and tai chi may also be used as functional exercises. Innumerable options exist for patients with myofascial pain to perform functional exercise. In fact, patient preference should dictate the mode of functional exercise to improve adherence to the exercise prescription.

Therapeutic Modality Considerations

Thomas L. Christ, Joseph M. Donnelly, and Carolyn McMakin

1. INTRODUCTION

This chapter presents common therapeutic modalities the clinician can utilize as an adjunct to manual therapy, therapeutic exercise, and dry needling or trigger point (TrP) injection for patients with myofascial pain syndrome and TrPs. Thermal modalities include superficial heat, therapeutic ultrasound, cryotherapy, and vapocoolant spray. Electrotherapeutic modalities include transcutaneous electrical nerve stimulation (TENS), neuromuscular electrical stimulation (NMES), and biofeedback. An introduction to frequency-specific microcurrent (FSM) and its application is also presented. Thermal and electrotherapeutic modalities have a rich history and many therapeutic benefits for the treatment of various musculoskeletal conditions and for the treatment of myofascial pain syndrome and TrPs. The evidence of the effectiveness of the different modalities on impairments related to TrPs is discussed in detail when available, and recommendations for patient selection and the application of modalities are also provided. Clinicians should perform a full detailed history and consider each of the precautions and contraindications related to the modality being selected and applied. It is important to remember that modalities should never be considered a monotherapeutic intervention and should be performed in combination with other therapeutic interventions along with a home management program.

THERMAL MODALITIES

2. HEAT

Superficial heat has been used for years as a means of pain relief and relaxation. Heat alone is not an effective modality for the treatment of TrPs but can be a helpful adjunct to other interventions. Quantitative sensory testing is essential prior to administering or recommending heat to identify signs and symptoms of peripheral and/or central sensitization because heat may not be indicated in the presence of peripheral sensitization

(see Chapter 1).

2.1. Background

Superficial moist heat with hydrocollator hot packs uses the principle of conduction to transfer heat from the hot pack to the individual. This transfer of heat increases circulation in the skin but does not increase circulation at the level of the muscle.¹ The increased circulation at the level of the skin may allow improved efficacy of other TrP interventions such as pressure release and stretching by reducing the tissue density. Benjaboonyanupap et al² showed that continuous ultrasound has been shown to be more effective in pain reduction and pain pressure threshold (PPT) following 20 minutes of superficial heating compared with continuous ultrasound before superficial heating. Similar results have been shown for other interventions that may be used to treat TrPs such as pressure release, TENS, and spray-and-stretch.³

Heat in the absence of peripheral sensitization can provide analgesia and reduce muscle tightness. Heat reduces the gamma efferent muscle activity within the muscle spindle, thereby reducing the afferent input from the intrafusal fibers to the alpha motor neuron pool.¹ This will inherently reduce the alpha motor neuron firing rate, thus causing relaxation.¹ Heat can also inhibit nociceptive signals and stimulate areas of the brain associated with comfort and relaxation.⁴

2.2. Patient Selection

Patients presenting with pain and tissue stiffness will often benefit from superficial heat prior to other interventions. Heat in the form of a shower is also readily available to most individuals as part of a home management program. Prior to the administration of heat, the clinician should review the precautions and contraindications to heat modalities and determine if it is safe for the patient.⁵

2.3. Application

The patient should be informed of the expected sensations such as mild-to-moderate warming that may take a few minutes after application to feel. A painful burning sensation is abnormal and the patient should be informed to avoid the same experience in the shower or bath.¹

It is important to remember not to apply the hot pack directly to the patient's skin. Six to eight layers of towels or hot pack covering should interface between the patient and the hot pack. Additionally, the patient should not put his or her body weight on the hot pack or a home moist heat pad because this accelerates the heat transfer and could result in a burn to the patient.¹

Heat is traditionally used as an adjunct to a treatment plan of care. Heat can be used intermittently at home through portable moist heating pads, a warm bath, or shower, but should only be an adjunct for the treatment of TrPs.

3. CRYOTHERAPY AND VAPOCOOLANT SPRAY

Cold has been used historically to treat acute musculoskeletal injuries and to manage edema. Cold has an analgesic effect that dampens the patient's perception of pain and slows local circulation. Cold therapy is commonly used following dry needling interventions and for pain management following treatment. Cold modalities include ice packs and gels, ice massage, and vapocoolant sprays. Vapocoolant sprays can be applied to the skin in the area of a TrP and its pain referral region with a "spray-and-stretch" technique. The essential therapeutic component is the stretch. "Stretch is the action, spray is distraction." However, the expression "spray-and-stretch" is preferred to "stretch and spray" because it is important that the spray be applied before or concurrently with, but not after, the muscle is stretched. Stretch without some additional technique to release muscle tension and suppress pain is likely to aggravate TrPs.

3.1. Background

Cold therapy is traditionally used in the acute inflammatory phase of injury, but can be used for the treatment of active TrPs as well.⁶ The use of cold therapy in the form of a cold pack can be applied after manual interventions such as pressure release or dry needling.⁶ Ice massage can be used prior to manual treatments to reduce pain caused from TrPs and improve PPT.⁷ Vapocoolant sprays can be a very effective means of deactivating symptomatic TrPs by utilizing a "spray-and-stretch" technique, which was introduced by Simons et al, 1983.⁸ A single-muscle syndrome of recent onset frequently responds with a full return of pain-free function when two or three sweeps of spray are applied while the muscle is being extended gently to its full stretch length.⁹ In addition, when many muscles in one region of the body, such as the shoulder, are involved and the TrPs are interacting strongly with one another, spray-and-stretch is a practical means of releasing an entire functional group of muscles together to make more rapid progress toward pain relief. The spray-and-stretch technique does not require the precise localization of the TrP that is needed for pressure release, dry needling, or injection. It only requires identification of where the taut bands are located in the muscle to ensure that those fibers are released.

The effectiveness of the vapocoolant spray (spray-and-stretch) is related to the analgesic properties of the chemical. The vapocoolant must be dispensed as a fine stream, rather than a dispersed spray as in products that are used for athletic injuries. The cooling effect of the vapocoolant spray occurs from the instant evaporation of the spray. Because of the rate of evaporation, it is pivotal that the clinician applies the spray from the appropriate distance (12-18 in from the skin). If applied too close to the skin, the liquid's temperature will be too warm at impact to produce much effect; if applied too far away, the liquid will contact the skin at subfreezing temperatures.

Ethyl chloride is too cold for optimum release of TrP tension as usually applied. It is a rapidly acting general anesthetic that has a dangerously low margin of safety, is flammable, and is explosive when 4% to 15% of the vapor is mixed with air.¹⁰ If ethyl chloride spray is

used, rigorous precautions must be observed. Fire hazards must be eliminated, and neither the patient nor the clinician should inhale the heavy vapor. Ethyl chloride should never be given to a patient for home use. There are other commercially available products that do not contain fluorocarbons or ethyl chloride that are safer for the patient and the environment.

There are multiple physiologic mechanisms for how the application of a cooling agent to the skin dampens nociception and pain perception. Trigger points can reduce the threshold of noxious stimulus required to generate nociception and a pain response. Cryotherapy can temporarily counteract the change in pain threshold. Decreasing the temperature of the surrounding tissues as well as the nerve will increase an individual's nociceptive threshold, thus requiring more noxious stimulus for the patient to perceive pain. Cryotherapy also reduces nerve conduction velocity, therefore slowing the rate of the noxious stimulus to the central nervous system.¹¹ Cryotherapy can help reduce inflammation in the tissue, reducing the influx of chemical mediators such as histamine, mast cells, substance P, calcitonin gene-related peptide, bradykinin, and others that can activate and sensitize peripheral receptors. This change can prevent worsening of symptoms and the potential progression to peripheral and central sensitization. The reduction in nociception and perception of the TrPs allows the muscles to be stretched without increasing the level of nociceptive input from the TrP.

3.2. Patient Selection

Patients presenting with acute pain or inflammation, as well as those receiving manual therapy, dry needling, or TrP injections may benefit from cryotherapy to reduce inflammation as well as posttreatment soreness. Prior to the administration of cryotherapy or vapocoolant spray, the clinician should determine if it is safe for the patient by considering the precautions and contraindications to this treatment.⁵

3.3. Application

Quantitative sensory testing (especially heat and cold tolerance) should be carried out prior to the application of cryotherapy. Cold packs can be applied over larger areas of the body. To prevent skin damage, towels should be used as an interface between the ice and skin; damp towels are preferred to dry towels to better facilitate the transfer of energy. Ice packs, gel packs, and bags of frozen vegetables can all be used as the cold pack, although true ice itself may be the most beneficial and safest because it will lose its cold properties over time.¹² Before the application of the ice pack, the patient should be informed of the expected sensations. The patient is likely to feel a cold sensation at first, followed by a warming sensation for a few minutes. This feeling gives way to an achy sensation and finally anesthesia. Some mild redness on the skin is expected. The application of cold packs should last no longer than 20 to 30 minutes with longer duration for larger areas.¹² Following treatment, pain should be temporarily lessened and patients should avoid activity that could aggravate their injury or TrPs. In each of the muscle chapters, corrective actions

are presented with suggestions of a home management program.

Ice massage can be performed over smaller areas and applied directly onto the skin. Ice massage can be used directly on the muscle belly over the TrPs, along the referred pain area, on the tendon, bursa, and other tissues. Ice massage requires freezing water in a paper cup, or in the fingers of a nonlatex glove, allowing the clinician to peel off part of the cup to expose the ice or breaking off one of the glove fingers and using the exposed ice.¹² The ice is slowly massaged over the target region in small circles for 5 to 10 minutes. Expected sensations for ice massage are the same as with ice packs and it is important to communicate with patients about their experience. The ice from the finger of the glove can be used in place of the vapocoolant spray by starting at the identified TrP in a muscle and moving into the pain referral area three to five times, followed by immediate stretching.

Vapocoolant sprays are applied directly to the skin. The patient must be positioned comfortably and well supported to allow relaxation of the muscles of interest. The spray is applied in a fine stream from 12 to 18 in away from the skin, at a 30° angle.¹³ Figure 75-1 depicts the spray-and-stretch technique for the upper fibers of the trapezius muscle and gluteus medius muscle. Clinicians should perform one spray of the entire muscle belly length and its pain referral area two to three times and then immediately place that muscle on stretch. While still on stretch, the clinician should follow up with two or three more full-length sprays (Spray-and-stretch).¹³ Latent TrPs may be activated incidental to spray-and-stretch therapy. Although one group of muscles is being passively stretched, their antagonists are shortening much more than usual. Fortunately, if latent TrPs in the antagonists are painfully activated in this way, they can be inactivated quickly by then spraying and stretching them. After application, the skin needs time to warm up again before reapplication. During this time, the patient can gently actively stretch the muscle or a moist heat pad can be applied. Vapocoolant sprays may provide pain relief and increase range of motion after one session, or may require several sessions and other skilled therapeutic interventions such as manual therapy, pressure release, dry needling, or TrP injection.

Figure 75-1. Application of vapocoolant spray for treatment of TrPs. A, Upper trapezius muscle. Note that the vapocoolant spray is applied over the muscle and pain referral pattern. B, Gluteus medius muscle. Note that the vapocoolant spray is applied from proximal to distal over the muscle through a full range of motion.

All forms of cryotherapy are performed in conjunction with other means of skilled therapeutic intervention for TrPs and are not considered stand-alone treatments. Clinicians should be mindful of their patient's responses to cryotherapy and make appropriate adjustments if necessary.

4. ULTRASOUND THERAPY

A large amount of literature on the efficacy of ultrasound therapy for patients with TrPs exists, although the effectiveness of the modality is still debated because of a lack of homogeneity in study designs. Ultrasound therapy has commonly been studied for its effects on pain (Visual Analog Score), PPT, and cervical range of motion.^{2,14–23} The various available parameters for ultrasound therapy and success of placebo groups make for inconsistency in the research, although some trends in ultrasound efficacy for TrPs are beginning to emerge.

4.1. Background

Ultrasound therapy has been shown to be effective in reducing patients' pain associated with TrPs. Several studies have used a visual analog scale (VAS) for subjective pain reports and show a reduction in pain with the utilization of ultrasound therapy for the treatment of

TrPs.^{2, 14–16, 18, 21–23}

Continuous ultrasound is the most commonly studied ultrasound parameter. Improvements in VAS scores with continuous ultrasound have been shown to occur immediately following treatment in some cases^{2, 18, 23} or following several intervention sessions in other studies.^{16, 21, 22} The results from nonthermal effects of pulsed ultrasound therapy, although far less researched, have also shown improvements in VAS pain scores in patients with TrPs, but not as effective when compared with continuous ultrasound.^{15, 22}

High-power pain threshold static ultrasound therapy is another method that has shown rapid improvements in VAS scores when compared with conventional continuous ultrasound therapy.¹⁶ However, this mode has not been commonly studied and lacks additional support. In this method, the sound head is held statically over the TrP as the intensity is increased to the patient's pain threshold level (up to 1.5 W/cm²) and is held in place for 4 to 5 seconds, and is reduced to half the intensity for 15 seconds. This procedure is repeated for 2 to 3 minutes.

The mechanisms for pain relief of performing ultrasound over TrPs are multifactorial. The application of the sound head and the deep heating excites the A β mechanoreceptors, thus exploiting the gate-control theory for pain modulation.¹⁵ The thermal effects of continuous ultrasound generate local vasodilation and subsequent increased circulation, which filters out neurokinins (pain-sensitizing substances) helping to reverse the hypoxic environment. The heating of the tissue reduces muscle spasm and allows sarcomeres to return to their normal length.^{2, 15} The increased blood supply to the TrP and resetting the sarcomere to its normal length are two important factors that need to be considered when treating TrPs.¹⁵ Sarrafzadeh et al¹⁵ suggest that with nonthermal ultrasound, rapid pressure changes within the tissue cause an increase in cell membrane permeability, allowing ions and molecules to be removed from the muscle tissue.

Pain pressure threshold, while subjective in nature, has been shown to be a reliable measure for muscle tenderness²¹ and is commonly used as an outcome measure when studying the effectiveness of treatment on TrPs and myofascial pain syndrome.^{2, 14, 15, 20, 21, 23} Both continuous (thermal)^{2, 14, 21, 23} and pulsed (mechanical)¹⁵ ultrasound therapy have been shown to be effective in the improvement of PPT. The mechanism of action to increase a patient's PPT is likely related to the reduction of neurokinins in the local tissue environment, thus reducing nociceptive input and pain perception. This chemical change aids in the disruption of the local energy crisis caused by ischemia and hypoxic environment in the area of the TrP by the flushing of nociceptive-sensitizing substances out of the tissue.¹⁵

Ultrasound therapy of TrPs in the cervical spine region to improve cervical range of motion has been investigated with mixed results.^{14–17, 21, 24} Improvements in range of motion are typically present with all modes of ultrasound, but the rate of improvement and reliability of the results are variable. High-powered ultrasound therapy has been shown to produce the fastest significant improvements in cervical range of motion¹⁶; however, as stated previously, the evidence is scant. Continuous ultrasound has also demonstrated good

improvements in cervical range of motion,^{16,21,24} although it often takes a frequency of 5 days a week for several weeks to see significant improvements. Pulsed ultrasound therapy is inconsistent in regard to improvements in cervical range of motion. Sarrafzadeh et al¹⁵ showed improvements in cervical lateral flexion following six sessions of pulsed ultrasound therapy, while on the contrary, Aguilera et al¹⁷ did not see significant improvements in cervical lateral flexion range of motion following only one treatment session with pulsed ultrasound. The reason for improvements in range of motion with thermal modes of ultrasound is likely due to its deep heating effects. Heat increases tissue extensibility, allowing the joint to go through further range of motion before being limited by the muscle containing TrPs.¹⁴

Overall, the literature suggests that ultrasound is an effective modality for reducing the pain perception and PPT, but is less conclusive with its effects on range of motion. The criticism with ultrasound therapy research is the lack of homogeneity and the observed improvements in placebo sham ultrasound groups. Outside of the differences in the effects of thermal and nonthermal ultrasound, there is no established parameters for treating TrPs. Placebo groups have been shown to improve significantly in pain scores,^{21–23} PPT,^{21,23} and cervical range of motion,^{14,21,24} further questioning the true efficacy of ultrasound therapy. In some cases, improvement may result from the subsequent interventions incorporated in the treatment sessions,^{14,22,24} but in other cases, no exercise treatment was provided and placebo groups still showed improvements comparable to the treatment groups.^{21,23}

4.2. Patient Selection

Patients with TrPs or myofascial pain syndrome in muscles that are easily accessible by the ultrasound head are appropriate for ultrasound therapy. The application, procedures, precautions, and contraindications for ultrasound therapy are beyond the scope of this chapter, and the clinician is advised to review these parameters in other sources prior to the application of ultrasound for the treatment of TrPs and myofascial pain syndrome.

4.3. Application

The clinician should inform the patient of expected sensation such as heating, and to inform the clinician if the sound head is too hot and becomes painful. The clinician must consider the patient's medical history and should review all the precautions and contraindications prior to treatment.⁵

Continuous ultrasound therapy is the most commonly studied mode and should be used for patients who have pain or restricted mobility due to the presence of TrPs. Continuous ultrasound provides deep heating to the tissue that reduces nociception and improves muscle tissue extensibility.^{2,18,23} Although it is more effective for the treatment of TrPs, continuous ultrasound has many more precautions and contraindications that must be considered before treatment.⁵ Pulsed ultrasound therapy may be beneficial for reducing

nociception associated with TrPs, but is not as effective for improving range of motion.^{15,17} The main advantage that pulsed ultrasound therapy has over continuous ultrasound therapy is that it does not create a deep tissue heating; therefore, it may be used in the acute stages of healing⁵ or when the patient presents with the signs and symptoms of peripheral sensitization. High-powered ultrasound therapy can be used for TrP-related nociception as well as range of motion, but there is a limited evidence of recommended dosage as well as precautions and contraindications to this mode of ultrasound.¹⁶ The inconsistency in the specific parameters is one of the main reasons for the clinical controversy over ultrasound therapy effectiveness. Recommended settings for continuous and pulsed ultrasound are provided in Box 75-1. Because of the paucity in available research on high-powered ultrasound, a full recommendation on parameters is not listed.

Box 75-1 Recommendation for ultrasound therapy parameters for the treatment of TrPs

Ultrasound Parameter Recommendations				
Mode	Intensity	Frequency	Duration	Applicator Diameter
Continuous ²⁵	<ul style="list-style-type: none"> Lowest intensity that still experiences desired effects. TRANSDERMAL MEDICATION DELIVERY

5. PHONOPHORESIS

Phonophoresis is the utilization of ultrasound therapy to drive a topical medication into the subcutaneous tissue.²⁵ Various topical medications, most commonly hydrocortisone and local analgesics such as lidocaine, have been administered via phonophoresis.²⁵ Although an abundance of research exists on the efficacy of phonophoresis for various musculoskeletal conditions, there is limited literature available on its effectiveness for the treatment of myofascial pain syndrome or TrPs.

5.1. Background

The topical medications used in phonophoresis can be applied either directly onto the ultrasound head or mixed with the ultrasound gel.²⁵ Because phonophoresis requires the use of ultrasound therapy to drive the medication into the desired tissue, phonophoresis will provide many of the same positive effects as ultrasound therapy. The predominate effects on TrPs include reduction of pain intensity on VAS, improvement in PPT, and improvement in range of motion.^{14, 15, 26} Many of the mechanisms of action are due to the ultrasound therapy as previously discussed in this chapter.

Some studies show significant differences between experimental phonophoresis groups compared with conventional ultrasound control groups on pain and PPT.^{15,26} In one study, hydrocortisone 1% gel was used as the topical medication. Both the phonophoresis and ultrasound groups showed significant improvements in pain and PPT; however, the phonophoresis group showed significantly greater improvements when compared between groups.¹⁵ Ustun et al²⁶ studied the effects of EMLA, a topical mixture of lidocaine (2.5%) and prilocaine (2.5%) used as the topical medication and compared with ultrasound therapy. Both groups showed significant reduction in pain after 15 sessions, but the eutectic mixture of local anesthetics (EMLA) phonophoresis group was significantly better when compared between groups.²⁶ In both of these studies, significant improvements were also found in cervical lateral flexion range of motion in both the phonophoresis and ultrasound groups, but no differences between groups existed.

Ay et al¹⁴ used diclofenac gel as the topical medication and did not find significant differences in the reduction of pain, PPT, or range of motion between the phonophoresis and ultrasound groups.

The medication selection is an important factor in the therapeutic effects of phonophoresis. The literature does not show that phonophoresis is superior to ultrasound in improving range of motion,^{14,15,26} which suggests that the improvements in range of motion are from the ultrasound therapy alone. Hydrocortisone is a powerful anti-inflammatory corticosteroid that was demonstrated to be significantly more effective than ultrasound alone in improving pain and PPT¹⁵; however, these results were not shown when diclofenac gel was used.¹⁴

5.2. Patient Selection

Patient selection for phonophoresis therapy is similar to ultrasound therapy. The patient must be prescribed the topical medication by a physician in order to receive phonophoresis treatment. Clinicians must consider all of the precautions and contraindications to ultrasound as well as any allergies to the medication being applied before performing phonophoresis.⁵

5.3. Application

The setup and application for phonophoresis treatment is similar to that of ultrasound, with the addition of the topical medication. The medication may stand in as the coupling medium¹⁴ or may be mixed with ultrasound gel. Both pulsed and continuous modes of ultrasound have been utilized to drive the topical medication into the desired tissue with the remaining parameters similar.^{14,15,26}

Improvements in pain may occur right after treatment because of the effects of the medication but likely will take several sessions to become significant.^{14,15,26} Improvements in range of motion may also occur following one session but will often take multiple intervention periods to become significant.^{14,15,26} Phonophoresis is not a stand-alone

treatment and should be performed in conjunction with therapeutic exercise and other skilled therapy.

6. IONTOPHORESIS

Iontophoresis is an electrical means for transcutaneous administration of drugs into the subcutaneous tissues. Iontophoresis is prescribed for a number of reasons, including pain, inflammation, and muscle spasm. Although these are all characteristics of TrPs, the literature is scarce on iontophoresis efficacy for the treatment of TrPs.

6.1. Background

Iontophoresis is a means of using charged molecules to drive topical medications past the largely impermeable stratum corneum layer of the skin into the subcutaneous tissue.²⁷ Negatively charged medications are repelled and directed into the skin by the cathode lead, and positively charged medications are repelled and directed into the skin by the anode lead.²⁸ Iontophoresis is a noninvasive, low-risk method of drug delivery that has beneficial pharmacokinetic properties such as faster release of the drug to its target tissue and easier control of dosage due to skipping the hepatic first-pass effect.²⁷

Historically, iontophoresis has been used for conditions such as tendonitis, joint replacement, whiplash-associated disorder, and a variety of other musculoskeletal conditions. Iontophoresis can also be used for the treatment of TrPs, although the evidence is limited.

Lidocaine, a popular local anesthetic, has been used in the treatment of myofascial pain and TrPs on various posterior neck and back muscles.²⁹ Kaya et al²⁹ demonstrated that 10 days of lidocaine iontophoresis treatment significantly reduced PPT and VAS pain score, increased cervical range of motion, and improved a variety of other outcomes. The control group received 10 days of direct current electrical stimulation without lidocaine and also showed significant improvements in all outcomes, thus questioning if lidocaine was a significant variable in the patients' improvement.²⁹ Older research has shown significant success with the administration of a dexamethasone and lidocaine-mixed solution in improving active glenohumeral abduction.³⁰ Lidocaine is a commonly used amide local anesthetic that works by blocking the sodium channels, thus inhibiting neural transmission.³¹ This physiologic effect makes it plausible that administration would reduce the pain associated with TrPs. Dexamethasone is a corticosteroid commonly prescribed for its anti-inflammatory effects, which could make it effective in flushing out the nociceptive substances present with TrPs.³¹

There is a need for more research on the efficacy of this mode of drug delivery for the treatment of TrPs.

6.2. Patient Selection

Patients dealing with pain related to TrPs are appropriate for iontophoresis as long as they

do not have any precautions or contraindications to electrotherapeutic modalities or currents.⁵ Additionally, clinicians should screen for any allergies to the medication being administered.

6.3. Application

The application of iontophoresis requires at least two electrodes to act as the medium for electrical conduction, the medication being administered, lead wires, and an electrical stimulation unit. The patient's skin should be cleaned with alcohol or soap and water, and excess hair should be removed before applying the electrodes. Negatively charged medications should be applied to the cathode electrode placed over the target tissue. Positively charged medications should be applied to the anode electrode placed over the target tissue.²⁸ Prior to initiating iontophoresis, the clinician should instruct the patient on expected sensations such as a low-level tingling or redness under the electrode, and adverse effects such as burning, stinging, blistering, or bright redness.²⁸

There are no universally accepted parameters for the administration of iontophoresis. The dosage of drug to be administered along with the patient's tolerance to higher intensities (current mA) will dictate the electrical stimulation settings.²⁸ An example of the relationship between dosage and patient tolerance is shown in Box 75-2. Notice how when the current increases the duration of treatment reduces. Higher currents drive the medication into the target tissue at a faster rate than lower currents.²⁸

Following treatment, the clinician should examine the patient's skin for signs of adverse effects such as blistering or bright redness that does not resolve within a few hours.²⁸ The patient may experience an improvement in symptoms, although this may be temporary as iontophoresis is not a stand-alone treatment and should be performed as an adjunct to other therapeutic interventions.

ELECTROTHERAPEUTIC MODALITIES

7. TRANSCUTANEOUS ELECTRICAL NERVE STIMULATION

TENS is an electrical modality commonly used for pain relief in addition to other therapeutic interventions. TENS can utilize a low- or high-frequency electrical current to activate internal antinociceptive mechanisms, either inhibiting nociceptive signaling or increasing the body's natural anti-nociceptive-relieving substances.^{32,33} TENS is well established as a means of temporary pain relief, but limited evidence exists on the long-term effectiveness of this modality. Additionally, evidence on TENS impact on TrPs is inconclusive, largely due to the inconsistency in the methodology of the research as well as the inability to establish sound parameters for the effectiveness of TENS on TrP-related outcomes such as pain scores (VAS), PPT, and range of motion.

7.1. Background

A bulk of literature exists on TENS effectiveness on pain reduction in a variety of musculoskeletal disorders.^{32, 34–36} The local and referred pain generated by TrPs is signaled through small-diameter A-delta and C fibers carrying noxious stimulus from the periphery to the dorsal horn of the spinal cord where the noxious stimulus is encoded in the substantia gelatinosa.³² Conventional high-frequency TENS exploits the “gate-control theory” to stimulate nonnoxious A-beta fibers that inhibit the transmission of the noxious A-delta and C fibers, thus inhibiting the transmission of noxious stimulus on the second-order neurons in the dorsal horn of the spinal cord.³² The effects of high-frequency TENS (>80 Hz) are typically short-lived and do not persist more than a few hours after application.³² Low-frequency TENS (<10 Hz) taps into the body’s natural release of enkephalin and β -endorphins, stimulated from the periaqueductal gray. This release activates the descending inhibitory pathways to the dorsal horn of the spinal cord, reducing nociceptive input, especially nociceptive input, from muscle nociceptors from forming effective synapses with second-order neurons in the spinal cord.³⁷ The effectiveness of TENS on patients with pain from TrPs follows the same pain science mechanisms as its use on any other musculoskeletal source of pain. Low-frequency TENS produces low-level muscle contractions and has been shown to improve blood flow within the muscle.³⁸ This effect may be beneficial in helping flush out nociceptive-sensitizing substances associated with TrPs such as substance P, bradykinine, prostaglandins, and serotonin.³³ A new study by Ferreira et al³⁴ examined the effects of combined high and low-frequency TENS by performing low-frequency TENS for 25 minutes followed immediately by high-frequency TENS for 25 minutes. Improvements in pain reports lasted up to 48 hours following intervention, far longer than effects typically last.

TENS effect on PPT is less conclusive as studies have produced mixed results. Ferreira et al³⁴ used low- and high-frequency TENS and found significant reductions in PPT lasting up to 48 hours. The muscle contraction from a low-frequency TENS may be beneficial in improving PPT by normalizing the endplate acetylcholine release and increasing blood flow to flush out the nociceptive-sensitizing substances within the TrPs,^{33, 34, 38} although not all studies using low-frequency TENS have shown improvements in PPT.³⁹ High-frequency TENS has shown both positive³² and no effect^{35, 40} on PPT. Burst TENS has shown to improve PPT in the short term³³ and may be an effective modality for patients experiencing pain from TrPs. The lack of homogeneity in the methods clouds the results and makes it difficult to state whether or not TENS is a beneficial modality for improving PPT in patients with myofascial pain syndrome or TrPs.

The effects of TENS on range of motion are also not clear. High-frequency TENS and burst TENS have shown to improve cervical range of motion.^{32, 33, 35} The pain relief with TENS can induce relaxation of the muscle and deactivation of the taut band, allowing the sarcomere to lengthen, giving the patient less resistance with motion.³³ But increased range of motion does not always occur as evidenced by other researchers who have shown no improvement.^{39, 40}

Overall, both high-frequency and low-frequency TENS may be a beneficial

intervention for reducing pain, and increasing PPT, and improving range of motion restrictions caused by TrPs. TENS should be considered an adjunct modality that could be used as an adjunct to a home management program in addition to other forms of skilled therapy including dry needling, manual therapy, and exercise (see Chapters 72 to 74). For patients experiencing higher levels of pain that may prevent them from participating in therapy, TENS can be beneficial in dampening nociceptive levels that may allow participation in therapy.

7.2. Patient Selection

Patients presenting with pain and impairments from TrPs may benefit from TENS to dampen pain and allow for function and participation during therapy. Clinicians should be always review the precautions and contraindications to electrotherapeutic modalities prior to administering TENS.⁵

7.3. Application

Prior to initiating TENS, the clinician should instruct the patient on expected sensations such as tingling and slight redness under the skin, and signs of adverse effects like burning, stinging, blistering, or bright redness.⁴¹ There are various parameters for application of TENS in a patient with myofascial pain or TrPs. To date, there is no consensus on a TENS protocol for the treatment of myofascial pain syndrome or TrPs; however, there are parameters that may address peripheral and or central sensitization and/or neuropathic pain.³⁴ Therefore, the clinician should use sound clinical reasoning to evaluate the patient's associated mechanisms of symptoms when determining TENS parameters for the patient. Electrode size can influence the current density, and generally, smaller electrodes are indicated for TrPs because they are able to localize the current to a more distinct tissue.⁴¹ Box 75-3 lists general guidelines for various settings of TENS.

Box 75-3 TENS parameters

TENS Parameter Recommendations⁴¹

Mode	Pulse Frequency	Pulse Duration (ls)	Intensity (mA)	Duration (min)
Conventional (high-frequency)	■ >80 Hz	■ 50-100	■ Sensory level, to patient tolerance	■ 20-30
Conventional (low-frequency)	■ <10 Hz	■ >150	■ Motor level, to elicit a	■ 20-45

			visible muscle twitch	
Burst	■ ~100 Hz, burst frequency 1-4 Hz	■ 200	■ Motor level, to elicit a visible muscle twitch	■ N/A

Abbreviation: TENS, transcutaneous electrical stimulation.

The ability of TENS to modulate nociceptive input through gate-control and/or descending modulating systems activates the bodies' endogenous opiate release. This relief of pain is typically not long lasting. TENS may augment or allow therapeutic procedures to be implemented, be part of a home management program, and afford the patient to be productive at home and in society. TENS is typically not a stand-alone modality and should be part of a comprehensive pain management strategy. TENS is an affordable modality and should be considered as an alternative to opioid prescriptions.

8. NEURO-MUSCULAR ELECTRICAL STIMULATION

Electrical stimulation has long been applied by clinicians for treating a variety of musculoskeletal disorders. NMES is one method of electrical stimulation that has been utilized to stimulate motor units to improve the synchronization and efficacy of muscle contractions. NMES mimics function of the motor cortex through artificial depolarization of the peripheral nerves (motor end plate) and has been shown to increase motor performance, strength, and hypertrophy.^{42, 43} NMES is less likely to be used to deactivate TrPs, but may be effective in retraining muscle activation patterns, functional activities, and awkward postures that are contributing factors to the development of TrPs.

8.1. Background

The activation and perpetuation of TrPs can occur for many reasons, including unaccustomed eccentric loading, eccentric exercise in an unconditioned muscle, or maximal or submaximal concentric loading.⁴⁴ Muscles that are inhibited or untrained are, therefore, more prone to the development of TrPs and are often difficult for patients to volitionally contract and strengthen because of pain, fatigue, and inefficiency of muscle activation patterns.

Postural considerations are also important factors. Patients presenting with forward head posture, upper cross syndrome, or lower cross syndrome often have muscle groups that are overlengthened and inhibited, and are difficult to activate volitionally. NMES may enhance muscle activation to improve motor control of these inhibited muscles through

artificial electrical stimulus to the motor end plate of the muscle. This stimulus mimics that generated by the motor cortex during volitional contraction by creating the same action potential propagation and subsequent release of the acetylcholine neurotransmitter.⁴² NMES does not function the same as volitional contraction nor does it have the same physiologic and mechanical effects. With NMES, all motor units are recruited at once rather than type I slow-twitch fibers being depolarized and activated first followed by type II fast-twitch fibers as in Hanneman's size principle.^{42,45} Additionally, in volitional contraction, the motor units have an opportunity to rotate their "on" and "off" time within a contraction, allowing brief periods of rest, which is not the case with NMES. With NMES, all motor units are turned "on" throughout the contraction, thus increasing the rate of muscle fatigue.⁴²

There is a paucity of NMES research directly related to TrPs, but an extensive amount of literature supports its ability to strengthen weak muscles and improve motor performance.^{42,43,46,47} There is a vast amount of research on NMES because it relates to postoperative rehabilitation following knee surgeries when the quadriceps femoris muscle group is inhibited or weakened and is associated with impairments in gait due to weakness and poor motor unit recruitment. NMES, combined with exercise, has been shown to be more effective than exercise alone in quadriceps strength and function.⁴³ There is limited evidence for NMES in other areas of the body, but the same principles can be applied. The posterior shoulder and scapular muscles are commonly either lengthened, weak, or inhibited and are typically a site of TrP development. NMES can be used as part of a neuromuscular reeducation program to retrain muscle function and muscle activation patterns, subsequently improving posture and function and preventing further TrP development.^{48,49}

8.2. Patient Selection

Patients who show signs of muscular imbalance such as forward head posture, upper cross syndrome, or lower cross syndrome (see Chapter 76) are likely to have muscle groups that are lengthened, inhibited, or weak, creating muscle overload and altered movement patterns. Patients with these impairments are at risk for developing TrPs because of either the overactivity or underactivity of the functional unit. A combination of NMES with volitional muscle contraction as a means to retrain the underactive muscle groups may be beneficial for patients presenting with inhibition weakness due to TrPs. Prior to the application of NMES, the clinician should review the precautions and contraindications to determine if the patient is appropriate for NMES.⁵

8.3. Application

There are a number of different parameters clinicians can use for NMES. Burst-modulated (Russian) is common and generally promotes faster and greater gains, although it increases the rate of fatigue and is less tolerable. Pulsed biphasic is another common waveform that is generally effective and more tolerable. For strengthening effects, the pulse duration should

be the highest level that the patient can tolerate,^{45,47} with larger muscles able to tolerate longer durations than smaller muscles. A pulse frequency of at least 30 pulses/s is needed to generate a forceful contraction, but can be as high as 80 pulses/s.⁴⁵ As mentioned, NMES tends to lead to muscle fatigue faster than volitional isolated muscle contractions. Therefore, a work-to-rest ratio should be established.^{45,47} A 1:5 work-to-rest ratio is recommended initially and can be progressed to 1:4 and 1:3 as muscle performance improves. The amplitude (intensity) is dependent on patient tolerance. For strength gains to occur, the intensity of the contraction should be near maximal levels, but pain and fatigue prevent reaching higher levels of intensity; therefore, the clinician should start at patient tolerance and slowly progress to greater amplitudes.^{45,47} Electrodes should be placed over the motor end plate, and a minimum of 2 in apart. Larger muscles may require larger electrodes and an additional channel, four electrodes rather than two.⁴⁷

Following NMES, the patient may experience delayed onset muscle soreness (DOMS) as well as some slight redness on the skin.⁴⁵ In this case the muscle should be examined for TrPs as the overload by the NMES may cause the formation of TrPs especially in the presence of DOMS. The clinician should be aware of signs and symptoms suggestive of rhabdomyolysis, because this has been reported in some cases with improper NMES prescription.⁴⁷ NMES can be used indirectly to treat TrPs by correcting postural and muscular overload. NMES is never a stand-alone therapy and should be used as an adjunct to a detailed clinical reasoning process and therapeutic exercise prescription. Once volitional activation can be achieved, NMES should be withdrawn to improve motor control during functional activities.

9. BIOFEEDBACK

Biofeedback is a way to monitor and attempt to modify a patient's autonomic functions. Biofeedback is often used to study a patient's muscle or brain activity through electromyography (EMG), functional MRI (fMRI), monitoring,⁵⁰ and other types of physiologic feedback. It can be an effective modality for patients with TrPs to help reduce their activity and modulate their perception of pain.

9.1. Background

Biofeedback utilizing EMG can help the clinician identify muscular dysfunctions caused by TrPs, or may be causing associated TrPs in other muscles leading to the patient's pain or movement impairments.^{51,52} Electrodes can be placed on the skin over the muscle belly or inserted into the muscle belly (in-dwelling) recording the electrical activity occurring at the motor end plate.⁴⁵ The raw data collected is rectified into visual or audio feedback that the clinician can use to interpret the activity occurring in the muscle. These data help the clinician to identify muscles that may be underactive or overactive, asymmetries, faulty motor unit recruitment, and ineffective timing and synchronization. It may also help identify unwarranted muscle activity that may be contributing to the patient's symptoms.

The auditory or visual feedback from the EMG data can be used to help retrain muscular dysfunctions, whether it be through recruitment of motor units or inhibition of overactive motor units. Although beneficial for any muscle group, EMG biofeedback has been predominately studied in the treatment of patients reporting temporomandibular joint (TMJ) pain by reducing muscular tension around the TMJ. These investigators found that muscle tension and pain scores remained reduced up to 6 months following conclusion of the intervention.^{51–53}

Biofeedback using fMRI proposes potential ability to train patients to manipulate the activity of the rostral anterior cingulate cortex associated with conscious pain perception.⁵⁴ deCharms et al,⁵⁴ in a study using real-time functional MRI, showed that through training, when subjects were presented with a noxious stimulus, they were able to increase or decrease the perception of pain on command.⁵⁴ The same held true for patients with persistent pain. Myofascial TrPs can lead to peripheral and central sensitization, and this type of biofeedback may be beneficial in helping these patients self-modulate their pain perception. However, because of the cost of this equipment, this intervention may not be feasible for all patients. Less expensive options for biofeedback should be researched.

9.2. Patient Selection

Following the patient's subjective report, the clinician should hypothesize if certain muscles are over- or underactive, leading to TrP activation and pain. Psychosocial variables should also be assessed because many of these conditions lead to increased muscle tension. Individuals under stress often experience increased muscle tension and pain.⁵² If the clinician feels that muscle tension or dysfunctional motor performance is a contributing factor in the patient's presentation, biofeedback may be indicated. Biofeedback is also indicated in patients with persistent pain caused by muscle pain and TrPs. Because biofeedback is strictly information gathering, and no stimulus is being applied to the patient, there are no precautions or contraindications other than allergies to the electrode, which makes biofeedback an appropriate intervention for most individuals.⁴⁵

9.3. Application

The setup for EMG biofeedback requires recording electrodes, a recording device, computer software to rectify the raw data, and an auditory or visual mode to present the information to the clinician and patient.⁴⁵ The correct size and location of the electrode is important to study the desired muscle and to avoid cross-talk. Other forms of biofeedback will have individual technology requirements for use.

Biofeedback is not a treatment in itself, but it provides useful information about an individual's performance, and allows the clinician to select interventions appropriately and provides quantitative data to monitor progress.

10. FREQUENCY-SPECIFIC MICROCURRENT

By Carolyn McMakin

FSM was first used to treat TrPs in 1996. The technique uses manual therapy combined with frequencies thought to address certain pathologies in specific tissues delivered as square wave pulses by a standard two-channel microcurrent device. The frequencies were developed by physicians in the early 1900s and used on devices not seen since the 1930s. A 1922 frequency list was discovered with one of the old devices in 1946. The device was abandoned and the list was filed away until 1996 when it came to be used in the treatment of myofascial pain syndrome and TrPs on a two-channel microcurrent device.^{55,56}

10.1. Background

The FSM technique uses a frequency on one channel described on the list as neutralizing a specific pathology combined and applied simultaneously with a frequency on a second channel described as addressing a specific tissue. The microcurrent device delivers the frequencies with ramped square wave pulses of subsensory current between 100 and 300 μ A. Research shows that water in the body is organized into structures resembling a semiconductor matrix allowing the instantaneous transmission of current and information throughout the body. There is considerable evidence in the biophysics literature that cells, nerves, and organ systems communicate by way of frequencies and biologic resonance. Cell membrane receptors have the ability to reconfigure in response to information provided by chemical signaling from the environment and by coherent signals supplied to or by the system to those same receptors. Cell membrane receptors connect to internal cellular structures and modify transcription factors that alter genetic expression, allowing the cell to respond appropriately to the environment. This is the most reasonable model for the mechanism of action for frequency effects on biologic tissue.⁵⁷⁻⁶¹

Microamperage current below 500 μ A has been shown to increase adenosine triphosphate (ATP) production by 500% in three different tissue culture studies.⁶²⁻⁶⁴ It is presumed, but not proven, that the increase in ATP production plays some role in the effectiveness of the therapy by providing the energy required to relax the sarcomeres.

The available data show that the frequency described as “reducing inflammation,” 40 Hz, reduces all of the inflammatory cytokines by factors of 10 and 20 times in 90 minutes. All of the inflammatory cytokines responded and all stopped in the normal range.⁶⁵ In an unpublished blinded animal trial, this same frequency was shown to reduce lipooxygenase-mediated inflammation by 62% in 4 minutes and cyclooxygenase-mediated inflammation by 30% in 4 minutes in every animal tested. This was a time-dependent response with half of the effect present at 2 minutes and the full effect present at 4 minutes.⁶⁶ These data suggest that the frequencies have their effect by modifying cell signaling and changing epigenetic expression to reduce the production of inflammatory peptides. There is no other mechanism that explains the unprecedented rate and magnitude of cytokine reduction down to, but not below, the normal range. When treating TrPs with specific treatment

protocols, the tissues begin to soften and change tone in seconds. This rapid response suggests, but doesn't confirm, the cell signaling mechanism model.

The frequency described as removing the scar tissue (13 Hz) appears to do so by way of resonance that loosens the cross-links holding the connective tissue in a shortened configuration. This particular frequency, when combined with the frequencies for various tissues, especially the nerve and fascia, anecdotally has a dramatic effect on increasing range of motion. It affects only the abnormal scar tissue and has not been observed to reduce normal repair tissue in a fully healed injury. If used before the repair tissue has matured, it can delay healing and should not be used when there is a new injury. There is only clinical observation for the effect of this frequency. Further research needs to be done to confirm its effects and mechanism.⁶⁷

The frequencies and treatment protocols found to be effective for TrPs have been refined in the last 21 years and are currently being used by more than 3000 clinicians in 13 countries.⁶⁸ Collected case reports on the treatment of myofascial pain syndrome in the head, neck, and face and the low back were published in 1998 and 2004.^{55,56}

10.2. Patient Selection

FSM uses subsensory current and the frequencies create fairly rapid tissue softening independent of manual pressure, making it an ideal technique for neurologically sensitized patients and for TrPs in muscles near sensitive vascular, visceral, or autonomic structures. The device contacts are placed at the nerve roots innervating the muscles in an entire biomechanical region as they exit the spine allowing for the treatment of multiple muscle-couples simultaneously. This makes FSM particularly useful for athletes and for patients with active, latent, and associated TrPs in multiple muscles and muscle functional units. The FSM myofascial protocols all begin with the frequencies to reduce nerve activity, making it particularly helpful in patients where nerve inflammation drives increased muscle tone and perpetuates TrP activity.

Patients with TrPs associated with the consumption of statins may not respond to this technique unless they take 200 to 400 mg of CoQ10 per day for a period of 2 weeks prior to treatment. Once the patient is taking CoQ10, he or she should respond as expected.

10.3. Precautions

Pacemaker

Microcurrent is classified as a TENS device, even though it delivers 1000 times less current than a TENS and has a completely different mechanism of action. TENS devices are contraindicated in patients with pacemakers; therefore, FSM should be used with caution in patients with a pacemaker, although no adverse events have been reported to date in this patient group.

Infection

The frequency to reduce inflammation, 40 Hz, will reduce inflammation even in the presence of active infection. The frequency appears to override the signaling from physical bacterial or viral lipopolysaccharides (LPS) fragments and will reduce inflammation for 2 to 6 hours. During the time when inflammation is reduced, active infection can and has been shown to proliferate. It is, therefore, inadvisable to use this frequency when the patient has an active infection anywhere unless the patient is on antibiotics.

New Injury

The frequency to remove the scar tissue, 13 Hz, should not be used when a patient has sustained a new injury in any place on the body. Because the body is a semiconductor, there is no place on the body where the frequency does not have an effect, and new injuries require the scar tissue to form in order to heal. Using the frequency to remove scarring within 6 weeks of a new injury will delay healing. Ninety-one hertz can be used safely to soften the tissue once the new injury is 4 weeks old, and 13 Hz can be used safely once the new injury is 6 weeks old.

Hydration

For FSM to be effective, the patient must be hydrated and should have consumed one quart of water in the 4 hours preceding treatment. This amount of water intake may be inappropriate for patients with compromised cardiac or renal function, and the clinician or patient should consult with the physician monitoring these conditions prior to the consumption of the recommended pretreatment water intake. Treatment may be attempted without the recommended water intake, but clinically we have found this to be less effective.

Detoxification Reactions

FSM treats multiple muscles in a short period of time, and patients who experience detoxification reactions such as fatigue or nausea after massage may find this detox reaction amplified when FSM is used in addition to manual therapy. Water intake immediately following treatment along with a meal that includes sulfur-bearing vegetables seems to ameliorate this detox reaction.

Stenosis

Some patients with central spinal or foraminal stenosis have been observed to experience increased pain when polarized positive DC current is used. In patients with known stenosis, alternating current should be used instead of polarized positive current.

Ligamentous Laxity

Because FSM can soften muscles and increase range of motion so dramatically in a short

period of time, it may not be appropriate for patients with known ligamentous laxity, especially in the cervical spine. Therapeutic measures should be taken to repair the injured ligaments.

10.4. Contraindications

Pregnancy

Because the frequency 40 Hz reduces prostaglandins and certain prostaglandins are required to maintain pregnancy, FSM should not be used on a patient known to be pregnant. No known adverse effects have been reported, but once a woman is known to be pregnant, FSM should not be used for any indication.

10.5. Application

Preparation

The well-hydrated patient should have the treatment area skin exposed, while preserving modesty with a gown or drape. FSM can be used in any muscle or muscle group including the pelvis, scalp, and jaw as well as axial and extremity muscles. Box 75-4 outlines a pretreatment script for clinicians.

Box 75-4 Typical pretreatment script used by the clinician

1. I am going to use FSM to treat your muscles. You will not be able to feel the current because it is the same kind of current your body produces on its own.
2. I am going to apply the current by wrapping these warm wet towels (or wraps) to the area to be treated. One contact will go at the spine where the nerves to the painful muscles leave the spine. We'll place the other contact so the current flows through the muscles we need to treat.
3. We can use conductive gel electrode pads instead of wet contacts if you prefer, as long as you are not sensitive to the adhesive.
4. Are you pregnant?
5. Do you have a pacemaker?
6. Do you have an active untreated infection anywhere?
7. Have you had any new physical injuries or wounds in the last 4 weeks?
8. Do you have any questions or concerns?

10.6. Equipment

FSM requires a two-channel microcurrent device that can provide accurate independent three-digit-specific frequencies on each channel using a ramped square wave. The device

should be a constant current generator with the device automatically varying the voltage to maintain the current levels set for patient treatment. Current levels should be between 20 and 500 μA and able to be used polarized positive or alternating. The polarized positive current is more accurately described as pulsed positive direct current with the negative portion or the wave removed. A typical tabletop manual device and a small programmable device are show below, but there are a number of microcurrent devices on the market that fulfill the requirements, and any device can be used that meets the criteria above.

The device typically comes with six-foot leads. The leads end in pin-plug tips that will fit into graphite conducting gloves that can be wrapped in a warm wet hand towel or washcloth. The pins will also fit into alligator clips that can be attached to a warm wet fabric wrap or cloth. Tap water used to wet the towels or wraps serves as the conductive agent. Distilled water will not conduct current and should not be used. Some clinics use towel warmers to keep the wet fabric wraps warm. The contacts are sanitized in the warmer and by simple washing in a washing machine. Adhesive conductive electrode pads can be used multiple times by the same patient but cannot be transferred from one patient to another. Figures 75-2 through 75-9 show the FSM equipment and patient setup.

Figure 75-2. The Precision Care (Precision Distributing, Vancouver WA) allows the clinician to set independent frequencies, adjust amperage, current polarity, and wave slope quickly and manually.

Figure 75-3. The CustomCare is a small handheld unit that can be programmed from a computer. Frequency protocols can be programmed into the small satellite unit for the times suggested in the tables. This device doesn't have a manual mode, and the frequency applications must be modified by the computer software and programmed on to the satellite.

Figure 75-4. The current is usually applied for myofascial work by wrapping a graphite glove in a warm wet hand towel or by attaching alligator clips to a warm wet hand towel or wash cloth. The water conducts the current and the towel provides a large conductive surface area for treating muscle groups together.

Figure 75-5. A wet fabric strip or “wrap” can be attached to the device by way of alligator clips and secured to the patient with the Velcro strips. The wrap application allows treatment while the patient is seated or moving.

Figure 75-6. Setup for treatment of neck and shoulder complex.

Figure 75-7. Setup for treatment of the cervical spine and suboccipital region.

Figure 75-8. Setup for treatment of the lumbar spine, psoas, and abdominal muscle groups.

Figure 75-9. Setup for treatment of widespread myofascial pain syndrome.

The manual therapy technique performed while the current is running does not typically require massage lotion because the fingers are used to apply local pressure on the taut bands of TrPs similar to pressure release techniques rather than requiring long effleurage strokes or deep pressure. The frequencies soften the tissue, so minimal manual pressure is required.

10.7. Application Options

The treatment variables depend on the area or region to be treated and the perceived causes of or perpetuating factors for the TrPs. In general, the current is applied with the positive leads covering the nerve roots related to the treated muscles where they exit the spine and

the negative leads are placed just distal to the muscles being treated so the current passes through the muscles in three dimensions. The frequencies used will vary depending on muscle location, function, innervation, and the factors causing or perpetuating the TrPs. As a general rule, frequencies for the nerve are used first.

Dosing

In general, patients are treated twice a week for 4 to 6 weeks. Patients with persistent chronic pain should be treated twice in the first week with treatment at least 2 days apart. Treatment can be discontinued as soon as pain and TrPs resolve. Data suggest chronic myofascial pain will resolve in approximately six treatments administered in 6 weeks. Simple or uncomplicated myofascial pain may resolve in one session, but at least one follow-up session is recommended. If the patient has spinal ligamentous laxity creating increased translation of spinal vertebral segments, resolution of TrPs will take much longer and additional treatments will need to address the ligamentous laxity.

The following application suggestions are presented in more detail in the textbook *Frequency Specific Microcurrent in Pain Management*⁶⁹ or in a 4-day training course or in online training modules (www.frequency-specific.com).

Treatment Application

Treatment of the cervical spine and the subscapularis and posterior shoulder muscles is displayed in Box 75-5.

Box 75-5 Parameters for treating cervical spine, subscapularis and posterior shoulder muscles

Frequency Used	Description/Condition/Tissue	Expected Action	Minutes
40/94	Inflammation/medulla	Reduce tone and TrPs in upper trapezius	2
40/10	Inflammation/spinal cord	Reduce tone in cervical paraspinal muscles	2
40/396	Inflammation/nerve	Should reduce tone and TrPs in cervical and shoulder muscles. Should reduce tone and tenderness in subscapularis	4
13/396	Scarring/nerve	Mobilize subscapularis and neck and shoulder muscles. Should increase shoulder mobility	4
13/142	Scarring/fascia	Mobilize subscapularis and neck	4

		and shoulder muscles. Should increase mobility, reduce tone and TrPs	
40/710	Inflammation/disc	Should reduce tone and TrPs in medial scalenes and paraspinals	2-4
40/157	Inflammation/cartilage, facet	Should reduce tone and TrPs in cervical paraspinal muscles	2-4
40/480	Inflammation/joint capsule, facet	Should reduce tone and TrPs in posterior cervical paraspinal muscles	2-4
91/142	Hardening/fascia	Should reduce tone and TrPs in all muscles between occiput and shoulder	2
81/142	Increase secretions/Fascia	Should further soften muscles and support fascia recovery	2
^a NOTE: 124/191 124/77	Repair disrupted/tendon Repair disrupted/connective tissue	If one of the rotator cuff tendons is disrupted, the TrPs will not resolve until these frequency pairs are used. These frequencies are time dependent. Repair may take extended time or multiple sessions. Use until TrPs resolve.	10-60

Manual Technique

The placement of the contacts for treating the shoulder complex is depicted in Figure 75-6. This allows the current to address all of the shoulder muscles and any potential adhesions between the subscapular nerve and subscapularis muscle that might impact shoulder mechanics. Palpate the subscapularis evaluating for TrPs and tenderness. Use settings 40/396 until subscapularis muscle tenderness is significantly reduced, then change the frequency to 13/396 and begin to mobilize the subscapularis muscle and shoulder complex. The manual technique involves firm gentle pressure applied to all of the muscles in the area being treated in a gentle kneading motion. Use frequencies, in order, as shown in Box 75-5. Response to this protocol has been clinically predictable and consistent.

Treating Cervical Spine and Suboccipital Complex

Treatment parameters for the cervical spine, the cervical paraspinal muscles, and the suboccipital muscles are displayed in Box 75-6.

Box 75-6 Parameters for treating cervical spine and suboccipital complex

Frequency Used	DescriptionCondition/Tissue	Expected Action	Minutes
40/94	Inflammation/medulla, accessory nerve	Should reduce tone and TrPs in SCM and upper trapezius and allow palpation of suboccipital muscles	2-4
40/10	Inflammation/spinal cord	Should reduce tone in cervical paraspinal muscles	2
40/396	Inflammation/nerve	Should soften all DRG-innervated muscles between contacts	4
124/100	Disruption/ligaments	Should reduce tone and TrPs in the suboccipital and cervical muscles associated with ligamentous injury	4
13/443	Scarring/dura	Should reduce tone and TrPs in rectus capitus posterior minor specifically. Rock suboccipital area during use	4
40/157	Inflammation/cartilage, facet	Should reduce tone and TrPs in upper cervical paraspinal muscles.	2-4
40/480	Inflammation/joint capsule, facet	Should reduce tone and TrPs in upper cervical paraspinal muscles	2-4
40/783	Inflammation/periosteum	Should reduce tone and TrPs in the cervical paraspinal muscles	2-4
91/480	Hardening/joint capsule	Should soften multifidi and paraspinal muscles overlying the facet joint capsule	2
40/710	Inflammation/disc	Should reduce tone and TrPs in lower cervical paraspinal musclesand anterior scalene muscles	2-4
13/396	Scarring/nerve	Should reduce adhesions between nerve and fascia and increase range of motion	2

91/142	Hardening/fascia	Should reduce tone, TrPs in cervical muscles between the contacts	2
91/62	Hardening/muscle belly	Should reduce tone, TrPs in cervical muscles between the contacts	2
81/142	Increase secretions/fascia	Should further soften muscles and fascia	2

DRG, dorsal root ganglion; SCM, sternocleidomastoid.

Manual Technique

Manual therapy with FSM differs from manual muscle therapy. Moderate manual pressure is used to palpate the treated muscles. Figure 75-7 shows the setup for treatment of the paraspinal muscles in the cervical region and the suboccipital muscles. The frequencies will soften the muscles and the manual pressure simply follows the muscle softening and assists the loosening of the scar tissue bonds. 40/94 will soften the upper trapezius muscle, and manual therapy senses and assists the upper trapezius muscle softening. Once the upper trapezius muscle softens, the suboccipital, the splenius, and the cervical paraspinal muscles become more apparent and the underlying tight muscles overlying the facet joints become apparent. The current 124/100 softens the suboccipital muscles, especially if the alar ligaments have ever been traumatized. Once the suboccipital muscles are softer, the rectus capitis posterior (RCP) minor muscle will stand out as tight in the midline of the suboccipital space. The RCP minor muscle has a connective tissue slip between it and the dura mater. The frequency to remove “scarring from the dura mater” 13/443 will soften the RCP minor where it attaches to the dura mater if it is gently rocked in 5 mm upward motions. Once the suboccipital muscles are softened, the cervical paraspinal muscles will be palpably tight and the taut bands overlying the facet joints will be more noticeable. These muscles will soften when the frequencies to reduce inflammation in the cartilage, the periosteum, and the joint capsule are used. The muscles overlying the joint capsule may still be firm or hard at this point and should soften when the frequency for “hardening in the joint capsule” is used. The next muscles to become apparent will be the scalene muscles and lower cervical paraspinal muscles. These muscles seem to soften in response to the frequency to reduce inflammation in the disc annulus.

Treating Lumbar Spine, Psoas Muscle Group, Abdominal Muscle Group

Treatment parameters for the lumbar spine, the psoas muscle group, and the abdominal muscle group are displayed in Box 75-7.

Box 75-7 Treating lumbar spine, psoas muscle group, rectus abdominus muscles

Frequency Used	DescriptionCondition/Tissue	Expected Action	Minutes
TrPs Associated With Disc Inflammation			
40/396	Inflammation/nerve	Should soften all DRG-innervated muscles between back and abdomen	4
40/710	Inflammation/disc annulus	Should reduce tone and TrPs in quadratus lumborum, rectus abdominus, psoas	4
40/630	Inflammation/disc as a whole	Should reduce tone and TrPs in quadratus lumborum, rectus abdominus, psoas	2
40/330	Inflammation/disc nucleus	Should reduce tone and TrPs in quadratus lumborum, rectus abdominus, psoas	4
13/396	Scarring/nerve Mobilize paraspinal muscles while using	Should reduce adhesions between nerve and fascia and increase range of motion	2
91/142	Hardening/fascia	Should reduce tone, TrPs in lumbar muscles	2
91/62	Hardening/muscle belly	Should reduce tone, TrPs in cervical muscles between the contacts	2
81/142	Increase secretions/fascia	Should further soften muscles and support fascia recovery	2
TrPs Associated With Facet Joints			
40/396	Inflammation/nerve	Should soften all DRG-innervated muscles between back and abdomen	4
40/783	Inflammation/periosteum	Should reduce tone and TrPs in the cervical paraspinal muscles	2-4
40/157	Inflammation/cartilage, facet	Should reduce tone and TrPs in lumbar paraspinal muscles	2-4
40/480	Inflammation/joint capsule, facet	Should reduce tone and TrPs in the cervical paraspinal muscles	2-4

91/480	Hardening/joint capsule	Should soften multifidi and paraspinal muscles overlying the facet joint capsule	2
13/396	Scarring/nerve Rock the knees to move the joints while using	Should reduce adhesions between nerve and fascia and increase range of motion	2
91/142	Hardening/fascia	Should reduce tone, TrPs in cervical muscles between the contacts	2
91/62	Hardening/muscle belly	Should reduce tone, TrPs in lumbar muscles	2
81/142	Increase secretions/fascia	Should further soften muscles and support fascia recovery	2
Psoas Muscle Group TrPs			
13/60 ^a , 142	Resolves psoas TrPs associated with scarring (13/) between the ureter (/60) and fascia (/142)	When prior kidney stone, infection or trauma is the cause, 13/60 reduces the pain, psoas tightness and resolves TrPs. Gentle rocking of abdominal muscles assists action. If psoas tightness is not associated with the ureter, this application will not have any effect on psoas TrPs.	10-20
Rectus Abdominus Muscle TrPs			
40/22 ^a	Resolves TrPs caused or perpetuated by food sensitivities and inflammation (40/) in the small intestine (/22)	If the TrPs are associated with inflammation in the small intestine, this frequency will soften the taut bands and eliminate the TrPs. If there is no intestinal inflammation, this application will have no effect on tone or TrPs	10-20
Abdominal Oblique TrPs			
40/7 ^a	Resolves TrPs associated with inflammation (40/) from ovarian cysts (/7 ^a)	If the TrPs are associated with inflammation from an ovarian cyst, this frequency will soften the taut bands and eliminate the TrPs. If there is no ovarian cyst, this application will have	10-20

		no effect on tone or TrPs.	
40/65 ^a , 129 ^a	Resolves TrPs associated with inflammation (40/) in the descending (/65 ^a) and sigmoid (/129 ^a) colon	If the TrPs are associated with inflammation in the descending or sigmoid colon, this frequency will soften the taut bands and eliminate the TrPs. If there is no intestinal inflammation, this application will have no effect on tone or TrPs.	

^aThese frequencies are described on the original frequency list as resonating with specific visceral organs; however, no claims for such effects can be made. Resolving TrPs in these specific muscles is the only clinical effect documented for these frequencies.

Manual Technique

Manual therapy for muscles in the lumbar spine involves steady firm pressure to follow the muscle as it softens in response to the frequencies applied. Figure 75-8 shows the setup for treatment of the lumbar spine, psoas, and abdominal muscle groups.

When using the frequencies to modify adhesions between the nerve and any structure, it is necessary to move the tissue while running the frequencies to remove the scar tissue. For TrPs associated with disc inflammation, the patient may be more comfortable in slight lumbar extension whether prone or supine, and the lumbar paraspinal muscles should be mobilized with a broad flat finger contact and a slight kneading motion. For TrPs associated with facet inflammation, the patient should be treated while supine with the knees bent and the back flat. Mobilizing the lumbar muscles in these patients while using the frequencies to alleviate scarring between the nerve and fascia or nerve and joint capsule is simply a matter of gently rocking the knees gently from side to side within the pain-free range. This movement allows the nerves to glide between fascial layers and increases segmental range of motion in lumbar rotation.

The manual technique for treating the psoas and abdominal muscle groups requires some care to avoid deep vascular and visceral structures. The clinician should use a broad flat-fingered contact, avoid any circular scrubbing motions, and simply apply firm steady but sensitive downward pressure while the frequency response causes tissue softening. If slow muscle guarding is identified at any point, the clinician should pause and reduce pressure.

Treating Widespread Multiple Trigger Points

The following FSM protocol is used when the patient has widespread and numerous TrPs in the upper and lower body (Box 75-8), is not on any statin medication, and does not have any other genetic muscle pathology or deficiency that would explain their presence. The

patient may or may not have the neuroendocrine component of fibromyalgia but may have been diagnosed as having fibromyalgia in addition to the diagnosis of myofascial pain syndrome. The contacts are placed at the neck and feet.

Box 75-8 Treatment parameters for patients with widespread multiple TrPs

Frequency Used	DescriptionCondition/Tissue	Expected Action	Minutes
40/10	Inflammation/spinal cord Use with alternating current for 10 min. Polarize current positive for the remainder of the treatment.	Should reduce pain, tone, and TrPs from distal to proximal. The TrPs in the lower extremity should soften and become less tender within 20 min. Those in the thigh, pelvis, and abdomen should be reduced within 40 min. The upper extremity and neck will be the last to resolve and may take up to 60 min.	60

Box 75-9 Shows common side effects and clinical observation

Side Effect Symptom	Occurrence Rate
Euphoria	Common
Detoxification reactions	Uncommon
Increased joint pain	Rare
Radicular pain	Rare
Midscapular pain	Rare

Manual Technique

There is no manual technique advised for this class of patient. The setup for treatment is shown in Figure 75-9. The data suggest that TrPs in this type of patient are neurologically driven by peripheral and/or spinal cord sensitization. Blood sample data show reductions in substance P and all inflammatory cytokines with this treatment. Substance P is generated by the neurons cell body in the dorsal root ganglion and its presence can be measured in the peripheral blood. The 10-fold reduction in substance P and all of the inflammatory cytokines suggests that the changes in pain, muscle tone, and TrPs may be linked to the

dramatic reductions in these peptides. Once the TrPs are effectively treated, local FSM treatment, gentle manual therapy, dry needling, or TrP injections can be applied to remaining localized active or latent TrPs.

10.8. Posttreatment Care

Most patients will become quite drowsy and experience a sense of induced euphoria with this treatment associated with the 10-fold increases in endorphins seen in the blood samples. Most patients return to normal states of awareness within 20 minutes. Patients should be monitored after treatment to make sure they are competent to drive.

This treatment usually increases range of motion and changes regional myofascial function very quickly. One treatment for the areas described in this section will usually produce a significant reduction in symptoms in a 30 to 60-minute treatment and often produces a 30% to 50% increase in range of motion in the same time period. The dramatic increase in range of motion often results in awareness of muscle tightness in mechanically related but untreated areas on the day after treatment. For example, when the cervical range of motion in flexion increases from 30° to 60° with the supine cervical treatment, the upper thoracic muscles may feel tight or restricted the next day. This feeling usually resolves on its own as the body accommodates to the increase in range, or the tight area can be treated.

If the pain has been persistent, there is an adjustment period during which the brain seems to keep “searching” for the pain. It is assumed that this represents central and spinal sensitization that now lacks a peripheral pain generator. The treatment protocols for this reaction are not covered in this book but can be found in an FSM textbook.⁶⁹

Treatments for areas not described in this section have similar responses, but the treatment protocols will be slightly different for different body areas and different for different TrP causes and perpetuating factors.

Experience suggests that patients with persistent chronic myofascial pain for a time period of 5 to 8 years will recover in an average of six treatments in 6 weeks. Treatment should be spaced 2 days apart, twice in the first week, twice in the second week, and once a week for 2 weeks. Patients with shorter chronicity may have permanent relief in two to three sessions over a 2-week period. Patients should be given gentle reconditioning exercises starting with light weights and low repetitions to strengthen newly recovered muscles. Patients should remain well hydrated and may benefit from a daily 500 mg magnesium (malate or glycinate) nutritional supplement and omega 3 essential fatty acids. Patients taking statins to lower cholesterol should add 200 to 400 mg a day of Co EnzymeQ-10 to ameliorate the effects of statins on muscle tissue.

10.9. Possible Side Effects

Euphoria

Most, but not all, patients treated with FSM experience a general sense of relaxation as the frequencies are applied. In some patients, this general relaxation increases to a state of

drowsy euphoria. The patient should be reassured that it is temporary and should be gone within 60 minutes following treatment. Most patients find it pleasant but surprising.

Detoxification Reactions

Some patients experience what has been described as a detoxification reaction several hours after treatment with symptoms that can include nausea, headache, bodyaches and, in extreme cases, vomiting. These symptoms are similar to those experienced by some patients after a manual body massage and are presumed to be caused by depletion of substrate in the liver detoxification pathways that process the waste products being removed from the muscles and fascia. This reaction can usually be avoided if the patient will drink one quart of water in the 2 hours following treatment and consume some vegetable containing sulfur or take a low-dose antioxidant vitamin supplement.

Increased Joint Pain

The rapid and dramatic increase in range of motion can create temporary increased local facet joint pain. Use local or oral anti-inflammatory agents for relief or use FSM protocols for facet joint pain.

Radicular Pain

Increased cervical spine range of motion can allow the excursion of periarticular spinal bone spurs into contact with the spinal nerve roots. The patient will experience relief from generalized TrP pain but may present 24 hours after treatment with specific dermatomal nerve pain and hyperesthesia in the C5, C6, or C7 nerve roots. Use topical or oral anti-inflammatory agents for relief or use FSM protocols for nerve pain applied with the contacts at the neck and hand.

Midscapular Pain From Stenosis

Some patients with cervical central canal stenosis experience an increase in midscapular or arm pain when polarized positive current is used. This can be avoided by treating with alternating current or reduced current levels.

Postural Considerations

“The Living Engine Light”

Joshua J. Lee, Robert D. Gerwin, Ryan Reed, Thomas Eberle, and Gabriel Somarriba

1. INTRODUCTION

Posture is the summative visual reflection of how the body has adapted to gravity and external forces in a particular position. In a sense, posture can be considered a theoretical construct, a view of the body as a constantly adapting framework, adjusting to the forces of gravity along with the stressors of habitually repeated movements. In its entirety, however, posture tells a story about the musculoskeletal system through both the alignment of posture and the capacity it holds for movement. Janda believed that the status of the central nervous system (CNS) and peripheral nervous system was reflected in the musculoskeletal system that provides the clinician with a wealth of information.¹ The musculoskeletal system provides the clinician with an opportunity to identify structural factors that can influence myofascial pain and dysfunction. It may also aid in the identification of musculature that has become dysfunctional based on visual observation and abnormal postural alignments. Through a thorough history; assessment of static, dynamic, and functional postures; and a sound clinical reasoning process, the clinician must determine how to utilize that information and organize the physical examination. Though a plethora of textbooks have been written solely on posture, this chapter primarily aims to highlight the components of posture related to muscle dysfunction and myofascial pain syndrome.

2. POSTURAL FACTORS

One of the most fascinating qualities of the human body is its incredible capacity to adapt. The body is never truly at rest, constantly working down to the cellular level to meet vital expectations and functional needs while resisting both intrinsic and extrinsic forces. Factors such as posture and muscle, posture and trigger points (TrPs), posture and pain, gravitational and biomechanical considerations, postural stability, posture development and

genetics, and postures of occupation and recreation are briefly discussed in this chapter. The clinician should also consider psychosocial variables that can affect posture as presented in Chapter 5.

2.1. Posture and Muscle

Postural stability and control are achieved by the coordination of the peripheral nervous system and CNS along with the passive restraints of bone, joint, cartilage, tendon, and ligaments. When overloaded, these structures may cause nociception, potentially translating into an experience of pain. Poor alignment may result in abnormal compressive or tensile loads. Furthermore, a lack of mobility may cause excessive compressive loading of joints leading to faulty alignment. With this loss of mobility, the faulty alignment may remain constant because of the associated tissue stiffness.² This may also be the result of muscle tightness or inhibition weakness because of biomechanical inefficiencies and TrPs, resulting in the inability of muscles to move the joint through the desired motion. Muscle tightness can maintain the body in faulty alignment, whereas muscle inhibition weakness can alter the body position, affecting alignment. Muscles in a resting lengthened position may test weaker because of passive vweak because of active insufficiency. Trigger points can be involved in both muscle tightness and inhibition weakness.

2.2. Posture and Trigger Points

In a well-functioning system, the body will have normal compensations and adaptations to forces with mild changes in alignment and symmetry. However, abnormal or non-neutral alignment, as defined by Putz-Anderson,³ can lead to a poorly functioning neuromusculoskeletal system with a decreased capacity to manage forces efficiently. This can lead to aberrant changes in alignment or a new framework on which the neuromuscular system must perform. The net result of a change in alignment leads to muscle overload. This dysfunctional framework can result in chronic structural and functional stressors that disrupt the body's homeostatic capacities for resisting external forces. This results in confounding effects on the body such as muscle imbalances that could further lead to postural imbalances, poor motor control, and poor postural control.¹ These compensations may place muscles in a prolonged lengthened or shortened position, precipitating the formation of TrPs. Janda⁴ stated, "Postural muscles, structurally adapted to resist prolonged gravitational stress, generally resist fatigue. When overly stressed these same postural muscles become irritable, tight, and shortened," instigating the formation of TrPs. Conversely, the antagonists of these postural muscles can demonstrate inhibitory characteristics or TrPs with inhibition weakness secondary to overload.⁵ The summative effects of TrPs and maladaptive alignments can result in impairing the function of posture, with visible telltale signs found during the postural assessment.

Although the visual representation of posture can be described as the alignment of the body, the intrinsic function and role of posture is primarily for movement. According to Sherrington, "posture follows movement like a shadow."⁶ The main component required

for movement is posture and not vice versa.⁷ Though typically assessed in static positions, posture is an inherently dynamic concept. This dynamic process can be described as the continuous attainment of the desired static position or as the active holding of body segments against gravity and other external forces mediated by the CNS.^{7,8} This active holding, or postural stabilization, is achieved through the positioning of joints via the coordinated muscular activity of agonists and antagonists (functional unit), allowing for an erect posture and locomotion of the body as a whole.⁹ However, the inhibitory motor characteristics of TrPs can disrupt the coordinated muscular activity, resulting in poor postural stabilization and poor movement capacity. Furthermore, abnormal alignment may also lead to altered and maladaptive movement patterns that have consequences on the CNS feeding into the effects of myofascial pain syndrome. See Chapter 4 “Perpetuating Factors” for further information on maladaptive movement patterns and their effect on the nociceptive system.

2.3. Posture and Pain

Contemporary views regarding posture and pain refute theoretical constructs regarding postural alignment, dysfunction, and pain. Older research shows an absence of a generalized relationship between postural findings and identified impairments.^{10,11} More recent research shows that there is no definitive relationship between postural abnormalities and pain.^{12–14} However, these findings may be explained by the fact that the studies utilized static measures, and posture and movement are dynamic. One must be careful concluding that the assessment of posture is not an essential component of the functional examination as it is the starting point for all movement. Several studies have shown structural pathologies in asymptomatic individuals; therefore, dysfunctional postures do not necessarily predict the presence of pain as the human body is highly adaptable.^{15–26} However, if the posture becomes pathologic, the movement system may become dysfunctional and signal for help through nociceptive mechanisms. As Lewit states, “The movement system is the most common source of pain in an organism and, in turn, pain is also the most common sign of a movement system dysfunction. The reason is obvious: the movement system is the largest system in the body, and moreover, it is the effector of our willpower. It does not possess any means of ‘defense’ other than to cause pain.”^{7,27}

It is essential to determine if the patient’s current report of symptoms is related to tissue pathologies, pain mechanisms, impairments, or dysfunctional posture. Postural assessment must go beyond the static observation and incorporate movement and function to determine its relationship to the patient’s symptoms.

2.4. Gravity and Biomechanical Considerations

Despite all of our individual variabilities, there is one major constant the body is subjected to at all times: the law of gravity. Though posture may be a theoretical construct, gravity is a known established law. The constant static force of gravity and how the body adapts to that force is what we have theorized to be posture. In an effort to capture the effects of

posture, Sahrman²⁸ categorized pain disorders into movement impairment categories based on the body's compensatory adaptations to favor movement in the path of least resistance. The line of gravity (LOG) as a static force has an effect on postural alignment and, therefore, movement. The static forces of gravity can contribute to the changes in the relationship between agonists and antagonists secondary to poor adaptations of postural alignment.²⁸

For example, in an individual with swayback posture, due to the LOG shifting posteriorly relative to the hip joint, the demand on the gluteal musculature is decreased, allowing for atrophy, while increasing the demand on the hip flexor muscles. These static forces contribute to increased activity in some muscle groups and atrophy in others.²⁸

Biomechanical concepts are the rules the body follows according to the law of gravity. These concepts are critical to consider when assessing and providing interventions for postural deviations that are being considered as a contributing factor to the patient's clinical presentation. The patient's body center of mass (BCOM) and body center of gravity (BCOG) are synonymous terms when the gravitational field is uniform. The BCOM essentially is the location in which the weight of the body may be considered to be concentrated.²⁹ The BCOM in a neutral standing erect position generally lies just in front of the S2 vertebra³⁰ and changes as a person moves. The BCOM in a person moving from sit to stand moves from a position anterior to the body to just below the S2 vertebra. The changing BCOM is important to understand and identify during the different sequences of a task when assessing dynamic postures. This affords the clinician the ability to identify both intrinsic and extrinsic forces on the musculoskeletal system and those forces that may be a contributing factor to muscle overload that can be modified.

The LOG is an invisible vertical line representing the force of gravity through the BCOG or BCOM in the downward direction toward the center of the earth. In normal posture, as seen in Figure 76-1, the LOG lies posterior to the cervical spine, anterior to the thoracic spine, posterior to the lumbar spine, and anterior to the sacrum.³⁰

Figure 76-1. Static postural alignment sagittal view. A, Skeletal alignment with plumb line. B, Anterior and posterior postural muscles of the trunk.²

When the LOG is within a person's base of support (BOS) the person is said to be in a stable and balanced position. When the LOG falls outside the BOS the person is said to be unstable or off balance.³¹ Identifying where the LOG falls in both the frontal and sagittal views is necessary to further evaluate movement impairments. From an anterior or posterior view, the LOG will assist the clinician to identify asymmetries within an individual. In the sagittal view, the LOG will assist the clinician in identifying the relationship between the LOG and the antigravity muscles.

Antigravity muscles act to counterbalance the pull of gravity and keep the body in an upright position.² The main role of antigravity muscles is to generate torque across joints to resist the forces of gravity. These muscles help to keep limbs, joints, and the body in proper alignment or posture so that the BCOG falls within the BOS. This concept is the relationship between balance and posture. Efficient posture permits proficient movement patterns and allows joints to be loaded symmetrically. Efficient postures decrease or distribute loads on cartilage, bone, connective tissue, tendons, and ligaments, and they result in decreased stress and strain on structures of the musculoskeletal system.³² Muscles are also required to work less in these inherently efficient postural positions.

2.5. Posture and Stability

Balance, or postural stability, is the ability of the body to maintain its center of gravity within the BOS. Postural stability is the culmination of the input, processing, and output of information from the peripheral nervous system to the CNS.¹ This information in particular comes from the vestibular, visual, and somatosensory systems, which can impact postural alignment over time. The visual system is responsible for the orientation of the eyes in the environment, which will affect the position of the head on the neck.¹ Visual perception also plays a role in purposeful movement and the facilitation of an appropriately coordinated motor response within our surroundings.³³

The vestibular system provides the CNS with information regarding the position of the body and head and feedback from a moving BOS.¹ The vestibular system and vertical line perception have implications on postural dysfunctions such as scoliosis and its development. However, it is not clear whether the contributions to a scoliosis develop from abnormal vertical line perception or if vertical line perception is altered in people with scoliosis.³³

Nonetheless, the CNS receives all peripheral input including proprioception, thermoreception, and nociception through the somatosensory system.¹ Proprioception or body perception plays a major role on movement in regard to its precision and efficiency. Relatedly, if the patient has clumsiness or poor coordination, this may be suggestive of abnormal proprioceptive control.³³ The patient's capacity for balance should also be considered in the clinician's examination as it will further delineate the patient's ability to stabilize posture against gravity.

2.6. Posture Development and Genetics

The development of posture, or postural ontogenesis, has a genetic component, whereas motor functions develop automatically and are dependent on the visual orientation and emotional needs of the infant.⁷ With motor functions, the morphologic development of the skeletal structure and its joint positions (hip joint shape, spinal curvature, plantar arch, etc.)³⁴ is very much dependent on the stabilizing function of muscles⁷ such as the diaphragm and the abdominal muscles.³⁴ Breathing and spinal stability in infants are related to development and genetically determined programs that influence the maturation of the CNS³⁵; neither need to be taught except when adverse events affect natural development.

Genetics plays an essential role in posture and some genetic predispositions cannot be controlled (see Chapter 4). Conditions such as osteoporosis, osteoarthritis, or scoliosis, which may have genetic components, can lead to postural dysfunctions, particularly spinal malalignment. This results in some anatomic changes that may not be modified without surgery; however, the variation in genetics relating to tissue mobility also has implications on the magnitude of alignment change in regard to postural dysfunctions such as scoliosis.³⁶

2.7. Posture and Occupation/Recreation

Habitual postures of occupation can be both static and repetitive and can lead to tissue adaptation, muscle overload, or degeneration.³⁷ Over time, these adaptive changes can result in observed postural deviations that will assist the clinician in directing the examination. Some of the more at-risk occupations include truck drivers, construction workers, administrative occupations, dentists, and dental hygienists, to name a few. These occupations require specific postural demands that contribute to abnormal and awkward postures, which may lead to prolonged shortening or lengthening of muscles and inefficiency of movement. Some common postural deviations include forward head posture (FHP), flat back, sway back, and scoliosis. Figure 76-22 illustrates common postural deviations and depicts muscles that may be shortened or elongated, possibly leading to overload and TrP formation.

Figure 76-2. Common postural dysfunctions affecting muscle lengths and strength. A, Flat back posture. B, Lordotic posture. C, Kyphotic forward head posture.²

Recreational or sporting activities with increased postural demands include weightlifting, swimming, cycling, running, and gymnastics, which, over time, may lead to postural deviations. The repetitive nature of recreational activities or sports may lead to wear and tear on the active and passive structures involved with posture and may make some muscles tight or weak leading to muscular imbalances, TrP formation, and overload, as identified in Figure 76-2.

3. CONSIDERATIONS FOR POSTURAL ASSESSMENT AND EXAMINATION

Postural assessment is an essential component of the examination for patients presenting with activity limitations and participation restrictions as a result of myofascial pain and movement impairment. The posture examination assists clinicians in identifying contributing factors to the patient's presentation along with activating and perpetuating factors of TrPs. A thorough subjective and physical examination with the inclusion of postural assessment must be performed before treatment to avoid creating assumptions based solely on the location of the patient's pain, as pain oftentimes stems from other

perpetuating factors and dysfunctions, with pain being the end result. There is a substantial amount of information that can be obtained from assessment of standing posture regarding the muscular system, and this should not be overlooked.³⁸ However, the clinician must consider what is considered “typical” posture and what is “dysfunctional” for each patient.

3.1. Postural Norms and Dysfunctions

Normative factors of postural function or alignment have always been difficult to establish because of the varied views of individual authors.⁹ Vele³⁹ stated that it was impossible to establish one standard for correct body posture because of a varied correct postural alignment for every individual. It is more or less a construct to have correct posture. Kuchera and Kuchera⁴⁰ define optimal posture as follows:

A balanced configuration of the body with respect to gravity. It depends on normal arches of the feet, vertical alignment of the ankles, and horizontal orientation (in the coronal plane) of the sacral base. The presence of an optimum posture suggests that there is perfect distribution of the body mass around the center of gravity. . . . Structural and functional stressors on the body, however, may prevent achievement of optimum posture. In this case, homeostatic mechanisms provide for ‘compensation’ in an effort to provide maximum postural function within the existing structure of the individual. Compensation is the counterbalancing of any defect of structure or function.

This description highlights the decreased likelihood of an example of optimal posture. Patients with persistent pain may present with mild asymmetries but so do many individuals who are asymptomatic.^{12–26} Ideal posture then must be identified in the context of the individual patient and their environmental demands. It is important to keep these considerations in mind when referencing neutral alignment, as sometimes a slight deviation from neutral alignment may not necessarily be pathologic. Nevertheless, the focus should be on the more noticeable dysfunctions and aberrant deviations from neutral and how they contribute to the patient’s current problem.

The source of postural dysfunctions and aberrant deviations is typically from postural disharmony or postural disturbances, which can be divided into the following deficits: anatomic, neurologic, and functional.⁷ Neurologic deficits, such as cerebellar, vestibular, and extrapyramidal impairments, typically arise from a neurologic dysfunction, whereas anatomic dysfunctions, such as femoral anteversion, postinjury morphologic changes, and sacral dysplasia, are typically innate or acquired and difficult to change.⁷ Postural dysfunctions related to neurologic deficits are beyond the scope of this chapter; however, the clinician should be discerning when the patient has neurologic deficits.

Functional deficits as defined by Kolar⁷ are the impairments in postural muscles resulting in decreased postural stabilization and function of the postural muscles during static positions and movement. Kolar⁷ describes functional deficits as a result of three main causes: central coordination disturbances during postural development; the manner in which stereotypical movements have been changed, strengthened, and modified, usually in the context of the individual’s psychological state; and dysfunction due to nociceptive

control. With dysfunction due to nociceptive control, when nociceptive information is transmitted secondary to a pathologic situation, the motor system will automatically make changes in motor function development, frequently resulting in the formation of TrPs in a muscle.

Postural impairments such as a slouched position are modifiable and respond well to cues to change alignment.³⁶ Structural or anatomic dysfunctions, on the other hand, are innate and difficult to change, regardless of the position of the individual, because of fixed alignments of the bony structures.³⁶

3.2. Static Standing Assessment

The most common and practical assessment of posture is static standing, because of the wealth of information that can be obtained regarding the status of the muscular system. Upon initial observation of static standing posture, the clinician should obtain a general assessment of symmetry, spinal curvatures, structural or biomechanical variations, positioning of the pelvis in relation to the axis of the diaphragm muscle, and the extent and distribution of muscle tension.^{1,7,41} The clinician should refer to Figure 76-1 in regard to neutral standing posture. Figure 76-1 shows the sagittal view of neutral standing posture with a plumb line as a reference to the LOG through neutral alignment, as well as the trunk and thigh muscles responsible for maintaining it. Also of note in Figure 76-1 are the postural muscles of the trunk as they are oftentimes the first to be involved with postural deviations. There are several variations to the landmarks in relation to the plumb line depending on the source. O'Sullivan et al⁴² showed disagreement among 295 physical therapists in four different European countries on what constituted seated neutral spine posture.

It is crucial to note the orientation of the eyes and facial features related to the position of the head as it is an important indicator, diagnostically, for chronic musculoskeletal pain. If the patient has facial asymmetry, or facial scoliosis (Figure 76-3A to D), where the bridge of the nose, eyes, and mouth are not parallel, this can indicate a severe issue with alignment affecting the entire body. Janda identified four points, or landmarks, on the face to be aligned: the bridge of the nose, the middle of the forehead, mid-mouth, and the mid-jaw (Figure 76-3E to F).¹

Figure 76-3. Facial scoliosis, with side by side comparison with lines (light green for actual position, yellow for 90° horizontal/vertical comparison). A, Eyes. B, Bridge of nose. C, Mouth line. D, All three combined. E, F, Example of normal facial alignment with comparison lines.

To acquire an observation of breathing patterns, respiration patterns should also be assessed in the standing position while the patient is unaware. Respiration and posture are interdependent functionally,⁴³ a concept that will be discussed in depth later in this chapter.

The age of the patient being examined must be considered as development of structures changes the typical alignment. The cumulative effects of lifestyle and physical stressors may change anatomic structures accordingly and may impact the examiner's postural assessment in regard to seeking a relatively normative comparison.

3.3. Regional Assessments

In order for the clinician to get a summative view of posture, they should evaluate each region of the spine and the extremities and correlate observed asymmetries or non-neutral alignment to the patient's presentation. Further details on specific muscle function, assessment, and treatments are located in their respective chapters in this text as referenced throughout the following sections. The following information incorporates both Janda's approach to muscle imbalances^{1,38} and the Sahrman²⁸ postural component of movement impairment syndromes approach.^{28,36} This section does not aim to fully cover either approach but rather focuses on a few common postural dysfunction findings based solely on their implications for muscles.

Pelvis and Hips

Because most chronic musculoskeletal pain is first evident in postural asymmetries of the pelvis, it is suggested by Page et al¹ to observe this area first, regardless of the area of primary symptoms. The pelvis can reflect deviations from the trunk as well as the

extremities.⁷ The pelvis should be assessed for any excessive tilting, torsion, shifting relative to the trunk, and rotation. Muscle tension distribution should be assessed around the hips and pelvis. Regarding alignment, from a lateral view the clinician should find minimal angular deviation, varying up to 12°, with a line drawn from the posterior superior iliac spine (PSIS) to the anterior superior iliac spine (ASIS) in comparison to horizontal.²⁸ Excessive anterior tilting of the pelvis (Figure 76-4A), or when the ASIS is 20° lower than the PSIS,²⁸ may have an associated increase in lumbar lordosis. In contrast to excessive anterior tilting, excessive posterior tilting (Figure 76-4B) occurs when the ASIS is roughly 20° higher than the PSIS.²⁸ Posterior tilt of the pelvis is commonly associated with a flat back or decreased lumbar lordosis.²⁸ The clinician should look for the ASIS to be in the same vertical plane as the pubic symphysis to assess for unilateral superior tilt of the pelvis (Figure 76-4C).²⁸ Excessive unilateral rotation of the pelvis can be denoted when the patient's unilateral ASIS is anterior to the contralateral ASIS.^{1,28} Box 76-1 depicts pelvic asymmetries and their associated muscle dysfunctions.^{7,28}

Box 76-1 Postural non-neutral alignment

Examples of muscle dysfunction of the pelvis and hip.^{7,28} Refer to identified chapters in this book for specific muscle assessment.

Pelvic Alignment	Shortened/Facilitated Muscles	Lengthened/Inhibited Muscles
Anterior tilt	Psoas muscle group (Chapter 51) Iliacus (Chapter 51) Erector spinae (Chapter 48)	Abdominal muscles Gluteus maximus
Posterior tilt	Hamstring muscles (Chapter 60) Abdominal muscles (Chapter 49)	Psoas muscle group
Superior lateral tilt	Ipsilateral quadratus lumborum (Chapter 50) Ipsilateral latissimus dorsi (Chapter 24) Ipsilateral hip abductor (Chapter 55, 56)	Contralateral hip abductors
Unilateral rotation	Tensor fasciae latae (Chapter 56) on the side in which the pelvis is rotated	

Figure 76-4. Pelvis and hip postural findings. A, Anterior pelvic tilt as denoted by the green line. B, Posterior pelvic tilt as denoted by the green line. C, Unilateral superior tilt of left pelvis as denoted by the green line.

The excessive facilitation or inhibition of the muscles of the hip and pelvis often causes secondary dysfunctions by association with other muscles, so it is important to denote findings during observation of these muscles. Hypertrophy or dominance of the hamstrings (Figure 76-5A) can be observed particularly in the lower two-thirds of the belly of the hamstrings. Observation of hypertrophy of the one-joint adductor muscles, typically the pectineus muscle, may present as an increased or deeper “S” shape in the proximal groin. This is also known as an adductor notch (Figure 76-5B) or increased adductor bulk, which could suggest TrPs in the adductor muscles.¹ When observing the gluteus maximus muscles, they should be examined mostly for symmetry and muscle tension. If there is unilateral sagging or bulk, it may give information on the motor function of the muscle.⁴⁴ Ipsilateral gluteus maximus muscle weakness can usually be depicted by a lower gluteal fold (Figure 76-5C). Box 76-2 depicts associated muscle dysfunction findings from the hamstring, adductors, and gluteus maximus muscles that may need further examination.

Box 76-2 Examples of dysfunction in the hamstrings, adductors, and gluteus maximus muscles and their associated muscle dysfunction¹

Refer to identified chapters in this book for specific muscle assessment.

	Associated Muscle Dysfunction
Hamstring hypertrophy/dominance (Chapter 60)	Inhibited or weakened gluteus maximus (Chapter 54) Thoracolumbar paraspinal hypertrophy

	(compensations for gluteus maximus weakness/inhibition)
Adductor hypertrophy/dominance (Chapter 59)	Inhibited or weakened hip abductor Inhibited or weakened abdominal wall musculature
Ipsilateral gluteus maximus atrophy/weakness (lower gluteal fold) (Chapter 54)	Ipsilateral hamstring muscle tightness/shortness/facilitated Ipsilateral hip extension compensations at the thoracolumbar paraspinal muscles resulting in repetitive instability of the thoracolumbar spinal segments

Figure 76-5. Myofascial dysfunction in the pelvis/hip. A, Bilateral hamstring hypertrophy in the lower two-thirds of the muscle belly. B, Adductor notch, more visible on the subject's right side (arrow). C, Lower gluteal fold on the subject's right side.

Thoracolumbar Spine

When first observing the posture of the spine, there should be a general appreciation of the spinal curves, assessing for symmetry, distribution of paraspinal tension, skin folds of the trunk, and the position of the head and neck. Normal alignment of the lumbar spine is widely dictated by the positioning of the sacrum and pelvis but looking for an inward curve roughly of 20° to 30° .²⁸ In the thoracic spine, normal alignment has an even distribution of flexion, with a mild posterior convexity attributed to the slight wedging of the vertebrae.³⁶ The alignment of the rib cage should be assessed in regard to the position of the thorax above the pelvis.⁷ A common deficit related to this positioning is an inspiratory position of the thorax coupled with pelvic anterior tilting, also known as open scissors syndrome

(Figure 76-6A).⁷ It is important to obtain a general appreciation of the curvature of the thoracic spine because of its regional interdependence on the cervical and lumbar spine as well as its relationship with the scapula. Furthermore, excessive thoracic kyphosis can suggest a shortened rectus abdominis muscle along with inhibited or lengthened thoracic paraspinal muscles.²⁸ Rotation of the thoracic spine should also be assessed anteriorly, viewing for asymmetries of the rib cage. The side with the more prominent rib cage indicates the side of rotation.³⁶ If the patient demonstrates an increased window in the arm space compared to the contralateral side, this could suggest possible lateral shifting of the spine toward the side of the increased window. The clinician should also assess for possible scoliotic curves, which inherently have asymmetric muscle lengths and areas of hypertrophy. Refer to Figure 76-7 for muscles that may be involved in a scoliotic thoracolumbar curve (Figure 76-6B). Excessive hypertrophy of thoracolumbar extensor muscles (Figure 76-6C) may indicate overactive compensations for poor stability of the deep spinal stabilizers of the lumbar spine, shortened or tight hip flexor muscles, or a weak or inhibited gluteus maximus muscle.¹ The clinician should also assess horizontal creases in the lumbar spine as this may suggest where excessive motion is occurring.

Figure 76-6. Postural dysfunction findings in the thoracolumbar region. A, Open scissors syndrome as denoted by the lines. B, Thoracolumbar scoliotic curve. C, Thoracolumbar paraspinal muscle hypertrophy as denoted by brackets.

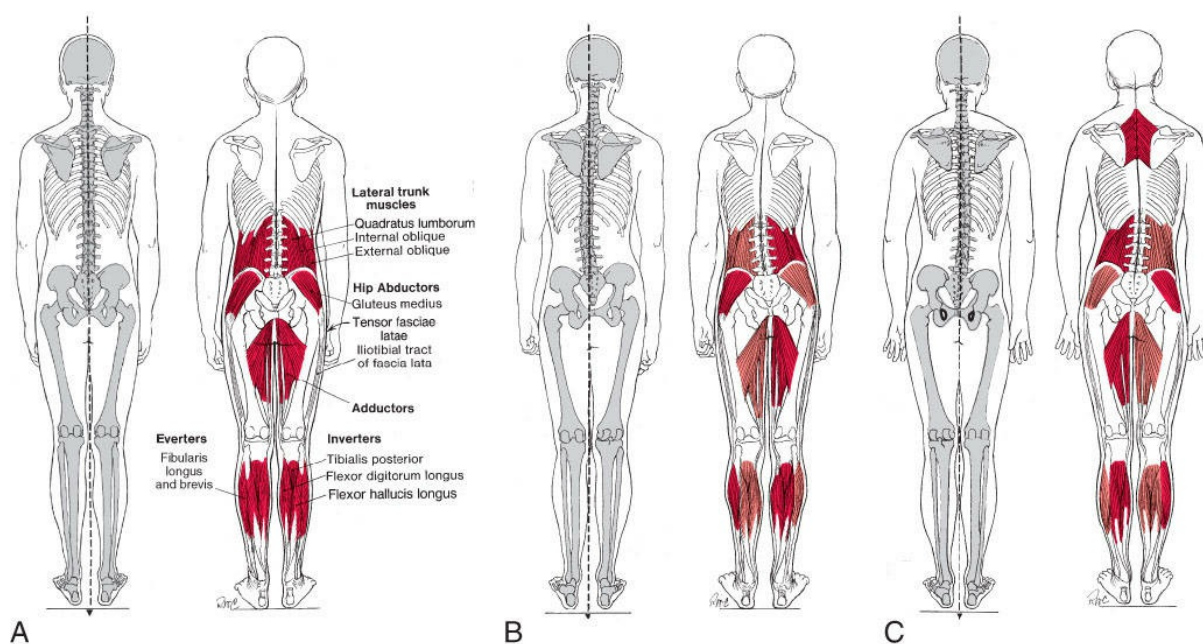

Figure 76-7. Effects of scoliosis on muscle length. A, Typical spinal alignment from a posterior view. B, Left thoracolumbar curve. C, Right slight thoracolumbar curve. Dark red depicts muscles that are shortened and light red are those that are typically elongated.²

Abdominal Wall

The abdominal wall should be assessed because of its suggested role in stabilizing the spine. If the abdomen is sagging or protruding, this may be due to a generalized weakness of the abdominal muscles. A lateral bulging of the abdomen, just superior to the beltline (Figure 76-8A), may indicate weakness of the transverse abdominis muscle¹ or lack of space between the 12th rib and the iliac crest. The upper and lower quadrants of the abdomen should also be compared. If the rib cage is superiorly elevated with an increased tension of the upper quadrant compared to the lower quadrant, this could suggest a faulty respiratory pattern and generation, which are vital for intra-abdominal pressure (IAP) regulation and postural stabilization, respectively.^{7,34,45} If a distinct groove lateral to the rectus abdominus muscle is observed (Figure 76-8B), it may indicate a decreased capacity for stabilization of the abdominal muscles in the anterior and posterior direction.¹ The abdominal wall should also be assessed for lateral hollowing or flaring of the ribs, which would demonstrate a poor function of the diaphragm muscle, abdominal oblique muscle weakness, or transverse abdominis muscle weakness. Furthermore, if the patient demonstrates a general drawing in of the abdominal wall with increased activity of the upper abdominal muscles (Figure 76-8B), this is referred to as an hourglass syndrome posture.⁷ With this posture, there is typically an inspiratory breathing pattern, hypertrophy, or increased tension of the paravertebral muscles about the thoracolumbar junction (Figure 76-6C), as well as an increase in anterior pelvic tilt.⁷ Refer to Chapters 45 and 49 regarding assessment and treatment of the diaphragm and abdominal musculature, respectively.

Figure 76-8. Postural dysfunction findings in the abdominal wall. A, Bilateral lateral bulging of the abdominal wall musculature. B, Lateral groove next to rectus abdominis muscle denoted by the yellow arrow, upper abdominal activity with hourglass posture denoted by the green arrow.

Cervical Spine and Head

When assessing the posture of the cervical spine, initially a general assessment of curve, muscle tension, and symmetry is obtained. Then the clinician should assess the relationship of the head to the rest of the body in regard to gravity and the workload on the cervical spine, looking for a 90-degree angle between the chin and the neck, also known as the throat line.³⁸ Ideally, the acoustic meatus should line up with the acromion process. If there is straightening of the throat line or an increase in the chin-neck angle (Figure 76-9A), this suggests a sign of increased tension of the suprahyoid muscles, which may contribute to temporomandibular joint (TMJ) dysfunction and often is found with TrPs upon palpation.³⁸ The sternocleidomastoid muscle should not be prominent; however, if there is a groove along the sternocleidomastoid (Figure 76-9B), this may suggest an early sign of weakness in the deep neck flexors.³⁸ Lastly, the clinician should assess the relationship of the scapulae with the neck, as many of the periscapular muscles have an inherent origin and insertion relationship with the cervical spine. The line of the neck and shoulder should be assessed for Gothic shoulders (Figure 76-9C), for upper trapezius muscle tightness, as well

as a levator notch (Figure 76-9C). This is an upward bulge of the superior angle of the scapula as a result of levator scapulae muscle tightness.¹ Refer to Chapter 6 for further examination and treatment of the upper trapezius muscle and Chapter 19 for the levator scapulae muscle.

Figure 76-9. Postural dysfunction findings in the head and cervical region. A, Increased chin-neck angle. B, Groove along the sternocleidomastoid muscle (arrow). C, Levator notch denoted by the yellow arrow on the left side. Gothic shoulder denoted by the green arrow on the right side.

Scapulae

General postural assessment of the scapulae should include distribution of muscle tightness, symmetry of the scapula, presence of winging, and general position of the scapulae in relation to the thoracic spine. The medial border of the scapulae should be parallel to the thoracic spine at the levels of T2 through T7 and approximately 3 in away from the spinous processes.²⁸ The resting position of the scapulae can be widely affected by the alignment of the thoracic spine.

The scapulae position should be assessed for bilateral or unilateral excessive elevation, depression, winging, and anterior tilting (Figure 76-10A). The scapulae should also be assessed for rotation, such as a downwardly rotated scapula (ie, the superior angle is further from the spine than the inferior angle), and abduction (Figure 76-10B) (ie, the medial border of the scapula is more than 3 in from the thoracic spinous processes). Box 76-3 depicts scapulae postural asymmetries and their associated muscle dysfunctions.^{1,28} The supraspinous or infraspinous fossa (Figure 76-10C) should also be assessed for hollowing, which could indicate possible inhibition and weakness of the posterior rotator cuff muscles. All of the muscles in Box 76-3 must be examined for TrPs. Please refer to Chapters 22, 23, 26, and 42 for further examination and treatment of the scapular musculature.

Box 76-3 Postural non-neutral alignment

Examples of muscle dysfunction of the scapulae and upper extremity.^{1,28} Refer to identified chapters in this book for specific muscle assessment.

Scapula Alignment	Shortened/Facilitated Muscles	Lengthened/Inhibited Muscles
Elevation	Upper trapezius (Chapter 6) Levator scapulae (Chapter 19)	
Depression		Upper trapezius Levator scapulae
Winging		Lower trapezius Serratus anterior (Chapter 46)
Anterior tilting	Pectoralis minor (Chapter 44) Short head of biceps brachii (Chapter 30) Coracobrachialis (Chapter 29)	Serratus anterior
Downward rotation	Levator scapula Rhomboids (Chapter 27) Deltoid (Chapter 28) Supraspinatus (Chapter 21)	Upper trapezius Lower fibers of the serratus anterior
Abduction	Pectoralis major (Chapter 42) Pectoralis minor (Chapter 44) Upper trapezius	Rhomboid Middle trapezius (Chapter 6)
Medial angle of antecubital fossa, oblique angle of anterior elbow crease	Pectoralis major Latissimus dorsi (Chapter 24)	
Head of humerus resting more than one-third anterior to acromion	Pectoralis major Infraspinatus (Chapter 22) Teres minor (Chapter 23)	Subscapularis (Chapter 26)

Figure 76-10. Postural dysfunction findings in the scapular region. A, Anterior tilting of the scapula. B, Scapular abduction. C, Hollowing of the infraspinous fossa.

Upper Extremity

General postural assessment of the upper extremities should include humeral head position relative to the acromion, general distribution of muscle tension, excessive pronation or supination of the antebrachium, and guarding, if present, of the shoulder or arm. The head of the humerus should be resting less than one-third anterior to the acromion, with the shaft of the humerus resting parallel to the thorax.²⁸ The antecubital fossa should be facing anteriorly, demonstrating neutral rotation of the shoulder and with the elbow in slight flexion.³⁶ Box 76-3 depicts an example of dysfunction of excessive anterior humeral head positioning and medial antecubital fossa/anterior elbow crease angle (Figure 76-11A) and associated muscle dysfunctions.^{1, 28}

Figure 76-11. Postural dysfunction findings in the upper extremity region. A, Medial angle of antecubital fossa/elbow crease angle (more apparent on the subject's left elbow). B, Excessive elbow flexion at rest. C, Suggested right scapular depression based on the hand position (right hand being lower than the left).

Evaluation of the shoulder girdle is necessary when assessing for dysfunctions of the elbow and hand. If the alignment of the shoulder girdle is dysfunctional, it should be corrected before examining the alignment of the elbow and forearm for a more accurate assessment of the elbow and forearm alignment.³⁶ When examining the elbow, a general view of the patient's resting position should be considered along with the general assessment of the extensor and flexor muscle mass in comparison to the rest of the arm. The anterior creases in the elbow should be compared bilaterally and should be fairly horizontal. The carrying angle of the elbow is not easily accessible in resting standing position but should be measured during the physical examination. Excessive flexion of unilateral or bilateral elbows at rest (Figure 76-11B) may suggest loss of range of motion (ROM) from repeated eccentric loading of the elbow flexor muscles,⁴⁶ possibly resulting in the formation of TrPs.

The forearm at rest should demonstrate neutral rotation, with the thumb oriented anteriorly and the digits facing medially³⁶ with the fingers more progressively flexed from the radial to the ulnar aspect of the hand.⁴⁷ Both hands should rest at a relatively even level. If one hand is observed to rest lower than the other, it may be a result of scapular depression (Figure 76-11C). Please refer to Chapters 30 to 32 and 34 to 38 for further details on examination and treatments of the muscles of the elbow and wrist.

Thigh and Knee

Postural assessment of the lower extremity should include the distribution of muscle

tension in the quadriceps muscle group, patella positioning, Q angle, angle of the popliteal crease, presence of genu recurvatum, and tibial torsion. The lower extremity commonly functions as a whole unit, and therefore, the alignment of the entire hip and leg must be taken into consideration.

Other observations include the bilateral comparison of the angle of the popliteal crease. The popliteal crease should be horizontal to the ground, and a deviation in angle (Figure 76-12A) can suggest a predilection of the hip to go into adduction/abduction or internal/external rotation, and/or can suggest foot and ankle torsions. Observation of a crease/groove near the distal lateral thigh may suggest a shorter tensor fascia latae, weak gluteus medius muscle, and a superolateral shift of the patella. If there is a superior positioning of the patella unilaterally, the rectus femoris muscle is likely in a shortened state. Observation of genu recurvatum often suggests vastus medialis muscle hypertrophy.¹ If the patient presents with genu varum (Figure 76-12B), it may suggest lengthened and/or weak lateral rotators of the hip.³⁶ All of these muscles must be examined for the presence of TrPs. Observation of knee flexion in standing may suggest an acute injury, excessive hamstring muscle shortness with an associated weakness of the quadriceps muscle group, or end-stage osteoarthritis, whereas unilateral knee flexion in standing may suggest a shorter lower limb on the contralateral side.³⁶ Please refer to Chapters 57 to 60 for further examination and treatment of the muscles of the hip and thigh.

Figure 76-12. Postural dysfunction findings in the thigh and knee. A, Oblique angle of

popliteal creases (deviating toward internal rotation of the femur bone/external rotation of the tibia bone [green line]). B, Genu varum depicted by green lines.

Foot and Ankle

Evaluation of the ankle and foot should include examination of plantar arch height, angle of resting dorsiflexion, heel shape, a comparison of muscle tension bilaterally, tibial torsion, general tendency toward pronation or supination, and toe-out angle. It is relatively easy for the clinician to overanalyze the posture of the foot and make quick conclusions regarding arch heights, pronation, and supination without considering its role as a team player for the entire musculoskeletal system. Conversely, muscle imbalances of the lower kinetic chain can disrupt the precise balance of the foot, leading to tendon stress, muscle overload, or deformities.¹ The clinician should take into account whether or not the patient utilizes a foot or ankle orthotic, as foot and ankle posture may change standing posture accordingly when barefoot.

The ankle in standing should be in relative neutral dorsiflexion at 0°. The clinician should observe if the patient's body weight is shifted excessively anteriorly or posteriorly (Figure 76-13A). Excessive weight shifting can be observed in the heel shape from a posterior view. If weight bearing is normal into the heel and forefoot, the heel should be rounded in shape. With a center mass directed posteriorly, the patient may have a quadratic or square-shaped heel (Figure 76-13B), suggesting poor shock absorption with further possible dysfunctions at the knee, hip, and spine. Conversely, with an excessively anteriorly directed center of mass, the heel may appear more pointed in shape (Figure 76-13C), suggesting excessive forefoot stress during gait.¹

Figure 76-13. Postural dysfunction findings in the ankle and heel region. A, Posterior sway. B, Quadratic heel (more apparent on the subject's right heel). C, Pointed heel (more apparent on the subject's left heel). D, Cylindrical lower leg (demonstrating soleus tightness).

In regard to general muscle appearance, a shorter and broader Achilles tendon may suggest a short or tight triceps surae. However, if the lower leg appears more cylindrical in shape, rather than the normal inverted bottleneck shape, it may suggest soleus tightness or hypertrophy (Figure 76-13D).¹ Length deficits in the soleus muscle may be a cause of back pain (see Chapter 66) and could suggest prior or current ankle or foot dysfunction. Refer to Chapters 63 to 69 for in-depth examination of the muscles of the foot and ankle that affect alignment.

4. JANDA'S CROSSED AND LAYER SYNDROMES

As observed in the prior section, dysfunctional postural findings may be found in local regions with associated lengthening or shortening, weakness, and/or tightness of muscles. However, the interplay between these impairments has the capacity to affect the entire musculoskeletal system, with a somewhat predictable pattern. With postural function, there are certain muscles with a predilection for being chronically inhibited and lengthened and other muscles with the opposite tendency of being hypertonic and shortened.⁷ Kolar et al⁹ through their observations and treatment of patients with chronic musculoskeletal pain and neurologic disorders, found that in response to joint dysfunction, the muscle responses were similar to patterns in lesions of the upper motor neurons, concluding that muscle imbalances originate and are controlled by the CNS.⁴ Kolar⁷ states the following:

The fact that some muscles are posturally inclined toward inhibition while others toward hypertonia, shortening or even contractures has been known for a long time, but these predispositions for muscular imbalance were not systematically organized until Janda described these observations. The layout of muscle tone (muscle tension) deficits is so characteristic that Janda describes them as syndromes – the upper and lower crossed syndromes and the layer syndrome.⁷

These syndromes are defined by particular patterns of muscle tightness and weakness that cross between the posterior and anterior sides of the body.¹ These observable changes of shortening/tightness and/or inhibition/lengthening of muscles used for posture stabilization can predispose them to overload, leading to the formation of TrPs, thus resulting in pain and decreased function. It should be emphasized, however, that the crossed syndromes were an observation made by Janda of a combined tendency of certain muscle groups to become inhibited or facilitated in either the neck and shoulder girdle or the lumbopelvic girdle. This is not suggesting a direct association with pain per se, but an inefficiency of movement and decreased optimal function secondary to a postural dysfunction, which may result in a report of pain by an individual. The crossed syndromes are to assist the clinician in formulating a hypothesis of possible related structures that are currently contributing to the patient's symptoms. This then helps guide and shape the clinician's examination, which should include minimally the examination for the presence of both active and latent TrPs, muscle length, strength deficits, and movement impairments. These observations are consistent with the functional unit described in each of the muscle chapters.

4.1. Upper Crossed Syndrome

Often coinciding with the term “FHP,” the upper crossed syndrome (UCS) (Figure 76-14) is evident when the position of the head, upper quarter, and cervicothoracic postural alignment is shifted from neutral, with the head moving forward relative to the shoulders. From a lateral view, the external acoustic meatus is positioned anterior to the acromion. The theory of UCS is that both the posterior cervical and the anterior thoracic musculature will become shortened over time, altering alignment and mobility.⁴⁸ More specifically, there is a shortening of the levator scapulae muscle, the upper portion of the trapezius, and the suboccipital muscles posteriorly, and shortening of the pectoralis major and minor and the sternocleidomastoid muscles anteriorly.⁷ On the other hand, the deep cervical flexor muscles, rhomboids, and lower trapezius muscles often become inhibited and lengthened.⁷

Figure 76-14. Upper cross syndrome.¹

The consequences of UCS are typically FHP with muscle length and strength deficits. Articular dysfunctions may be common at the occiput-C1, C4/C5, and T4/T5 segments, as these are transitional zones of curvature in the spine.⁴⁹ Janda noted that these transitional zones, in which there are focal areas of stress within the spine, correspond to areas where neighboring vertebrae change in morphology.¹

In individuals with FHP, there is an associated rounded shoulder posture with inhibited scapular depressor muscles, leading to early shoulder elevation during shoulder abduction.⁴¹ This has been correlated with a muscle imbalance between the upper trapezius muscles being overactive and the lower trapezius muscles being underactive,⁵⁰ leading to the glenohumeral joint being positioned higher secondary to the malalignment of the scapulae.⁷ This may also lead to the protraction of the scapulae, impacting the supraspinatus muscle and its likely degeneration with concurrent overloading from the

action caused by an overactive levator scapulae muscle (Chapters 19 and 21, respectively).⁷ This could lead to associated TrPs in the upper trapezius and levator scapulae muscles, with individuals presenting with neck pain and associated FHP or the UCS.⁵¹ This muscle imbalance is commonly associated with shoulder impingement syndromes.⁵²

FHP alters body mechanics, predisposing the individual to develop TrPs by overloading muscles when compensatory efforts are made to overcome limitations imposed by FHP. Maximal voluntary isometric contraction is reduced in the cervical muscles, consistent with the effects of suboptimal muscle fiber length.⁵³ Neck pain secondary to FHP is also associated with decreased upper limb external rotation and weakness of shoulder abduction.⁵⁴ Respiratory function can also be compromised with FHP, with reduced vital capacity and decreased forced expiratory volume.⁵⁵ There is a general notion that FHP is associated with TMJ dysfunction, perhaps because the mandible is displaced posteriorly, a displacement commonly associated with TMJ-related pain.⁵⁶ However, opinions are conflicting in this regard as studies have been mixed in their reports of a relationship between head posture and TMJ disorders.^{57–59} The problem is exacerbated by inconsistency in the criteria for the diagnosis of TMJ disorder, and the poor quality of the studies. Some studies only looked at intrinsic joint dysfunction, and few studies have looked at the relationship of FHP, orofacial TrPs, and TMJ pain. Perhaps unexpectedly, FHP was not associated with rounded (protracted) shoulder posture in young adults, although FHP was associated with neck pain and disability.⁶⁰ Laptop and smartphone use for an extended period of time is a risk factor for FHP-induced headache and neck and shoulder pain in young adults.^{61,62} Similarly, studies of office workers show a correlation between FHP and neck pain.⁶³

Consideration of postures during computer use has been a necessary part of head and neck pain assessment among students, often referred to as ergonomic assessment when applied to the workplace, but now should also be considered when assessing headache and neck pain in persons who use laptop computers. Wearing high heels is directly correlated with potentially harmful postural changes in adolescent girls, including FHP, lumbar hyperlordosis, and knee valgus.⁶⁴ The problem with these and similar studies is that they are very small in numbers of subjects, although they are consistent with other studies of the effect of ergonomic stress on muscle.

Backpacks can put young children at risk for neck and back pain later in life. Wearing a backpack weighing 7.5% of a child's body weight results in a significant decrease in the craniovertebral angle producing FHP,⁶⁵ which is likely to be an important risk factor for maintaining an FHP in adolescence and adulthood, although longitudinal studies have not been done yet. FHP is associated with moderate carpal tunnel syndrome, but no causal relationship can be implied.⁶⁶ Children who mouth breathe are also more likely to have an FHP.⁶⁷

Treatment of FHP is mostly accomplished through physical therapy programs that include posture corrective exercises. These have been shown in randomized controlled trials (RCTs) to decrease FHP.⁶⁸ A series of exercises that included McKenzie exercises, Kendall

exercises, and self-stretches improved the craniovertebral angle and the scapular index,⁶⁹ and an RCT looking at Pilates decreased pain and neck disability.⁷⁰ A combination of upper thoracic spine mobilization and mobility exercises had better outcomes than upper cervical spine mobilization.⁷¹ Suboccipital release improved the treatment outcome when added to craniocervical flexion exercises.⁷² Cervical exercises also reduced FHP induced by smartphone use.⁷³ The difficulty with some of these studies, like some of the studies cited previously, is that the number of subjects is small.

4.2. Lower Crossed Syndrome

Lower crossed syndrome (LCS), also known as the distal or pelvic crossed syndrome, has been classified into two subtypes: type A posture and type B posture.¹ The more commonly known subtype, type A posture (Figure 76-15), occurs when there is a presentation of tight erector spinae muscles and fascia in the lumbosacral segments, tight rectus femoris, tensor fasciae latae, hamstrings, and iliopsoas muscles, and concomitant weakness of the abdominal and gluteal muscles.⁷ As a result, theoretically, this leads to an anterior pelvic tilt with an increase in the lumbar lordosis.⁷ Also in subtype A posture, there is a tendency to use more hip flexion and lumbar extension movement for mobility.¹ Subtype B posture (Figure 76-16) is more associated with FHP (Figure 76-14), with the same impairments as FHP, but with concomitant thoracic kyphosis, decreased lumbar lordosis, and the BCOG positioned posteriorly with secondary genu recurvatum.¹

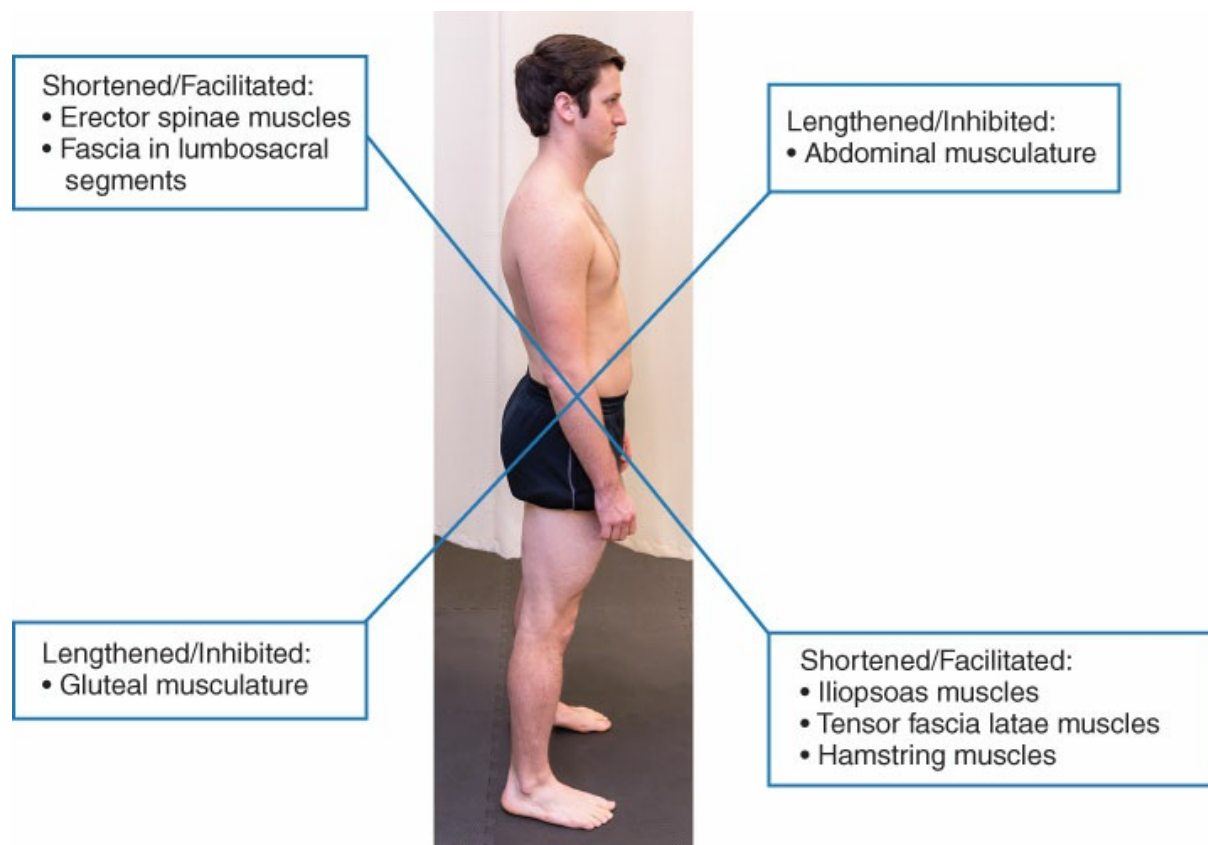

Figure 76-15. Lower cross syndrome (subtype A).¹

Figure 76-16. Lower cross syndrome (subtype B).¹

The evidence, perhaps not surprisingly, is varied and conflicted when it comes to musculoskeletal pain and certain components of the LCS and lumbopelvic posture. There is also a void of valid studies regarding the relationship of TrPs on LCS posture or lumbopelvic posture in general. However, it can be hypothesized that in the following studies, mentions of shortening or lengthening of muscles can precipitate the formation of TrPs and should be included in the examination.

There are studies in support of hip extension mobility deficits secondary to tight hip flexor muscles with an association of low back pain⁷⁴⁻⁷⁷ and shorter iliopsoas muscle as contributing to low back pain,^{78,79} characteristics found in LCS. A study performed by Ranger et al⁸⁰ suggested that shorter lumbar paraspinal fascia was associated with high-intensity low back pain via magnetic resonance imaging. Furthermore, a study performed by Malai et al⁸¹ suggested that hold-relax stretching of the iliopsoas muscle in patients with chronic nonspecific lower back pain with lumbar hyperlordosis was significant for reducing pain, improving hip flexor muscle length, decreasing the lumbar lordosis angle, and

enhancing transverse abdominus muscle activation. However, a study performed by Walker et al¹¹ found that there was no relationship between standing lumbar lordosis, pelvic tilt, and abdominal muscle performance. A study performed by Nourbakhsh and Arab¹⁴ found that there was no strong association with low back pain (LBP) and structural factors such as size of lordosis, pelvic tilt, iliopsoas length, or lumbar paraspinal length.

Furthermore, Heino et al¹⁰ found that there was no clear relationship between hip extension ROM and standing pelvic tilt, standing lumbar lordosis, or abdominal muscle performance and even suggested that clinicians should not base treatment from a visual inspection of postural malalignments, specifically stretching of the hip flexor myofascia, based on a view of posture alone. Heino et al¹⁰ suggested that specific examination procedures should be the guiding factors for treatment. It should be noted, though, that the study performed by Heino et al¹⁰ was performed on healthy younger individuals (ages 21-49) and the study by Walker et al¹¹ was performed on healthy younger individuals (ages 20-33) without lower back pain.

Gluteal muscle weakness or inhibition is one of the associated findings with LCS. Evidence has shown some key links between gluteal muscle weakness and other muscle dysfunctions, similar to the observations found in LCS. Lee and Oh⁸² and Arab et al⁸³ found that there was a suggested association of gluteus maximus muscle weakness and hamstring muscle length deficits. Furthermore, in the study by Arab et al⁸³ it was suggested that in patients with sacroiliac joint dysfunction with gluteus maximus muscle weakness, there was a significant association with hamstring muscle length deficit. It was suggested by van Wingerden et al⁸⁴ that hamstring muscle tightness in patients with low back pain was a compensatory mechanism to adjust for pelvic instability. However, the study performed by Nourbakhsh and Arab¹⁴ suggested that there was no association between hamstring muscle length, pelvic tilt, or low back pain. Lee et al⁸² found that without normalization of gluteus maximus muscle strength, it demonstrated a nonsignificant negative correlation with hamstring muscle length; however, with normalization of the participant's gluteus maximus muscle strength by height and weight, there was a positive significant correlation with hamstring muscle length. This finding holds huge implications for prior studies and erroneous conclusions regarding strength variables and associations with postural variables, because of the high correlation of body size and strength. However, in this study by Lee et al,⁸² it should be noted that participants were all healthy young males and the study did not include any participants with lower back pain.

Increased tension in the thoracic paraspinal muscles or hypertrophy of lumbar paraspinal muscles may be the result of abdominal muscle weakness² or, if accompanied by LBP as a compensatory mechanism to hip flexor muscle shortening, weak gluteal and abdominal muscles.⁸⁵ Hultman et al⁸⁶ and Lankhorst et al⁸⁷ also found a decrease in lumbar extensibility in patients with low back pain. The study performed by Nourbakhsh and Arab¹⁴ found that subjects with low back pain had the highest association with lumbar extensor endurance deficits.

Inhibited or lengthened abdominal muscles and their relationship to the rest of the LCS

characteristics have been under contention by several studies such as Youdas et al,⁸⁸ Walker,¹¹ and Levine et al,⁸⁹ suggesting that there was no association between abdominal muscle strength, pelvic tilt, and lumbar lordosis. Toppenberg and Bullock⁹⁰ and Youdas et al⁸⁸ suggested that there was no significant relationship between lumbar lordosis and abdominal muscle length. There are several studies, however, suggesting that abdominal muscle weakness is related to lower back pain.^{78, 91-94} Nonetheless, considering the varied and convoluted debate on abdominal or core strength and the testing methods to obtain these results, many of these studies will need to be read in detail for individual opinion.

The most common pathology resulting from components of LCS is typically persistent chronic lower back pain. However, treatment of persistent chronic lower back pain has been debated for decades by researchers, with limited consensus. What is lacking in the research is the postural considerations of TrPs, particularly in the lumbar region. Please refer to Sections 5 and 6 in this text for more details on the examination and treatment of TrPs in the trunk and hip musculature.

With the extreme variability of body types and postures, it might be expected that there is no specific relationship or correlation of certain aspects of posture with pain, based on current set norms for posture. For example, in a study by Laird et al¹² of 62 participants with and without low back pain, it was concluded that there were no significant differences with standing lordosis angles. However, this study did not define or describe low back pain other than having had LBP for 12 or more weeks with or without leg pain and scored more than a 2 out of 10 on the numeric pain rating scale. Based on similar studies, it would be easy for a clinician to interpret such findings as a reason to disregard certain variables, such as lordosis angles, during the postural examination.

4.3. Layer Syndrome

Also known as stratification syndrome, the layer syndrome as described by Janda is the combination of both the UCS and the LCS.¹ It essentially denotes the layering of muscular hypertrophy or shortening and hypotrophy or lengthening.⁷ From a dorsal perspective (Figure 76-17), there is typically muscular hypertrophy or shortening of the hamstring muscles, erector spinae muscles in the thoracolumbar region, erector spinae muscles in the cervical region, upper trapezius, and levator scapulae muscles.⁷ This is paired with muscular hypotrophy or lengthening of the gluteal muscles and lower stabilizers of the scapulae.¹ Ventrally, there is typically muscular hypertrophy or shortening of pectoralis, sternocleidomastoid, iliopsoas, and rectus femoris muscles.⁷ This is paired with muscular hypotrophy or lengthening of the abdominal muscles and deep cervical neck flexor muscles.¹

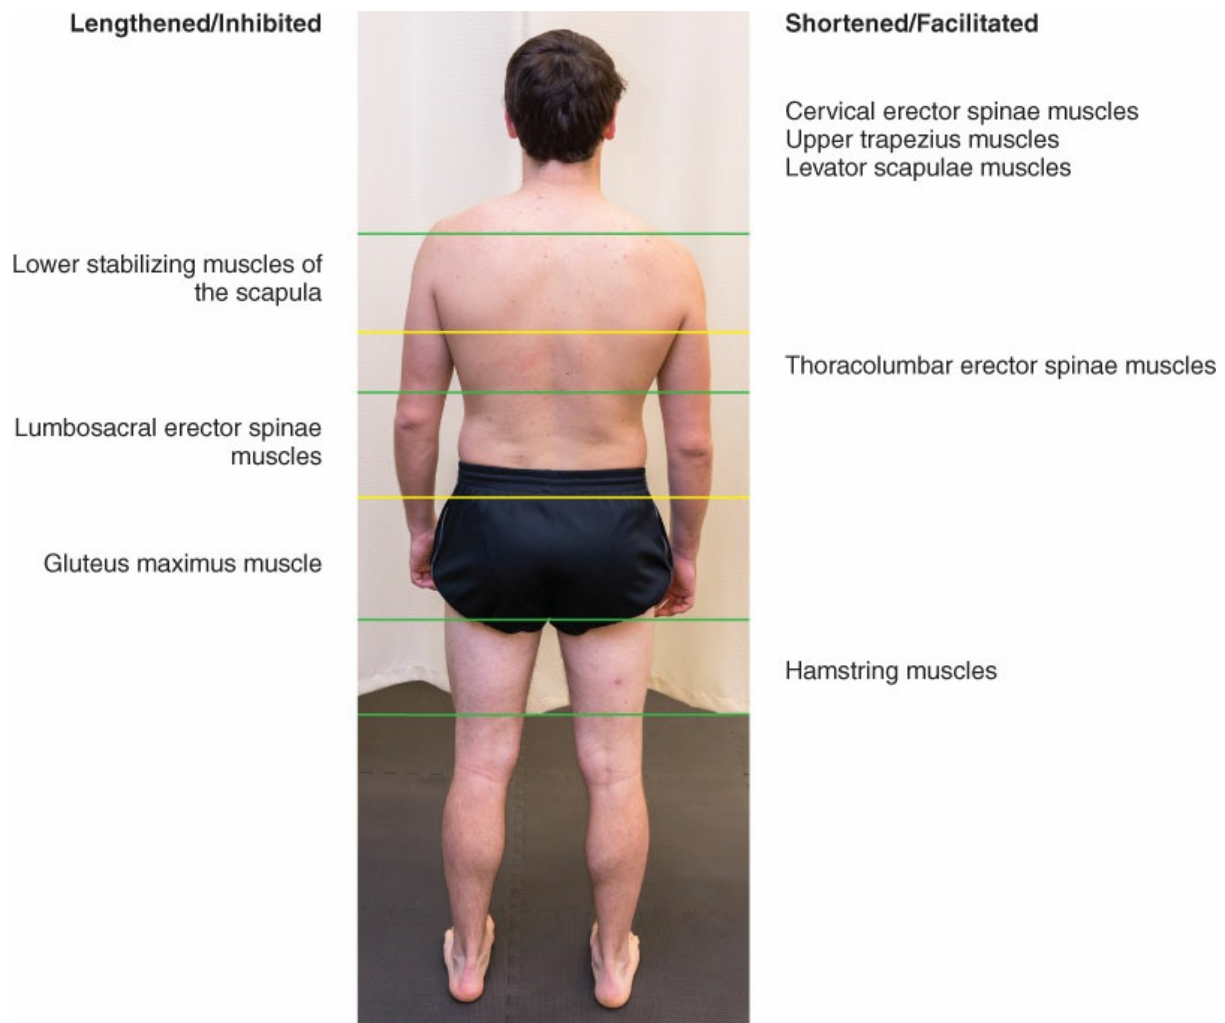

Figure 76-17. Layer syndrome (dorsal aspect).¹

4.4. Summary of the Janda Approach Regarding Postural Syndromes

In regard to treatment of the layer syndrome, UCS, or LCS, it is suggested to consider the Janda approach in managing these postures. In general, the Janda approach to the postural syndromes begins with a static postural assessment followed by observation of single-leg stance and gait.¹ Next, movement pattern characteristics are assessed as well as muscle length of suspect musculature for tightness or shortness.¹ Once muscle imbalances are evaluated, the clinician then hypothesizes on the cause of dysfunction based on the information gathered and selects interventions accordingly. Treatment begins with normalizing the periphery, which essentially involves normalizing the afferent input into the sensorimotor system via postural corrections and applying biomechanical corrections via manual therapy techniques to provide an optimal environment for healing. Once the peripheral structures are normalized, there must be a restoration of muscle balance. If there is no coordination between muscles, the strongest muscle in the chain cannot be functional. Likewise, in the presence of tight or short antagonistic muscles as described in the UCS, LCS, and layer syndrome, restoring normal muscle tension and length must be addressed before strengthening weak musculature.¹ Hypothetically, with those shortened and tight

muscles, there is a predisposition for TrP formation; therefore, assessing these predictable muscle groups may be essential in regard to treating the TrPs to restore normal muscle tension and function. “Sensorimotor training”¹ follows the restoration of muscle balance, increasing proprioceptive input to facilitate automatic and appropriately timed muscle coordination in order to facilitate a reflexive joint and postural stabilization, rather than specific muscle strengthening. Finally, endurance of coordinated movement patterns with a focus on low-intensity exercises performed at high volume is emphasized because of fatigue being the predisposing factor to compensated movement patterns.¹ The home exercise prescription is absolutely vital as the patient must be practicing consistently in order to make changes at the CNS level. See Chapter 4 “Perpetuating Factors” for further information on maladaptive movement patterns and their effect on the nociceptive system. The clinician should seek the appropriate sources as referenced for further information on the Janda approach to treatment.^{1,7,95}

5. POSTURAL CONSIDERATIONS OF BREATHING

The primary objective of respiration, the exchange of oxygen and carbon dioxide, is to meet the metabolic demands of the body.⁹⁶ This exchange is achieved through breathing, which is regulated and coordinated by the autonomic nervous system and influenced by physical, chemical, and emotional factors. However, with injury or pain, faulty respiration occurs at a subcortical level as compensation. This can lead to a faulty breathing pattern becoming perpetuated at the subcortical level, and eventually being an imbedded motor program, even when the initial trigger or threat is no longer present.¹ There is also the likelihood of the formation of TrPs in muscles that must compensate for the dysfunctional stabilization of the spine secondary to diaphragm muscle not fulfilling its role as a postural stabilizer.

Breathing, on a neural and mechanical level, extrinsically and intrinsically serves several purposes for posture and movement and can be seen through more obvious examples such as musicians sniffing to coordinate the initial note, martial artists breathing or yelling when they strike or flow into the next step, tennis players yelling before they hit the ball, or weight lifters grunting prior to exertion.

This section aims to focus on the role of breathing on posture and movement. See Chapter 45 for further details on the mechanics of normal respiration as illustrated in Figures 45-8 and 45-9.

5.1. The Postural Function of the Diaphragm Muscle

Lewit stated, “If breathing is not normalized—no other movement pattern can be.”⁹⁷ Because of the inherent relationship of breathing with movement, breathing naturally has an influence on postural function as well.⁸ Both posture and movement are linked by the diaphragm muscle.⁵ Refer to Chapter 45 for the anatomy and function of the diaphragm muscle. The diaphragm muscle is often overlooked despite its known role in vital functions. However, the diaphragm muscle, when performing poorly, can be the underlying cause of dysfunctional stabilization of posture or uncoordinated movements because of its role in

the IAP and the integrated spinal stability system (ISSS).⁹⁸

The diaphragm muscle has a dual role as both a respiratory and postural muscle, which is essential for spinal stability and resultant movements.⁹⁸ With the involvement of the CNS, the diaphragm muscle assists with postural body control⁸ through flattening or caudally descending the dome of the diaphragm muscle during either respiration or trunk postural stabilization.⁸

During its caudal descent during postural exertion, the diaphragm muscle works as a piston, building pressure on the abdominal viscera and increasing IAP against the pelvic floor and abdominal muscles.⁸ This results in an eccentric expansion of the abdominal wall to an adequate abdominal and thoracic wall volume and then maintained isometrically. In an ideal scenario, such as lifting a heavy object, this “eccentric–isometric” muscle activity will match the degree of muscle exertion and work necessary to meet the demands of the motion.⁸

The regulation of IAP occurs via the diaphragm, pelvic floor, multifidi, and transversus abdominis muscles, providing anterior lumbopelvic postural stability.⁹⁸ As discussed by Frank et al,⁹⁸ there is a general consensus that an increase in IAP creates spinal stability^{99–105} and is a parameter for influencing spinal mechanics and stiffness. Thus, IAP then coordinates with the ISSS for dynamic stability of the spine.

The ISSS, as described by Kolar et al,⁸ is a balanced system of coactivation between spinal extensor muscles in the cervical and upper thoracic region, the deep cervical flexor muscles, as well as the diaphragm, pelvic floor, and all sections of the abdominal and spinal extensor muscles in the lower thoracic and lumbar region.⁹⁸ Coordinating with IAP, the ISSS creates spinal stiffness, contributing to dynamic stability of the spine.⁹⁸ The muscles of the ISSS constitute the “deep core” and, via a “feed forward control mechanism,” their activation precedes most voluntary movements.⁹⁸

ISSS provides the stable base or punctum fixum on which muscles can produce motion.⁹⁸ An example of this provided by Frank et al⁹⁸ occurs when the psoas major muscle relies on the thoracolumbar spine as a BOS to act as a hip flexor; however, if the ISSS is inefficient, the psoas major muscle may cause anterior shear stress on the lumbar spine from muscular forces and pull. Furthermore, a study performed by Kolar et al¹⁰⁶ demonstrated that IAP regulation and ISSS can be disturbed by a decreased capacity of the diaphragm’s postural function, resulting in compensatory activity of the superficial spinal extensors. As a result, there are increased compressive forces on the spine.¹⁰⁶ The decreased capacity of the diaphragm’s postural function also results in an imbalance between lower and upper chest musculature, leading to an abnormal position of the thoracic rib cage and chest.¹⁰⁶ Abnormal stabilization function of the diaphragm typically is paired with dysfunctional breathing patterns.⁸

5.2. Assessment of the Diaphragm Muscle

The evaluation of breathing patterns is crucial for the assessment of the stabilization

function of the spine.⁷ It demonstrates the functional interplay and relationship between the activation of the diaphragm and the abdominal muscles.⁷

Assessment of Breathing and the Diaphragm

Normal contraction of the diaphragm pushes the abdominal contents down toward the pelvis, causing protrusion of the abdomen and increased lung volume in the lower chest during inhalation. Normal resting inhalation involves coordinated contraction of the diaphragm with expansion of the *lower* thorax and elevation of the rib cage, all of which increase lung volume. With the caudal descent of the diaphragm, there should also be an increase in IAP if there is normal maintenance of abdominal wall and pelvic floor tension.⁹⁸ With tidal breathing there should be relaxation of the accessory breathing muscles with ventral movement of the sternum and without motion in the transverse plane.⁷

When assessing breathing, the clinician should first assess posture in static standing and assess for the patient's natural breathing patterns, the shape and size of the thoracic wall, natural muscle tension of the abdominal wall, shoulder position (for protraction or retraction), head position, and whether paradoxical breathing is present. With normal tidal breathing, there should be an observation of symmetrical expansion of the lower thoracic and abdominal cavities, particularly the lower aperture of the thorax with ventral movement of the sternum.³⁵ Following the observation of breathing and posture, it is suggested to follow this with the seated diaphragm test and the IAP test to further assess diaphragmatic activity with appropriate ability to generate and maintain IAP. It should be noted that these tests are for qualitative purposes as objective measures are limited.⁹⁸ Refer to the following sources on how to perform the seated diaphragm muscle test and the IAP test.^{9, 95, 98}

The mechanics of normal respiration are presented in detail in Chapter 45 and illustrated in Figures 45-7 and 45-8.

Dysfunctional Breathing

If the patient demonstrates an hourglass syndrome posture, as described in the abdominal wall section of the static standing postural assessment, this would indicate the presence of inverse or paradoxical diaphragm function.⁷ With paradoxical respiration, these chest and abdominal functions oppose each other. On inhalation, the chest expands (moves up and out) while the abdomen moves in, elevating the diaphragm and decreasing lung volume. On exhalation, the reverse occurs. Consequently, a normal effort produces inadequate tidal volume, and the muscles of the upper chest, especially the scalene muscles, overwork to exchange sufficient air via cranial pull on the upper ribs. This usually results in a nociceptive chain of the cervical region (Box 76-4) secondary to the scalene muscles along with the sternocleidomastoid muscles pulling the cervical spine forward, causing an FHP at the craniocervical junction.⁵¹ This results in movement restrictions in the upper cervical spine, the cervicothoracic junction, and the upper ribs⁵¹ secondary to poor coordination of

the major components of the respiratory apparatus.

Box 76-4 Associated muscles of the nociceptive chain to include for examination of TrPs to improve diaphragmatic breathing and function

Cervical Region	Thoracic Region	Lumbar/Abdominal Region	Shoulder Girdle
Sternocleidomastoid	Pectoralis major	Pelvic floor	Subscapularis
Scalenes	Pectoralis minor	Diaphragm	Infraspinatus
Posterior cervical	Diaphragm	Gluteus maximus	Supraspinatus
Splenii	Subscapularis	Gluteus medius	Deltoids
Upper trapezius	Serratus anterior	Piriformis	Teres major
Levator scapulae	Iliocostalis thoracis	Iliacus	Triceps brachii long head
		Short adductors	
		Hamstrings	
		Rectus femoris	
		Tensor fascia latae	

Adapted from Liebenson C. *Rehabilitation of the Spine a Practitioner's Manual*. 2nd ed. Baltimore, MD: Lippincott Williams & Wilkins; 2007 (p. 784).

Respiratory function can also be compromised with FHP. This is due to a dominance of accessory inspiratory respiratory muscles versus utilizing the diaphragm, contributing to an inspiratory position of the rib cage with stiffness of the thoracic spine due.⁵¹ A reduced vital capacity and decreased forced expiratory volume secondary to FHP have been reported.⁵⁵ Furthermore, Kolnes¹⁰⁷ observed that chronic costal or upper chest patterns of breathing can lead to a constant excessive facilitation of the respiratory muscles, such as the scalenes and sternocleidomastoid muscles, perpetuating FHP and TrPs.

Dysfunctional Postural Function of the Diaphragm

In regard to the dysfunctional postural function of the diaphragm muscle, in the hourglass syndrome posture, the diaphragm flattens significantly less. The centrum tendineum of the diaphragm becomes the punctum fixum and pulls the intercostal spaces and lower ribs inward via the pull of the diaphragm attachments on the lower ribs. As a result of the nonproportional activation, the lumbar portions of the diaphragm contract more, and as a result of compensation for poor postural diaphragmatic function and coordinated IAP, the superficial paraspinal muscles near the thoracolumbar junction hypertrophy over time⁷ and inhibit the abdominal wall muscles.⁹⁵ Furthermore, associated TrPs in the thoracic region typically occur in the diaphragm, pectoralis major, and dorsal erector spinae muscles with concomitant joint restriction of the thoracic spine and rib cage.⁵¹ If an altered or

dysfunctional respiratory postural pattern is identified, it suggests the presence of poor inter- and intramuscular coordination, which is mediated by the CNS.¹⁰⁸

5.3. Treatment Considerations for the Diaphragm's Dual Role

In order to have physiologic stabilization of the spine, there must be normal physiologic breathing and vice versa.¹⁰⁸ However, without that physiologic stabilization of the spine, this can cause inappropriate or unstabilized muscle pull throughout the entire body, precipitating the formation of TrPs.

Trigger points in the kinetic chain muscles can have great influences on faulty breathing patterns, such as paradoxical breathing or faulty postural patterns.^{51, 97, 109} Page et al also described nociceptive chains similar to the kinetic chain, with associated TrPs throughout the chain. It was observed that nociceptive chains were typically unilateral and are mostly present in patients with chronic pain.¹ Box 76-4 depicts the associated nociceptive chains that warrant examination for TrPs.

Because of the ability TrPs to alter firing sequences in the kinetic chains,¹⁰⁹ the TrPs in the nociceptive chains may need to be assessed and treated in order to restore balance of diaphragmatic breathing and function.

If the patient has poor mobility of the thoracic spine, abdominal wall, or the thoracic wall, it will likely be difficult to maintain or achieve physiologic breathing patterns and adequate trunk stabilization.¹⁰⁸ For improvement of independent thoracic wall movement, the mobility of the thoracic fascia, with emphasis on the lower intercostal spaces, should be improved.¹⁰⁸

Once the diaphragm has improved capacity for function, the patient must then relearn appropriate diaphragmatic breathing. To learn normal diaphragmatic breathing, while in a recumbent position, the patient exhales fully with one hand on the chest and the other on the abdomen (Figure 20-15B). Diaphragmatic respiration alone is most easily learned if the patient holds the chest fixed in the collapsed position, rather than expanded (Figure 20-15C), and concentrates on breathing by alternately contracting the diaphragm and abdominal muscles (allowing the abdomen to move out during inhalation and move in during exhalation) without expanding the upper chest or elevating the sternum. When smooth easy diaphragmatic breathing is achieved, the patient then learns to coordinate costal and diaphragmatic respiration during inhalation (Figure 20-12) and exhalation (Figure 20-13). When respiration is coordinated, the chest and abdomen move in and out together. The patient should note the closeness of the hands during exhalation and their separation during inhalation; the hands move up and down together. It may help for the patient to then think of also expanding the “lateral bellows” or “bucket handles” (expanding the lower rib cage laterally) and elevating the sternum (the “pump handle”) to expand the chest during full, normal, coordinated inhalation. Positional feedback from the hands is often helpful for a patient to learn this technique. If the patient has difficulty with this, manual pressure at the lower rib cage with a quick stretch upon full exhalation can stimulate activation of the diaphragm. The patient can be instructed to provide this

pressure and stretch in supine.

The patient should practice coordinated breathing at intervals throughout the day and before bed each night. Taking each breath to the count of “4 in” and a count of “4 out,” then a pause, “hold-and-relax” for a count of 4 improves pacing and provides rhythm. The patient should become aware of using this coordinated breathing throughout the day.

Having learned to breathe properly while recumbent, the patient must transfer this learning to the upright posture. The patient sits in a chair with a firm flat seat (Figure 20-13), tilts the front of the pelvis forward and down (exaggerating the lumbar lordosis), and draws in a slow deep breath. This anterior pelvic tilt separates the anterior chest from the symphysis pubis, making it easy and natural to contract the diaphragm and to protrude the abdomen while inhaling. Then, by rocking the pelvis backward (posterior pelvic tilt or abdominal curl movement) and leaning slightly forward during slow exhalation, the abdomen moves in and the increased IAP pushing up against the diaphragm assists elevation of the relaxed diaphragm.

6. COMMON POSTURES

Common statically held postures such as prolonged sitting, desk jobs and office work, driving, and sleeping can overload muscles and other structures. This section will discuss suggestions of ideal positions for these common postures; however, the clinician should accommodate for the individual patient when making suggestions for accommodations.

6.1. Sitting

Prolonged sitting has been regarded as the “new smoking” by many clinicians and researchers, because of the implications of sitting on all-cause mortality.^{110,111} Wilmoth et al¹¹² suggest that sedentary behavior in general had an association with diabetes, cardiovascular disease, and all-cause mortality. Frequent rest breaks are recommended by the Occupational Safety and Health Administration (OSHA). Although the OSHA recommends a 10-minute break every 2 hours for computer workers, frequent shorter rest breaks may be more beneficial, as it can allow the patient to recognize and adjust posture. With any activity or occupation that requires sitting for hours at a time, seated positioning is critical.

Sitting alignment is a widely debated topic with unclear parameters on how much lumbar flexion is appropriate, as increased lumbar flexion has some associations with LBP.⁴²

Normal supported sitting alignment for most people is described by Sahrman³⁶ as having the “spine erect and supported, the shoulders aligned over the hips, the feet supported, and the hips flexed to 90°,” whereas in unsupported sitting, the pelvis will be in a slight posterior tilt resulting in a flatter lumbar spine with a relatively unchanged thoracic and cervical spinal alignment in comparison to standing. However, Sahrman³⁶ states that “because of the variation in posture and anthropometrics among individuals, no chair or sitting surface is perfect for everyone.” With variations in spinal curvatures, height, and

limb proportions, each individual who does not meet the “ergonomic” norm is always at a disadvantage, having to sit in a chair that may not support them adequately. Chair modifications can be made, such as a lumbar roll or support for individuals with increased lumbar lordosis, making note that the support only fills the space of the lordosis and the chair, not pushing the lumbar spine into extension.

Another approach to correcting poor sitting posture would be Brugger’s sitting posture, utilizing a postural cogwheel-like mechanism.¹ By changing the bottom cogwheel—the pelvis—the patient has control of the reversal of curves and assumes appropriate sitting posture by changing one region of the body.¹

In the age of technologic advances in which cellphones and laptops are commonly used, prolonged use of such devices, as mentioned earlier in the chapter, can result in FHP-induced headache as well as neck and shoulder pain in younger adults.^{61, 62} As seen in Figure 76-6, the patient, in order to maintain his viewing angle, has to sit with an excessive posterior tilt of the pelvis, causing the abnormal reversal of curves as described in Brugger’s sitting position.¹ Constant viewing of the device’s screen results in FHP, and a lack of support under his elbows causes further protraction of the scapulae. With the correction of pillows and support under his elbows as seen in Figure 76-18, the patient now has improved reversal of curves, decreased FHP, and improved overall alignment.

Figure 76-18. A, Poor sitting posture secondary to phone use. B and C, Corrected sitting posture with pillows.

6.2. Computer or Workstation Ergonomic Analysis

According to the Bureau of Labor Statistics,¹¹³ over half of the workforce (~77 million Americans) uses a computer at work. This increasing number of employees using a computer for work has sparked interest in the ergonomics of the workstation. Additionally, musculoskeletal complaints have continued to increase and are reported to be from 20% to 75% of computer workers.¹¹⁴ Laptop and smartphone use for an extended period of time is a risk factor for FHP-induced headache, neck pain, and shoulder pain in young adults.^{61, 62}

Numerous companies have entered the market to provide equipment that is better suited for an ergonomic workstation.

Correction of the individual's workstation is often the most powerful intervention. For desk workers, a desktop computer or a laptop with a docking station should be used, with the keyboard allowing the elbows and shoulders to be relaxed at 90° (Figure 76-19A). The computer screen or laptop should be directly in front of the body and at an angle, two-thirds of the screen below eye level, that encourages erect posture while minimizing glare.

Figure 76-19. Workstation. A, Efficient sitting posture. B and C, Neutral standing posture with a standing desk.

Documents should be placed on a stand at the same level as the computer screen (rather than flat on the desk to one side) for optimum viewing and to avoid excessive muscular strain. Reflections on eyeglasses and contact lenses can be managed by changing the relative position of the light source or by using antiglare lenses. Nearsightedness should also be corrected, because it favors a head-forward posture, which shortens the sternocleidomastoid muscles. Patients who have recently received new progressive lenses should have their workstation reevaluated to ensure good ergonomics.

The computer mouse should be at the level of the keyboard, which may require the addition of a keyboard and/or mouse tray. The patient should consider alternating sides for mouse use. Although this discipline can take weeks or months to learn, it is possible to become ambidextrous with the mouse, which can halt the perpetuation of TrPs in many upper extremity and shoulder girdle muscles.

According to international standards, based on ergonomic principles,¹¹⁵ the comfort zone for the wrist is defined as between 45° flexion, 45° extension, 20° ulnar deviation, or 15° radial deviation.¹¹⁶ Decreasing the computer keyboard slope also decreases the wrist extension needed to use the keyboard.¹¹⁷ The location of the mouse is also relevant in the overload of wrist extensor muscles and a central mouse position, with the mouse centered between the keyboard and the user's body one of the best choices regarding general stress in the upper extremity,¹¹⁸ although the best recommended position to avoid excessive wrist extension was locating the mouse by the side of a narrower keyboard, without a number

keypad.¹¹⁸ There is moderate evidence for the use of vibratory feedback in the mouse.¹¹⁹

Interrupting prolonged typing or data entry every 30 minutes or so to do the finger-flutter exercise (Figure 35-6) can help the wrist extensor muscles recover from prolonged activity. This exercise is performed by dropping the hands to the sides of the body, completely relaxed, and moving the arms and elbows to cause passive relaxed shaking of the hands and fingers.

When considering office seating postures, the chair is important to assess. It is important to have seating with weight-bearing on the ischial tuberosities, so that diaphragmatic breathing is easier. If the chair has a headrest, it should not push the head forward. Lumbar rolls, as discussed earlier, must ensure that the lumbar lordosis is supported but not increased.³⁶ A wedge cushion that anteriorly tips the pelvis or an adjustable chair is an option if the patient presents with excessive posterior tilting of the pelvis as discussed earlier.¹ Lastly, consider the positioning of the hips on the chair. It is recommended that the hips attain 90° of flexion along with the knees, and the feet can be placed flat on the floor. This is the primary consideration of the seat height that is required. If the seat height is at its lowest point and hip flexion remains above 90°, then a raised flat surface may be placed on the floor to elevate the floor height but not the chair (Box 76-5).

Box 76-5 Key points to a proper ergonomic workstation setup

1. The monitor height should be placed so that the eyes are in a horizontal plane.
2. The keyboard and mouse should be positioned so that the elbow is in 90° flexion.
3. The wrists should be in a slightly extended position.
4. The hips should be at a 90-degree angle and the feet placed flat on the floor.
5. The head, shoulder, and hips should be aligned, with the back supported by the chair.

Achieving the alignment as indicated above facilitates a position that is efficient and maintains the spine in a neutral position. The chairs that are available for purchase are endless, but having a chair that can adjust up and down and also has an adjustable back is of greatest value. Standing desks are also a viable option for active posture as depicted in Figure 76-19B and C.

6.3. Driving Posture

Driving, whether it is a small trip to the grocery store or a cross-country trip, includes numerous actions that drivers are required to complete at any given point. A simplified list of these actions includes, but is not limited to, twisting to check a blind spot, looking behind when reversing, keeping the hands on the wheel with several rotations made, depressing the brake/accelerator, and changing gears. Throughout all of these tasks, however, the driver is seated for the most part. This would call for increased importance of

a neutral and efficient driving position for all drivers. With the increase in vehicle selection, from tiny compact cars to large trucks, the seating systems are relatively similar. What will matter most in regard to the vehicle is its capabilities of adjusting.

Sitting posture while operating a vehicle is demonstrated in Figure 76-20. This optimal position while driving is what should be achieved prior to operating a vehicle. This position will allow most driving tasks to occur without greater demand or physical strain on the body.

Figure 76-20. Driving posture showing the key joints considered while sitting in a vehicle. A, Sedan. B, Sport utility vehicle (SUV).

With seat height, the hips should be relatively flexed, with hips at the height of the knees. The driver must also have easy access to view the entire dashboard without the need to lean forward or sit up higher. Most new cars have the option of adjusting the seat height; however, in the event the seat height is not adjustable, a pad may be used to achieve the correct seat height. Seat depth, on the other hand, is a position that is at times difficult to adjust as most vehicles do not have this option. Normally, there should be an inch between the popliteal space and the chair to avoid excessive compression of the nerves and vessels in that location.

When a driver sits in the car for the first time, a common initial adjustment is typically the anterior/posterior positioning of the chair. Ideally, the chair should be positioned where the driver can manage to press the accelerator and brakes while the back maintains contact with the seat and the knees are able to maintain roughly 20° to 30° of flexion. If the steering wheel is adjustable, it is recommended that the elbows maintain a position of about 120° of flexion while the arms are in the normal position on the steering wheel. However, for safety purposes, per the National Highway Traffic Safety Administration (NHTSA),¹²⁰

the driver's chest should always remain at least 10 in away from the air bag. There are exceptions for different body types and medical conditions. Please refer to the NHTSA's website for further information on the subject, and if the reader is from a country other than the United States, please refer to the appropriate government website for up-to-date information.

The seat of the car should be used to provide support to the thoracic and lumbar spine. The suggested angle is 100° to 120°. This slightly extended posture decreases the stress on the spine. Regarding the cervical spine, it is important to consider the headrest. The design of the headrest is mostly considered in regard to safety. In the event of a motor vehicle accident, the headrest would support the head when a rear force makes contact with the vehicle. However, the headrest should also be positioned in such a way that the occiput makes contact with the center of the headrest. This helps to provide cervical support, as well as cue the driver to avoid FHP.

Once the main adjustments have been made, the driver should then proceed to adjust the rear view and side mirrors. The mirrors should be positioned in such a way that the driver does not have to excessively alter sitting position in order to view.

6.4. Sleeping Postures

Sleep is the human body's method for recovery and repair for maintenance of physical and mental health.¹²¹ As individuals face their daily stressors of life, they must sleep to replenish for the next day. Roughly one-third of human life is spent sleeping, which means that a large portion of life is spent in a relatively static position. This unfortunately also has implications in regard to TrPs. Trigger points can impede sleep because of pain and because of the muscle being in a lengthened or shortened position. Trigger points can be activated and perpetuated during sleep. Sleep is also impeded in patients with pain in general, whether it is shoulder pain or LBP. Patients often report that they cannot find a comfortable position for sleep. However, modifying the patient's sleeping position can improve sleep quality, decrease strain on muscles with TrPs, and facilitate improved recovery.

Although many people have their own preferences for sleeping postures, the main objective for most sleep postures should be to find a neutral position or alignment while adjusting for the patient's anatomy. Starting with the cervical spine, it is important to consider the positioning of the pillow. Regardless of whether it is a supine, side-lying, or prone position, the head should remain in neutral rotation, with the nose in line with the sternum. In supine positioning, if the patient demonstrates a severe forward head, the clinician may need to accommodate for that with additional pillows but without creating excessive cervical flexion (Figure 76-21B). The end goal of pillow positioning in both supine and side-lying would be to provide enough support of the cervical spine to promote relaxation of cervical spine musculature. If the patient has an excessive lordotic curve in supine positioning, it may be necessary to place a few folded bedsheets under the lumbar spine to take up the space and provide adequate support. Another adjustment to this would

be to place a pillow or two under the knees to decrease load on the lumbar spine. The firmness or softness of the mattress should also be taken into consideration.

In side-lying positioning, if the patient presents with slight side bending, it may again be necessary to place a few folded bedsheets under the lumbar spine to take up the space and provide adequate support. A pillow can be placed between the knees to promote a better positioning of the hips, as well as a pillow on the superior arm to provide support of the shoulder (Figure 76-21).

Figure 76-21. Recommended sleeping postures. A, Side-lying emphasizing a neutral spine. B, Supine. C, Prone with $\frac{1}{4}$ turn to decrease stress on cervical musculature.

In prone positioning, it is important that the patient is placed in a relatively oblique position via pillow placements as seen in Figure 76-21C. The head should still be as neutral as possible even in this position, angling the head with the edge of the pillow. The superior leg should be flexed with a pillow underneath the knee for improved support. Modifications should be performed with the thought of decreasing strain on painful regions and placing muscles in a neutral resting position.

7. SUMMARY

Posture is very much like a map—it does not necessarily show any particular destination, but it shows the broad picture. However, without considering static or dynamic posture, treating myofascial pain is very much akin to journeying without any of the roads. Therefore, when a clinician chooses to disregard postural malalignments during the examination, then the examination must essentially be performed without any general direction of where to go. The argument can be made that viewing posture can skew or bias the clinician; however, it depends on the relative ability of the clinician to read the map. When assessing posture, the clinician is viewing a relatively still snapshot of an inherently dynamic system. Therefore, the clinician must consider the body as a whole functioning unit.

The clinician must ascertain if the patient's postural alignment is contributing to the medical history as gathered by the clinician or if the patient's postural adaptations are no longer functional and have the capacity to accept the forces of gravity and the patient's daily life stressors. With every postural assessment, the clinician should be looking at postural dysfunctions or poor adaptations that are currently contributing to the symptoms with which the patient is reporting and presenting.

As mentioned in the introduction of this chapter, posture is the summative visual reflection of how the body has adapted to gravity and external forces in a particular

position. Posture may not conclude pain; rather, it maps it out for the clinician. It is up to the clinician to utilize clinical reasoning skills to interpret the map to plan a route to their intended destination. Then, the examination becomes like a well-planned journey, leading toward treatment or how to approach the next step.

Footwear Considerations

Deborah M. Wendland

1. INTRODUCTION

Footwear is a possible contributor to the overload of muscles of the lower extremity and can be a possible treatment for trigger points (TrPs) (Chapters 64, 65, 66, and 71). Footwear, along with foot orthotic devices and taping, should be assessed and addressed in patients with myofascial pain. Specifically, footwear is paramount for muscles around the ankle (eg, fibularis longus and brevis, tibialis posterior, soleus, and gastrocnemius) and in the foot. The recruitment and function of these muscles should be examined in light of their environment (ie, shoes, foot orthotic devices, and taping).

Trigger points have been associated with changes in muscle activity and recruitment patterns.^{1–3} Pain itself can result in and from a change in movement patterns. When increased loading of a muscle occurs in the presence of TrPs, the movement pattern is uncoordinated and inconsistent.⁴ Moreover, postural habits can also perpetuate pain.⁵ As a case in point, gastrocnemius and soleus TrPs may cause calf, Achilles tendon, and heel pain along with decreased ankle range of motion (ROM).^{6,7} Given these impairments, it is not surprising that function can be affected.⁷ Addressing the TrPs improves ankle ROM⁶ and function.⁷ Changes can occur in the presence of TrPs and also be mitigated by the treatment of TrPs. Likewise, these changes may be improved, supported, or maintained by utilizing footwear, foot orthotic devices, and/or taping.

Certain foot postures, gait biomechanics, and even fatigue, all modifiable by footwear, can contribute to the development of TrPs and/or changes in muscle recruitment patterns.^{8,9} Common foot types include pes planus (flat foot) and pes cavus (high-arched foot). These foot types are linked to the height of the medial longitudinal arch (MLA) and are associated with common physical (including gait) or injury presentations.

Pes planus is linked to a low MLA and exhibits an increased flexibility of the foot. Injuries typically associated with pes planus are those responding to increased or abnormal joint movement or muscle overuse. Specifically, excessive or abnormal pronation is a common movement pattern seen in people with pes planus. This movement pattern is

associated with the altered function of the tibialis posterior and fibularis longus muscles.¹⁰ Alterations in the function of the flexor digitorum longus and the flexor hallucis longus muscles should also be considered, given their role in the support of the longitudinal arch of the foot.¹¹ Associated problems may include muscle overuse or dysfunction (eg, tibialis posterior), proximal joint pain, plantar fasciitis, and foot/toe limitations or deformities.¹² Footwear, foot orthotic device selection, or taping can be useful in mitigating these associated complications.^{12–17}

Pes cavus, on the other hand, is associated with a high MLA and tends to result in a foot with a stiffer structure.¹⁸ Injuries associated with pes cavus are those that relate to the foot's inability to absorb shock or distribute load.^{18,19} People with this foot type have a tendency to lack sufficient pronation, which helps to absorb ground reaction forces. These changes in foot mechanics are linked to changes in the muscle activation patterns during gait, contributing to muscle overuse, which can contribute to or perpetuate TrPs. Fortunately, the selection of footwear or the use of foot orthotic devices can be influential to minimize dysfunctions associated with cavus-related movement and muscle activation patterns.¹⁹

Fatigue must also be considered as a contributor for TrPs (Chapter 66). As a possible contributor, it is important to assess causes of fatigue that are modifiable. Modifiable factors like energy shielding techniques may include shoe selection and/or the use of foot orthoses. An increased metabolic cost has been associated with the increased muscle activity associated with high-heeled walking.²⁰ But Curran et al reported that when wearing high heels with foot orthoses, heart rate and energy consumption were both lowered.²¹ These results demonstrate that footwear and its modification can affect metabolic cost. Understanding why metabolic cost is affected (eg, changing walking speed or heel height) can facilitate the ability to minimize a metabolic cost increase, especially when treating TrPs.

2. PHYSICAL STRESS

The Physical Stress Theory²² was designed to guide practice and the selection of appropriate treatment interventions. At its core, the critical principle is that biologic tissue responds to stress in a predictable way.²² With this insight, clinicians can modify stresses to improve tissue healing and then develop a program that progressively reloads tissue to improve stress tolerance.²² To achieve this design, the clinician must recognize the origins of stress and how it may be affecting tissue loading responses and healing.

With injury and inflammation, tissue needs to be off-loaded to allow healing to occur.²² Similarly, in the case of TrPs, muscle needs to be supported or off-loaded in a way that facilitates healing and the removal of conditions that may be contributing to the activation and perpetuation of the TrPs. Muscle activation changes with gait and can be altered by shoe type, foot orthotic device, or taping. Moreover, muscles are recruited differently depending on posture. Given the influence of posture and activity on muscle recruitment and function, clinicians should recognize that both posture and movement

patterns can be modified by adjusting footwear selection and fit, including the use of foot orthotic devices or taping within footwear.

First, prior to modifying foot position or movement, stressors to biologic tissue should be assessed. Postures maintained over time can cause overuse of some muscle groups and underuse of others. With muscle imbalance, some muscles can become shortened and other muscles may become lengthened. As such, it is crucial to assess posture (see Chapter 76) so that muscle balance can be addressed. Furthermore, it is also important to assess how an individual moves to determine muscle balance in practice. Together, posture and gait assessment facilitate the understanding of muscle loading factors that contribute to the body's healing or lack thereof.²²

Once stressors are determined, the clinician needs to consider how tissue can be off-loaded to allow for healing. Because stress results from movement or position, it is vital to learn and design various ways to minimize these abnormal or repetitive loads to tissues. Altered loading can occur with exercise, a modification in footwear design or fit, the use of foot orthotic devices, or taping. In the presence of injury, regardless of its origin, the tissue will be less responsive to stress and will therefore require off-loading to facilitate healing.²²

Once tissue has healed, reloading needs to occur so the weakened tissue can return to its previous functional level and better tolerate stress.²² This reloading can facilitate the balancing of muscles in a way that allows for improved patterns of motion and decreased continued stress (overuse) of muscle and other tissues. Reloading can occur by changing the fit of the shoe or by modifying the shoe itself; foot orthotic devices or taping can also facilitate reloading of the muscle tissue.

3. FOOTWEAR

Footwear is one means by which feet can be supported and the biomechanics of gait can be altered. Of primary concern with using footwear to address the mechanics of motion is shoe fit. Beyond shoe fit, shoe construction can impact foot posture and gait mechanics through the density of material, the positioning of material thickness, shoe design (eg, boot vs. low top; heel height), and even the mechanism of shoe closure (eg, lacing or straps). Together, shoe fit and construction should be selected based on the patient presentation as well as the patient response to the selected intervention.

Shoe fit is among the most critical components of footwear selection. With an inappropriate fit, a seemingly appropriate shoe selection will prove ineffective in accomplishing the intended task. In fact, a poorly fitting shoe may even cause blister or callus formation, an increased risk for falls,²³ and a change in movement patterns, including overrecruitment of muscles (eg, toe flexors to aid in keeping a shoe on). With well-fitted footwear, gait speed may increase along with the confidence of the wearer.²³

Rarely are adults measured for footwear anymore. Even with measurement using a Brannock device, shoe size is dependent on the last around which the shoe is built. Thus, even with measurement, it is important that a shoe is actually assessed for fit. It is especially critical that shoe fit is assessed with whatever modifications may be made to footwear or

with the inclusion of a foot orthotic device if one is to be used.

Proper Shoe Fitting

A major challenge to shoe fit assessment is that the shoe, a static object, needs to accommodate the foot, a dynamic tissue, that varies in size and shape as it moves, bears weight, and changes temperature.²⁴ Although shoe fit may be based on 15 or more individual assessments,²⁴ these assessments can be narrowed to a simple mnemonic to assist the fitting process. Figure 77-1 identifies the parts of a shoe to facilitate the assessment of shoe fit. To assess shoe fit, one should remember his or her ABCS (Box 77-1).

Figure 77-1. Important parts of the shoe to be considered by the clinician.

Box 77-1 Mnemonic for proper shoe fit: ABCS

A, Arch

The arch location and size are critical for shoe fit. The arch should be sized such that it snugly contacts the foot.²⁴ The arch of the shoe should be located at the same position as the arch of the foot and should be consistent in length.

B, Ball

The ball of the foot should be situated in the same spot as the widest part of the shoe. That is, the length from the heel to the ball of the foot should be equal to that from the heel to the “ball” of the shoe. This must be the case on both the medial and lateral sides of the shoe to allow for accurate bending of the shoe. Similarly, the ball should be appropriately placed from the end of the shoe such that the toe to ball lengths match.²⁴ The width of the shoe, including its tread, should also correspond to the width of the foot.

C, Cut

The shoe must be an appropriate cut such that the trim lines of the shoe or even the stitching does not impinge on the foot or apply undue pressures to any spot.²⁴ Special attention needs to be given to areas of bony landmarks such as the malleoli, navicular bone, or toes. The cut should also be such that gapping is not seen

between the shoe and the foot. Rather, the foot should have sufficient space to move without allowing excessive shear movement.

S, Size

The size of the shoe, assessed in standing, includes the length, the width, and the depth. The length of the shoe should allow 1/2" to 5/8" beyond the longest toe,²⁴ which in many cases is the second toe. The width of the shoe can be assessed along with its depth using a simple standing test.

The upper part of the shoe (vamp) should be able to be pinched in a way that there is material that can be grasped, showing that room in the area of the toes and forefoot is sufficient (Figure 77-2). If the shoe is too snug, material will not be able to be grasped and lifted. Care should be taken to identify that even the lesser toes are not being pinched.²⁴ Some shoes come in various widths (A, B, C, etc.) but may also come in "extra wide." These distinctions are footwear brand specific. Similarly, shoes come in extra-depth sizes as well. Extra-depth shoes may be selected to accommodate for a foot deformity or a foot orthotic device if the removal of the shoe's insole is not enough. Finally, as size is assessed, it is important to identify that the heel fit is appropriate²⁴ and movement at the heel is minimal.

Figure 77-2. Assessment of vamp fit by grasping material to ensure adequate space. One should be able to grasp a small amount of material at the forefoot location.

Shoe Design

Although fit is critical, it is also important to recognize that the actual design of a shoe will affect the mechanics of the body. Shoes come in various styles that can affect foot and gait biomechanics differently. By managing these biomechanics, movement patterns and muscle recruitment may be altered. This alteration in muscle recruitment and movement patterns may serve to off-load specific muscles, thus facilitating healing and appropriate loading and preventing the formation or perpetuation of TrPs. Footwear can be used to control motion or shift loading such that the gait pattern is affected. Furthermore, certain shoe style aspects, such as the high heel, are commonly worn and can have major ramifications on biomechanics.

One shoe purpose is control of motion. Motion can be controlled in footwear by a number of mechanisms. Many athletic shoes, for instance, are termed “motion control” because the medial midsole is thicker (rearfoot post or wedge) or more dense^{13, 14} compared to the lateral midsole. With the thicker or stiffer material in the location that has excessive motion, motion in that direction is restricted.^{14, 25} The heel counter can also be used as a means to control motion. The longer the heel counter, the more motion is controlled. Motion can be selectively controlled by having one side of the counter longer than the other. Motion toward the side of the longer counter will be more limited. The addition of a stabilizer at the back of the shoe can also lead to increased motion control. Likewise, a low heel can be lengthened either medially (Thomas heel) or laterally (reverse Thomas heel) to mitigate excessive motion medially or laterally, respectively.

Shoe Modifications

Modifications can be made to the shoe itself to increase stability. Shoe modifications, including a flange or flare (material added to the sole of the shoe to make it wider and more stable) or stabilizer (material added to the side of the shoe), will limit motion toward the side on which the modification is placed.¹² Modifications that can be added to footwear are consistent with modifications that can be made to foot orthotic devices as well.

The literature reports shoes as being able to reduce rearfoot motion when comparing motion control shoes to neutral shoes^{13, 14} or cushion shoes,²⁵ whether the individual was fatigued or not.¹³ Additionally, Lilley et al found that motion control shoes also limited medial rotation at the knee.¹⁴ Furthermore, motion control shoes have been shown to reduce instantaneous loading rate, especially in those with a lower arch.²⁵ Despite Butler et al’s findings that instantaneous loading rate was affected by arch height, they suggested that the choice of footwear should be matched to the foot mechanics rather than to the posture in which the foot presents.²⁵ With these opportunities for control of motion, it becomes apparent that footwear could decrease muscle activity in muscles that try to control motion in these ways (eg, tibialis posterior and fibularis muscles). It is important to note that when motion control is not needed, a motion control shoe should not be worn. Rather, a neutral shoe should be selected (eg, for people with pes cavus).¹⁹

The sole or tread of a shoe may affect gait mechanics. Appropriate flexibility of the shoe sole can decrease the overload to the plantar flexor muscles (Chapters 65 and 66). Likewise,

a rocker bottom may affect the gait mechanics of an individual.²⁶ Depending on where the apex of the rocker lies, a rocker is typically used to off-load different areas of the forefoot.²⁶ A rocker bottom helps to return motion that was otherwise taken away, but may also result in reduced electromyography activity at the tibialis anterior muscle while producing increased gastrocnemius muscle activity.²⁶ Using a rocker bottom can result in kinematic changes at both the ankle and the hip.²⁶ These kinematic changes must be acknowledged so that shoe choices are appropriately made and total biomechanical changes are monitored.

The intensity of a modification affects the variability of the biomechanical response with gait. Thies et al reported that the degree of the rocker bottom has an effect on outcome. Specifically, toe clearance was better with 10° and 15° rockers, but with a further increase of the rocker to 20°, a decrease in gait speed was noted when walking on a decline.²⁷ Step variability, on the other hand, did not appear to be significantly affected by varying the degree of the rocker bottom.²⁷ Thus, the degree to which footwear is modified can affect the gait pattern and likely the muscle activity. Gait should be assessed on an individual basis to determine the individual response to the footwear.

Heel height is another footwear variable that should be considered when assessing how to modify the forces applied to tissue or the loading of muscle. With consideration of lower extremity posture alone, it is easy to see that wearing higher heels results in the shifting of body weight from the whole foot toward the forefoot. However, because an individual wants to be able to perceive his or her environment, he or she makes further modifications to his or her posture to enable the head to remain forward-looking. These postural changes, along with increased pressure born at the forefoot, should be considered because gait mechanics may also change in response to discomfort felt in the forefoot or further up the kinetic chain. The frequency of wearing this kind of shoe and possible impact of any pain report must also be considered.

A number of specific changes to muscle activity have been reported with heeled walking. Murley et al report that as heel height increases, muscle activity increases at the erector spinae, rectus femoris, soleus, and fibularis longus muscles and decreases at both the medial gastrocnemius and tibialis anterior muscles.²⁸ Other investigators found an increase in peak amplitude with heeled walking versus barefoot walking in the tibialis anterior, soleus, vastus lateralis, rectus femoris, biceps femoris, and semimembranosus muscles.²⁰ The presence of variability between studies (eg, tibialis anterior) makes it important to explicitly assess the response of each individual to footwear or other foot interventions.

Like with a rocker shoe, the actual height (intensity) of the heel must also be considered. Stefanyshyn et al reported that muscle activation changes with the changing kinematics and kinetics of gait according to height of the heel.²⁹ Specifically, they reported increased activity in the soleus and rectus femoris muscles with increasing heel height. However, they did not find a graded increase in the hamstrings, vastus medialis, tibialis anterior, or gastrocnemius muscles with increasing heel height.²⁹ It is thus important to recognize that loading of the tissues can be modified by changing the height of the heel, even without eliminating the heel entirely.²⁹ Similarly, unlike high-heeled shoes, negative

heeled shoes were shown to have increased muscle activity in the lateral hamstring, tibialis anterior, and lateral gastrocnemius muscles.³⁰ Moreover, the frequency with which a particular heel height is worn will also affect muscular activity response.²⁸

Another component of the shoe construction itself, the closure mechanism (eg, lacing), affects the fit of the shoe. Associated with this component is the type of shoe, including its height (boot vs. low-top shoe). Shoe fit has been shown to affect gait mechanics.³¹ Slippage of the foot within a shoe can contribute to muscle overload (see Chapter 66). The weight of a shoe or boot can also affect the muscle activation pattern. The heavier the shoe, the higher the muscle activity level (see Chapter 68).³² Again, the gait mechanics and slippage must be assessed on a case-by-case basis.

Orthotic Devices

The use of foot orthotic devices is another method by which muscle loads or activity can be diminished and healing supported. Foot orthoses come in many varieties and can be customized by selection of material density and material thickness, including placement of thickness (posting or padding). As with footwear, higher density material and posting will tend to restrict motion.¹² Padding, on the other hand, may serve as a means to off-load particular areas (metatarsal pads).¹²

Specific foot orthotic devices can be considered as an approach to manage certain musculoskeletal conditions. In general, overpronation can be managed with medial posting at the forefoot, rearfoot, or both.^{12,15} Like with the stabilizing shoe modifications to the medial side, medial posting will limit motion in the direction of the posting. More motion control is obtained when rearfoot posting is used, either alone or in combination.¹⁵ Likewise, a foot orthotic device with a lateral bar has been shown to decrease the muscle activity of the fibularis longus muscle.³³ Again, lateral posting will limit motion in a way similar to modifications on the lateral side of the shoe.

Use of specific paddings or foot orthotic modifiers can be helpful for certain patient presentations.¹² Usage of a foot orthotic device has also been reported to change the activity of the plantar flexor muscles.^{34,35} Specifically, Achilles tendon dysfunction can be off-loaded with the use of a heel lift.¹² A heel lift resulted in decreased activity in the gastrocnemius muscle across sexes^{34,35} but resulted in variable effects on the activity of the tibialis anterior muscle.^{34,35} Metatarsal pads, bars, or similar mechanisms of off-loading have been used to treat metatarsalgia, neuromas, sesamoiditis, and the like.^{12,36} Decreasing pain complaints can alter gait mechanics and thus muscle activity. When semi-custom and custom foot orthotic devices in individuals with different arch heights were compared, it was reported that the semi-custom device was a suitable alternative to the custom device.³⁷ When changes are made using a foot orthotic device, it should be noted that the response is variable by individual and should therefore be individually assessed.³⁸

Taping

Taping is one more method by which the load on a muscle or muscles can be modified to support healing as well as reloading. Taping has been shown to alter the activity of muscles in the leg in the case of people with low MLA or flat-arched feet.^{16,17} Specifically, antipronation type of taping such as a low-Dye technique has been shown to decrease the maximal activity at the tibialis anterior and tibialis posterior muscles.^{16,17} The fibularis longus muscle had variable results.^{16,17} Similar results were seen for ankle bracing as well.¹⁷ With this support for neuromuscular change with mechanical support to the foot, it should be considered that the use of such a technique could be helpful to reduce excessive forces experienced in the feet and assist in determining a more permanent solution (eg, foot orthotic device) to force management.

4. COMMON FOOT PRESENTATIONS

Pronatory Foot Type

In the case of an individual with a pronatory foot (Box 77-2), foot position and movement patterns could be contributory to TrPs or in response to TrPs. Several means can be used to mitigate the excess amounts of load placed on the muscles that are attempting to control the excessive motion, including the tibialis posterior muscle. Beyond shoe fit, the selection of a shoe with some type of motion control may be utilized (eg, medial midsole with increased thickness compared to the lateral midsole, increased material density to the medial shoe, increased bulk of the heel counter, especially medially, and the addition of some version of a heel stabilizer or flare). Beyond motion control, a good means to control excessive motion is the use of a foot orthotic device that may control excessive pronation by several different mechanisms including increased density or thickness on the medial side (medial posting). Depending on foot structure, the increase in thickness medially (medial post) could occur at the forefoot, the rearfoot, or both. As a more temporary control of excessive motion into pronation, taping or bracing can be utilized.^{16,17,39} These more temporary means of controlling excessive motion may serve as a trial basis for a more permanent solution to control motion (eg, foot orthotic device or footwear modification).

Box 77-2 Strategies for abnormal pronatory foot

- Thomas heel

Supinatory Foot Type

For people with a more supinatory or high-arched foot (Box 77-3), the natural tendency is to have decreased motion and a stiffer foot. With a stiffer foot, typically a more cushioned shoe and insole are most appropriate. Motion control footwear should be avoided and a neutral shoe should be selected.¹⁹ In severe cases, footwear with a lateral flange or longer lateral counter may be necessary to facilitate movement in the direction of pronation for a more efficient gait pattern. Additionally, a reverse Thomas heel could be an effective means to control excessive supinatory motion. A foot orthosis with a lateral bar could serve as a means to decrease activity at the fibularis longus.³³

Box 77-3 Strategies for abnormal supinatory foot

Shoe	Foot Orthotic Device	Taping

Although the pronatory and supinatory foot are among the most common foot types that are associated with specific muscle activation patterns, muscle activation associated with gait is variable. With such variability, it is important to assess each individual's gait along with his or her response to any adjustments made with his or her footwear, foot orthotic device, or taping. Certain adjustment can be expected to affect muscle activation in certain ways (Box 77-4).

Box 77-4 Considerations for loading and off-loading different muscles using footwear, foot orthotic devices, or taping strategies

5. SUMMARY

The impact of footwear, foot orthotic devices, and taping should be considered when assessing contributors and perpetuators of TrPs. Any of these factors can contribute to muscle activation dysfunction. Similarly, footwear, foot orthotic devices, and/or taping or their simple modification can also support the remediation of TrPs and promote improved muscle function.

Certain foot postures are both common and amenable to modification through the use of footwear, foot orthotic devices, and taping. Specifically, pes planus, which may influence the mechanical loading of the tibialis posterior, fibularis longus, flexor digitorum longus, and flexor hallucis longus muscles, can be supported through motion control. Motion control footwear, for example, can use an extended counter, medial posting, wider base (medial flare), or the optimization of material density to accomplish the increased control of excessive pronation. Foot orthotic devices can similarly use medial posting to limit excessive motion.

Pes cavus, another common foot posture, can be addressed with footwear or foot orthotic devices that provide cushioning to absorb pressure. Furthermore, lateral control within footwear (lateral posting or lateral flare) or foot orthotic devices (lateral posting) can facilitate movement into normal pronation. Together, these work to address this more rigid foot type.

Other modifications can be applied to footwear or foot orthotic devices, such as a metatarsal pad, to off-load the metatarsal heads or the sesamoid bones. A heel lift can be used to off-load the Achilles tendon and the plantar flexor muscles. Additionally, taping techniques can be very useful to determine what more permanent solution may be effective in managing movement challenges of the lower extremity. All of these work as the means by which the clinician can facilitate both off-loading and reloading tissue so that healing can occur (Physical Stress Theory).
